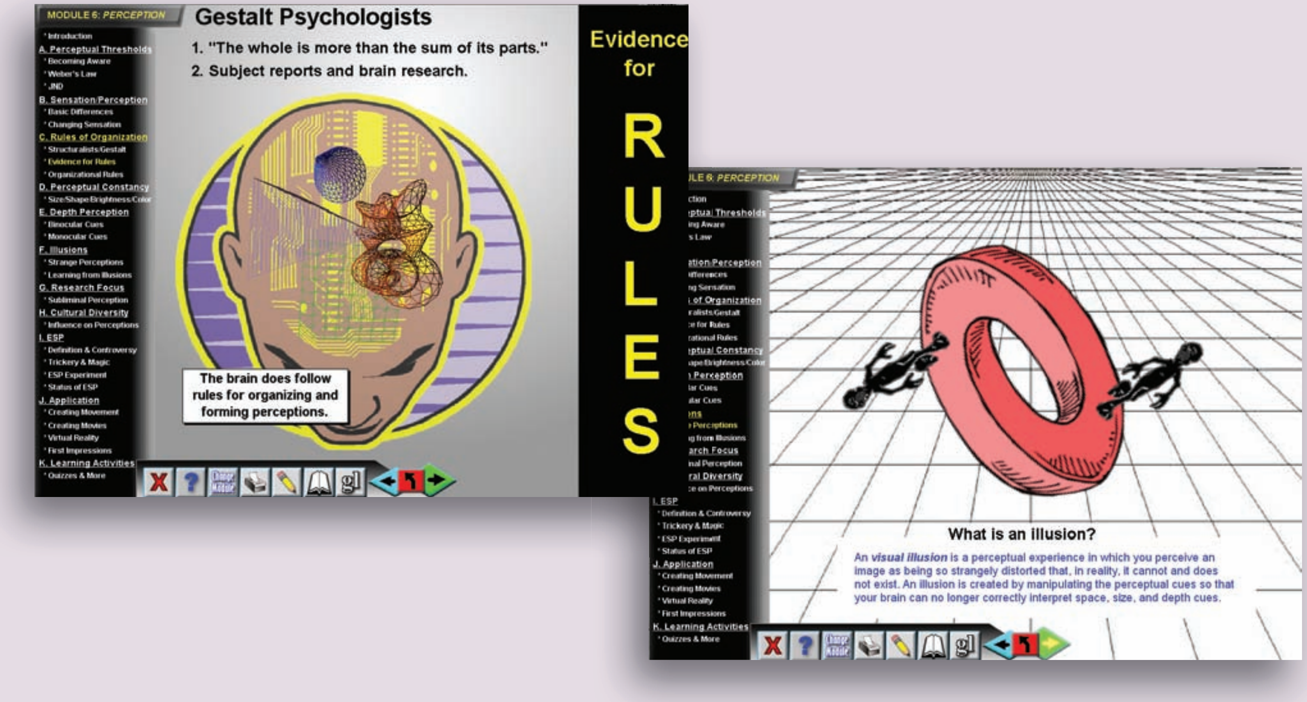
PowerStudy 4.5™



MODULE 6: PERCEPTION
Introduction
A. Perceptual Thresholds
Becoming Aware
Weber's Law
JND
B. Sensation/Perception
Basic Differences
Changing Sensation
C. Rules of Organization
Structuralists/Gestalt
Evidence for Rules
Organizational Rules
D. Perceptual Constancy
Size/Shape/Brightness/Color
E. Depth Perception
Binocular Cues
Monocular Cues
F. Illusions
Strange Perceptions
Learning from Illusions
G. Research Focus
Subliminal Perception
H. Cultural Diversity
Influence on Perceptions
I. ESP
Definition & Controversy
Trickery & Magic
ESP Experiment
Status of ESP
J. Application
Creating Movement
Creating Movies
Virtual Reality
First Impressions
K. Learning Activities
Quizzes & More
Change Module
gl
Evidence for RULES

Gestalt Psychologists

1. "The whole is more than the sum of its parts."
2. Subject reports and brain research.

The brain does follow rules for organizing and forming perceptions.

What is an illusion?

An *visual illusion* is a perceptual experience in which you perceive an image as being so strangely distorted that, in reality, it cannot and does not exist. An illusion is created by manipulating the perceptual cues so that your brain can no longer correctly interpret space, size, and depth cues.

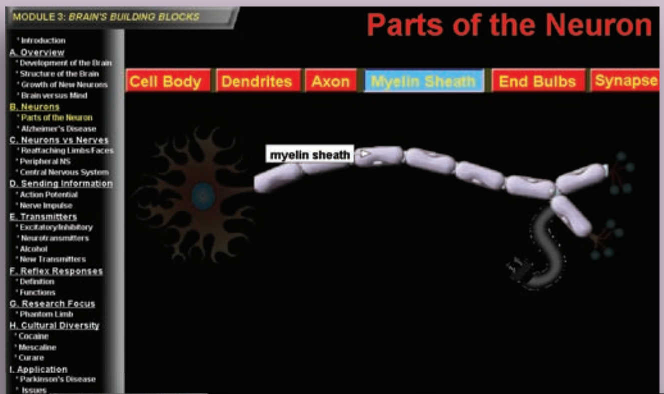
Created with *you* in mind, **PowerStudy 4.5™** is a dynamic study partner that further brings core concepts in psychology to life. Co-written by text author Rod Plotnik, **PowerStudy** actively involves you in your own learning, illuminating topics covered in this text's modules—and helping you improve your performance in psychology.

Each of **PowerStudy's** 14 Super Modules is a 40–50-minute interactive multimedia presentation. Ideal for visual learners, these self-paced, step-by-step media explorations include engaging animations and narration that clarify concepts.

For every other text module, the cross-platform DVD-ROM offers extensive study materials and activities, including interactive key terms, critical thinking questions, summary tests, and more.

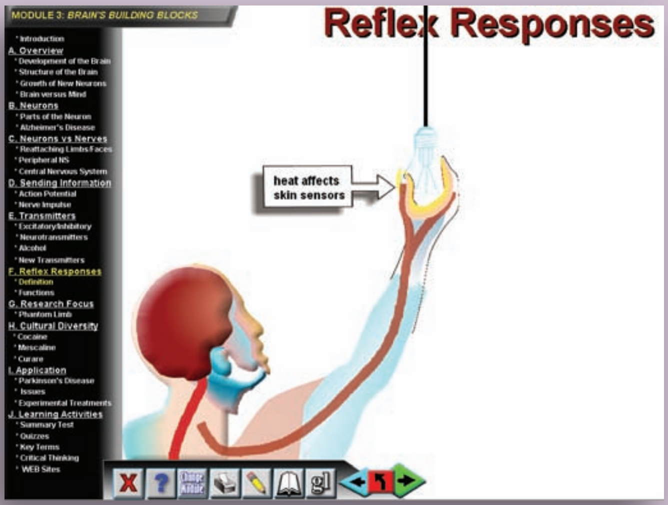
Super Modules

- 2: Psychology and Science
- 3: Brain's Building Blocks
- 4: Incredible Nervous System
- 6: Perception
- 8: Hypnosis and Drugs
- 9: Classical Conditioning
- 10: Operant and Cognitive Approaches
- 11: Types of Memory
- 12: Remembering and Forgetting
- 17: Infancy and Childhood
- 18: Adolescence and Adulthood
- 21: Health, Stress and Coping
- 22: Assessment and Anxiety Disorders
- 23: Mood Disorder and Schizophrenia



MODULE 3: BRAIN'S BUILDING BLOCKS
Parts of the Neuron
Cell Body
Dendrites
Axon
Myelin Sheath
End Bulbs
Synapse
myelin sheath

MODULE 6: PERCEPTION
Why did people buy more popcorn?
EAT POPCORN



MODULE 3: BRAIN'S BUILDING BLOCKS
Reflex Responses
heat affects skin sensors

PowerStudy is fun, easy-to-use, and effective—find out for yourself!

Don't miss out on the multimedia study partner that illuminates and reinforces what you learn in this text.

If a DVD isn't packaged with this text, go to CengageBrain.com and purchase **PowerStudy** before your first test using **ISBN 978-0-495-90866-1**.

For more information about how you can use **PowerStudy** to full advantage, see pages xxxv and xxxvi of this text.

To All Students Everywhere:

We begin each revision with great enthusiasm, which usually begins to fade at the halfway point. The one sure way we have to revive our motivation is to read the many uplifting students' comments that we have received. To show you what we mean, we've included a sample of their wonderful comments, for which we are eternally grateful. (If you too would like to comment on the text, please fill out and send in the form on the last page of this text.)

The psychology book was amazing. I do not know how and where to begin, because I just loved it so much.
—**Natosha,**
Saint Dominic Academy

I really liked how easy the book was to comprehend. The examples help make the definitions easy to memorize.
—**Natalie,**
Ononadaga Community College

The diagrams were easy to understand. Good pictures and real-life examples people can *relate* to. Best psychology book I've read.
—**Sarah,** Rochester Community College

Since I consider myself a visual learner, I benefited a lot from the pictures, drawings, and graphs included throughout the book. Also the "chunking" made the material fun to learn.
—**Roxanne,** Wharton County Junior College

How visual it is. The many pictures helped me to remember the text better. The simple writing style, but still academic, was helpful to make it interesting. I am really glad that we read this book. It made my course!
—**Julia,** Norwalk Community College

I enjoyed so much the photos, the text, the stories, the whole layout of the book—I truly learned just from reading and remembered things because of the way they were used in the book, like next to a picture or highlighted!
—**Richelle,** Western Iowa Tech Community College

I was astonished at how gripping this textbook was. I actually looked forward to the reading. I really enjoyed the real-life situations that were incorporated into each module. I have decided to keep this book and do more reading than what was required during class.
—**Amanda,**
Lanier Technical College

Your book made learning all the material really easy & very interesting. The way you explained everything made sense & kept me intrigued & wanting to learn more. No joke.
—**Avani,** Henry Ford Community College

The summary tests!! I couldn't have passed psychology without those tests!! THANK YOU!! I'll keep this book forever!!
—**Shannon,** Griffith University

I truly enjoyed the "little stories." They help me understand what we were studying. Please continue on with the Cultural Diversity sections!
—**Pharik,** Platt College

This is one of the best textbooks I've read and enjoyed; you did a great job organizing and writing material in such a friendly way. I plan on keeping this book as I enjoyed it so much.
—**Janet,** Ivy Tech Community College

The newspaper articles at the end of each chapter were so interesting, I wanted to read every single one. Thank you for putting together such a visual book and making everything seem so much more interesting.
—**Tracy,** Wayne Community College

APPENDIX Statistics in Psychology 610

MODULE **1**
Discovering Psychology 2

A. Definition & Goals
Definition of Psychology 4
Goals of Psychology 4

B. Modern Approaches 5
Answering Questions 5
Biological Approach 6
Cognitive Approach 7
Behavioral Approach 8
Psychoanalytic Approach 9
Humanistic Approach 10
Cross-Cultural Approach 11
Evolutionary Approach 11
Eclectic Approach 11

C. Historical Approaches 12
Structuralism 12
Functionalism 12
Gestalt Approach 13
Behaviorism 13
Survival of Approaches 13

D. Cultural Diversity: Early Discrimination 14
Women in Psychology 14
Minorities in Psychology 14
Righting the Wrongs 14

Concept Review 15

E. Research Focus: Taking Class Notes 16
Best Strategy for Taking Class Notes? 16

F. Careers in Psychology 17
Psychologist Versus Psychiatrist 17
Many Career Settings 17

G. Research Areas 18
Areas of Specialization 18
Making Decisions 19

H. Application: Study Skills 20
Improving Study Habits 20
Setting Goals 20
Rewarding Yourself 21
Taking Notes 21
Stopping Procrastination 21

Summary Test 22

Critical Thinking 24

Links to Learning 25

MODULE **2**
Psychology & Science 26

A. Answering Questions 28
Survey 28
Case Study 28
Experiment 28

B. Surveys 29
Kind of Information 29
Disadvantages 29
Advantages 29

C. Case Study 30
Kind of Information 30
Personal Case Study: Testimonial 30
Error and Bias 30

D. Cultural Diversity: Use of Placebos 31
Examples of Mind over Body 31
Conclusion: Testimonials and Placebos 31

E. Correlation 32
Definition 32
Correlation Coefficients 32
Correlation Versus Causation 33
Correlation as Clues 33
Correlation and Predictions 33

F. Decisions about Doing Research 34
Choosing Research Techniques 34
Choosing Research Settings 35

G. Scientific Method: Experiment 36
Advantages of the Scientific Method 36
Conducting an Experiment: Seven Rules 36
Conclusion 37

Concept Review 38

H. Research Focus: ADHD Controversies 39
Controversy: Diagnosis 39
Controversy: Treatment 39
Controversy: Long-Term Effects 39

I. Application: Research Concerns 40
Concerns about Being a Subject 40
Code of Ethics 40
Role of Deception 40
Ethics of Animal Research 41

Summary Test 42

Critical Thinking 44

Links to Learning 45

MODULE 3
Brain's Building Blocks 46

A. Overview: Human Brain 48
Development of the Brain 48
Structure of the Brain 48
Growth of New Neurons 49
Brain Versus Mind 49

B. Neurons: Structure & Function 50
Parts of the Neuron 50
Alzheimer's Disease and Neurons 50

C. Neurons Versus Nerves 51
Reattaching Limbs 51
Transplanting a Face 51
Peripheral Nervous System 51
Central Nervous System 51

D. Sending Information 52
Sequence: Action Potential 52
Sequence: Nerve Impulse 52

E. Transmitters 54
Excitatory and Inhibitory 54
Neurotransmitters 54
Alcohol 55
New Transmitters 55

F. Reflex Responses 56
Definition and Sequence 56
Functions of a Reflex 56

Concept Review 57

G. Research Focus: What Is a Phantom Limb? 58
Case Study 58
Definition and Data 58
Answers and Treatment 58

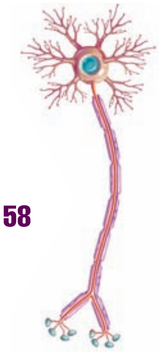
H. Cultural Diversity: Plants & Drugs 59
Cocaine 59
Curare 59
Mescaline 59

I. Application: Experimental Treatments 60
Parkinson's Disease 60
Issues Involving Transplants 60
Experimental Treatments 61

Summary Test 62

Critical Thinking 64

Links to Learning 65



MODULE 4
Incredible Nervous System 66

A. Genes & Evolution 68
Genetic Instructions 68
Errors in Genetic Instructions 69
Genetic Testing 69
Evolution of the Human Brain 69

B. Studying the Living Brain 70
Brain Scans 70
Brain Scans: MRI & fMRI 70
Brain Scans and Cognitive Neuroscience 71
Faces Versus Bodies 71

C. Organization of the Brain 72
Divisions of the Nervous System 72
Major Parts of the Brain 73

D. Control Centers: Four Lobes 74
Overall View of the Cortex 74
Frontal Lobe: Functions 75
Parietal Lobe: Functions 77
Temporal Lobe: Functions 78
Occipital Lobe: Functions 79

E. Limbic System: Old Brain 80
Structures and Functions 80
Autonomic Nervous System 81

F. Endocrine System 82
Definition 82
Control Center 82
Other Glands 82

Concept Review 83

G. Research Focus: Sex Differences in the Brain? 84
Scientific Debate 84

H. Cultural Diversity: Brain Size & Racial Myths 85
Skull Size and Intelligence 85
Brain Size and Intelligence 85

I. Application: Split Brain 86
Definition and Testing 86
Behaviors Following Split Brain 87
Different Functions of Hemispheres 87
Left- or Right-Brained? 87

MODULE 7

Sleep & Dreams 146

A. Continuum of Consciousness 148
Different States 148
Several Kinds 149

B. Rhythms of Sleeping & Waking 150
Biological Clocks 150
Location of Biological Clocks 150
Circadian Problems and Treatments 151

C. World of Sleep 152
Stages of Sleep 152
Non-REM Sleep 152
REM Sleep 153
Awake and Alert 153
Sequence of Stages 154

D. Research Focus: Circadian Preference 155
Are You a Morning or Evening Person? 155
Body Temperature Differences 155
Brain Differences 155
Behavioral and Cognitive Differences 155

E. Questions about Sleep 156
How Much Sleep Do I Need? 156
Why Do I Sleep? 156
What If I Miss Sleep? 157
What Causes Sleep? 157

Concept Review 158

F. Cultural Diversity: Incidence of SAD 159
Problem and Treatment 159
Occurrence of SAD 159
Cultural Differences 159

G. World of Dreams 160
Theories of Dream Interpretation 160
Typical Dreams 161

H. Application: Sleep Problems & Treatments 162
Occurrence 162
Insomnia 162
Nondrug Treatment 162
Drug Treatment 162
Sleep Apnea 163
Narcolepsy 163
Sleep Disturbances 163

Types of Memory 238

A. Three Types of Memory 240
Sensory Memory 240
Short-Term Memory 240
Long-Term Memory 240
Memory Processes 240

B. Sensory Memory: Recording 241
Iconic Memory 241
Echoic Memory 241
Functions of Sensory Memory 241

C. Short-Term Memory: Working 242
Definition 242
Two Features 242
Chunking 243
Functions of Short-Term Memory 243

D. Long-Term Memory: Storing 244
Putting Information into Long-Term Memory 244
Features of Long-Term Memory 244
Separate Memory Systems 245
Declarative Versus Procedural or Nondeclarative 246

E. Research Focus: Do Emotions Affect Memories? 247
Hormones and Memories 247
Memories of Emotional Events 247

F. Encoding: Transferring 248
Two Kinds of Encoding 248
Rehearsing and Encoding 249
Levels of Processing 249

G. Repressed Memories 250
Recovered Memories 250
Definition of Repressed Memories 250
Therapist’s Role in Recovered Memories 250
Implanting False Memories 251
Accuracy of Recovered Memories 251

Concept Review 252

H. Cultural Diversity: Oral Versus Written 253
United States Versus Africa 253
Remembering Spoken Information 253

I. Application: Unusual Memories 254
Photographic Memory 254
Extraordinary Episodic Memory 254
Super Memory for Faces 254
Flashbulb Memory 255

Summary Test 256

Critical Thinking 258

MODULE 14
Thought & Language 304

A. Forming Concepts 306
- Exemplar Model 306
- Prototype Theory 306
- Early Formation 307
- Categories in the Brain 307
- Functions of Concepts 307

B. Solving Problems 308
- Different Ways of Thinking 308
- Three Strategies for Solving Problems 309

C. Thinking Creatively 310
- How Is Creativity Defined? 310
- Is IQ Related to Creativity? 311
- How Do Creative People Think and Behave? 311
- Is Creativity Related to Mental Disorders? 311

D. Language: Basic Rules 312
- Four Rules of Language 312
- Understanding Language 313
- Different Structure, Same Meaning 313

E. Acquiring Language 314
- Four Stages in Acquiring Language 314
- Going through the Stages 315
- What Are Innate Factors? 316
- What Are Environmental Factors? 316

Concept Review 317

F. Decisions, Thought & Language 318
- Decisions 318
- Words and Thoughts 319

G. Research Focus: Dyslexia 320
- What Kind of Problem Is Dyslexia? 320

H. Cultural Diversity: Influences on Thinking 321
- Differences in Thinking 321
- Male–Female Differences 321
- Difference in Language, Similarity in Thought 321

I. Application: Do Animals Have Language? 322
- Criteria for Language 322
- Dolphins 322
- Gorilla and Chimpanzee 323
- Bonobo Chimp: Star Pupil 323

MODULE **15**
Motivation 328

A. Theories of Motivation 330
Instinct 330
Brain: Reward/Pleasure Center 330
Incentives 331
Cognitive Factors 331
Explaining Human Motivation 331

B. Biological & Social Needs 332
Biological Needs 332
Social Needs 332
Satisfying Needs 332
Maslow's Hierarchy of Needs 333

$E = mc^2$
$\pi = 3.14$
$y = mx+b$
F

C. Hunger 334
Optimal Weight 334
Overweight 334
Three Hunger Factors 334
Biological Hunger Factors 335
Genetic Hunger Factors 336
Psychosocial Hunger Factors 337

D. Sexual Behavior 338
Genetic Influences on Sexual Behavior 338
Biological Influences 339
Psychological Influences on Sexual Behavior 340
Male–Female Sex Differences 342
Homosexuality 343
Sexual Response, Problems, and Treatments 344
AIDS: Acquired Immune Deficiency Syndrome 345

E. Cultural Diversity: Genital Cutting 346
Good Tradition or Cruel Mutilation? 346

Concept Review 347

F. Achievement 348
Need for Achievement 348
Fear of Failure 349
Underachievement 349
Three Components of Success 349
Cognitive Influences 350
Intrinsic Motivation 350

G. Research Focus: Overcoming Educational Disadvantages 351
Why Did Poor and Minority Children Do Well? 351

H. Application: Eating Problems & Treatments 352
Dieting: Problems, Concerns, and Benefits 352
Serious Eating Disorders 353

Summary Test 354

MODULE **16**
Emotion 358

A. Peripheral Theories 360
Studying Emotions 360
James-Lange Theory 360
Facial Feedback Theory 360

B. Cognitive Appraisal Theory 361
Thoughts and Emotions 361
Schachter-Singer Experiment 361
Cognitive Appraisal Theory 361

C. Affective Neuroscience Approach 362
Four Qualities of Emotions 362
Emotional Detector and Memorizer 362
Brain Circuits for Emotions 363
Fear and the Amygdala 363

D. Universal Facial Expressions 364
Definition 364
Cross-Cultural Evidence 364
Genetic Evidence 364

E. Functions of Emotions 365
Social Signals 365
Survival, Attention & Memory 365
Arousal and Motivation 365

F. Happiness 366
Positive Emotions 366
Long-Term Happiness 366

G. Cultural Diversity: Emotions across Cultures 367
Showing Emotions 367
Perceiving Emotions 367

Concept Review 368

H. Research Focus: Emotional Intelligence 369
What Is Emotional Intelligence? 369

I. Application: Lie Detection 370
What Is the Theory? 370
What Is a Lie Detector Test? 370
How Accurate Are Lie Detector Tests? 371

MODULE **18**
Adolescence & Adulthood 406

A. Puberty & Sexual Behavior 408
Girls during Puberty 408
Boys during Puberty 408
Adolescents: Sexually Mature 409

B. Cognitive & Emotional Changes 410
Definition 410
Piaget's Cognitive Stages: Continued 410
Brain Development: Reason and Emotion 411
Kohlberg's Theory of Moral Reasoning 412
Parenting Styles and Effects 413
Adolescence: Big Picture 414
Beyond Adolescence 415

C. Personality & Social Changes 416
Definition 416
Development of Self-Esteem 416
Adulthood: Erikson's Psychosocial Stages 417
Personality Change 417

D. Gender Roles, Love & Relationships 418
Definition: Gender Roles 418
Kinds of Love 419
Choosing a Partner 420
Cohabiting 420
Marriage 420

Concept Review 421

E. Research Focus: Happy Marriages 422
What's a Love Lab? 422

F. Cultural Diversity: Preferences for Partners 423
Measuring Cultural Influences 423
Desirable Traits 423
Reasons for Marrying 423

G. Physical Changes: Aging 424
Kinds of Aging 424
Aging and Physiological Changes 424
Sexual Changes with Aging 425

H. Application: Suicide 426
Teenage/Young Adult Suicide 426
Problems Related to Suicide 426
Preventing Suicide 427
Suicide in the Elderly 427

Summary Test 428

MODULE 22
Assessment & Anxiety Disorders 508

A. Factors in Mental Disorders 510
- Causes of Abnormal Behavior 510
- Definitions of Abnormal Behavior 511

B. Assessing Mental Disorders 512
- Definition of Assessment 512
- Three Methods of Assessment 512

C. Diagnosing Mental Disorders 513
- Real-Life Assessment 513
- DSM-IV-TR 513
- Nine Major Problems: Axis I 514
- Other Problems and Disorders: Axes II, III, IV, V 515
- Potential Problems with Using the DSM-IV-TR 516
- Frequency of Mental Disorders 516

D. Anxiety Disorders 517
- Generalized Anxiety Disorder 517
- Panic Disorder 517
- Phobias 518
- Obsessive-Compulsive Disorder 519
- Posttraumatic Stress Disorder 519

E. Somatoform Disorders 520
- Definition and Examples 520
- Mass Hysteria 520

Concept Review 521

F. Cultural Diversity: An Asian Disorder 522
- Taijin Kyofusho, or TKS 522
- Social Customs 522

G. Research Focus: School Shootings 523
- What Drove Teens to Kill Fellow Students and Teachers? 523

H. Application: Treating Phobias 524
- Specific Phobia: Flying 524
- Cognitive-Behavioral Therapy 524
- Exposure Therapy 524
- Social Phobia: Public Speaking 525
- Drug Treatment of Phobias 525

To the Instructor: Changes and Features

What Are the Major Content Changes?

During the past decade, new findings in the related areas of biology, genetics, and cognitive neuroscience have had a great impact on the field of psychology. Because such findings help psychologists better understand and explain behavior, we included many new and exciting discoveries not only from the field of psychology but also from the related fields of biology, genetics, and cognitive neuroscience.

In updating the 9th edition, we added more than 1,000 new references, all from recent years!

Here is a sample of some of the major content changes in the 9th edition:

Module 1: Discovering Psychology. New coverage on the evolutionary approach and eclectic approach; added clinical/counseling psychology and industrial/organizational psychology to research areas of psychology; updated prevalence rate of autism; new content on the genes involved in autism; new examples for savant syndrome; new research on early brain development in children with autism; new research on sex differences in test anxiety; new content on how autism is perceived in other cultures; new cross-cultural content focusing on the differences in development and severity of test anxiety between India and United States; updated statistics on women and minorities in psychology; new information on careers in psychology; new research on first-year college students' reports of study habits and time management; new content about advantage of spaced-out study sessions vs. cramming.

Module 2: Psychology & Science. New module-opening case example of Blake E. S. Taylor, successful college student with ADHD; new cultural diversity placebo example of Korean centipedes; new findings about how ADHD medications fail to improve some important cognitive and social functions; updated statistics on prevalence of ADHD, including gender, age, and ethnicity information; updated list of problems placebos have been shown to effectively treat and new content on how placebos can create similar changes in brain as real drugs; additional coverage of how correlations leave many questions unanswered; new animal model research example of using genetically altered mice to identify causes of schizophrenia; areas of the brains of ADHD children develop much slower than in children without ADHD, additional coverage of ADHD misdiagnosis; updated the number of children on ADHD medications and revised list of ADHD medication side effects; updated list of ways animal research has furthered our understanding of psychology.

Module 3: Brain's Building Blocks. New module-opening case example for Alzheimer's disease; updated the prevalence, diagnosis, causes, and treatment of Alzheimer's; glial cells (astrocytes) don't only have supportive function, but new research shows some glial cells may transmit electrical signals; updated info on John Thompson and Isabelle (face transplant case); new coverage of Orexin (hypocretin), a recently discovered neurotransmitter involved in the brain's pleasure/reward system; new phantom limb case example of Sgt. Christian Bagge; new research shows the brain can correct its representation of the body to incorporate the loss of limb; update on Michael J. Fox's condition with Parkinson's disease; present results from a case study that found that adult stem cell transplantation improved motor functioning in a patient with Parkinson's disease; expanded coverage of deep brain stimulation (DBS); new Critical Thinking article about mirror neurons: "Mirrors in Your Brain?"

Module 4: Incredible Nervous System. New coverage on genetic differences between identical twins; new case example for fragile X syndrome and brain injury; updated information on anencephaly; new coverage on polymorphic genes, dominant genes, and recessive genes; new coverage on Down syndrome; new coverage on genetic testing; revised coverage on the evolution of the human brain, including new content on genetic mutations, adaptive and maladaptive genes, adaptations, and evolutionary approach; new research examples using brain scans; new coverage on the limitations of brain scans; new content on the frontal lobe and aging; reorganized and updated content on functions of the parietal lobe; updated Research Focus section on sex differences in the brain.

Module 5: Sensation. New module-opening case example and content on artificial eyes; revised hearing range section to include ear-splitting ring tones college students hear, but older adults cannot; new content on the risk of going deaf by listening to MP3 players too loud for extended periods of time; updated content on supertasters, including sex differences and evolutionary advantage; updated stats about losing sense of smell during aging; added evolutionary function of olfaction; new section on how smells encourage us to make purchases based on instinct rather than rational thinking; updated Cultural Diversity section on disgust; Research Focus section now explores how the price of medication is positively associated with our expectations of its effectiveness and consequently the strength of its placebo effect; abbreviated definition of the following concepts to improve clarity: pain, gate control theory, endorphins, acupuncture, and neural deafness; new examples about how our religious beliefs can influence our experience of pain; new discussion about placebo effects of acupuncture; updated Application section with a new case example for artificial photoreceptors; updated stats on number of people with conduction deafness; added content on areas of advancement in cochlear implants.

Module 6: Perception. Updated stats and content on breast cancer and accuracy of reading mammograms; new information on the use of gestalt principles when doctors read mammograms; new examples to illustrate depth perception; new coverage on strange perceptions using a motion illusion; new research shows physiological evidence that subliminal messages attract the brain's attention on a subconscious level; new research shows that subliminal messages cannot change our behaviors; new content on how unconscious attitudes may influence our behaviors and decision making; updated Cultural Diversity section to include research on perception of faces and how an individual's cultural background influences processing of a simple task; the racial complexion transformations from the TV reality series "Black.White." are used to highlight the powerful effect race can have on our first impressions of others; new Critical Thinking section about synesthesia: "Taste Shapes? Hear Colors? Smell Sounds?"

Module 7: Sleep & Dreams. Updated content on controlled processes includes research showing that listening to a conversation while driving increases brain activity in language areas and decreases activity in spatial areas; updated statistics on cell phone usage and accidents; new section on shift workers; new research on flight attendants and jet lag; new content on an experimental drug that may reset the circadian clock; new coverage of REM behavior disorder; updated Research Focus section on circadian preference; updated content on effects of sleep deprivation; new cross-cultural research about people's beliefs in dreams; new coverage of threat simulation theory of dream interpretation; new case example for narcolepsy; new Critical Thinking section: "Texting, How Distracting Can It Be?"

Module 8: Hypnosis & Drugs. New research refutes the altered state theory of hypnosis and supports the sociocognitive theory of hypnosis; new research shows hypnotized patients require less pain medication and recover sooner than patients who don't receive hypnosis; updated many drug-related statistics throughout the module, including, but not limited to, cost of drugs on society, money spent on illegal drugs, and prevalence of drug users; updated dangers of methamphetamine, marijuana, and

MDMA use; new content on today's energy drinks; new content on withdrawal symptoms from caffeine, marijuana, and cigarette use; new content on buprenorphine in the treatment of heroin addiction; updated content on the influence of genetic risk factors on the susceptibility for alcoholism; updated content on the problems with alcohol use; new research shows that in some cases the DARE program has been counterproductive in getting teens to reduce alcohol and other drug use; new research shows heavy drug use can make a person more sensitive to stress and thus more likely to use drugs to reduce anxiety; new coverage on medications to treat alcoholism (naltrexone, acamprosate, Antabuse) and their success rates; new Critical Thinking section: "Brain-Boosting Drugs, Myth or Fact?"

Module 9: Classical Conditioning. Revised the definitions for learning and behavior; new coverage on "fear neurons" and "extinction neurons" in the amygdala and their role in conditioning and extinction; added rates of children's dental fears in Taiwan to the Cultural Diversity section; new Critical Thinking section: "Powerful Marketing Changes Your Brain."

Module 10: Operant & Cognitive Approaches. New research shows the use of physical punishment in schools to discourage undesirable behaviors increases absenteeism; reorganized punishment section; added noncompliance and time-out definitions and examples; new example for positive punishment is a controversial school discipline strategy of applying electric shock to students when they misbehave; new research on mirror neurons suggests that observational learning may have a biological foundation; new research shows unique patterns of brain activity occur immediately before "ah-ha!" experiences; new Research Focus section about viewing relational and physical aggression in media and behaviors in real life; in Application section, updated costs to take care of a person with autism.

Module 11: Types of Memory. New module-opening case example of Daniel Tammet, who chunks numbers by visual images; new research on how hormones lead to molecular changes that help brain cells form memories; new case example for recovered memory; new content on the use of brain imaging to examine the biological underpinnings of impaired memory; new research on accuracy of recovered memories of childhood sexual abuse; new content on extraordinary episodic memory and super memory for faces (super-recognizers).

Module 12: Remembering & Forgetting. New research shows brain region for processing and producing sound is less activated as tip-of-the-tongue experiences become more frequent; new content on the role of the hippocampus in retrieving memories; new research shows that reduced activity in the hippocampus and amygdala leads to people forgetting their unwanted memories; new eyewitness testimony example; updated stats on number of people wrongfully convicted of crimes in the United States and percentage of these people convicted based on mistaken eyewitness testimony; new Critical Thinking section: "Can Bad Memories Be Erased?"

Module 13: Intelligence. New module-opening case examples of Alia Sabur and Jay Greenberg to introduce multiple types of intelligence; new content on how educators are designing classroom curriculum based on the multiple-intelligence approach; updated content on the WAIS, which is now in its 4th version; added the term *mental retardation* is in transition to be changed to *intellectual disability;* added that belief in one's ability to succeed is a predictor of academic performance; added that despite the common stereotype of gifted kids being socially awkward, they are usually socially well adjusted; new research shows that practice and determination, rather than innate factors, are critical factors in developing giftedness; new content on the reasons for the difference in IQ scores between African Americans and Whites; new research with Romanian children compares the intellectual functioning of children placed in foster care with those remaining in state-run institutions; new content in Application section on parent training as an effective intervention program for disadvantaged children; new data from the longest and most extensive research study on intelligence show that childhood intelligence affects adults in significant ways; new Critical Thinking section: "Smartest or Strongest Man in America?"

Module 14: Thought & Language. New module-opening case example of Shawn Carter (Jay-Z) to introduce the topic of creativity; new savant case example of Stephen Wiltshire; new research finds that children who are exposed to two languages from birth learn the two distinct vocabularies and grammar rules as quickly as their monolingual peers learn the rules for one language; new content on how parentese has important cross-cultural benefits; new research finds watching TV reduces conversations between parent and child; new research shows that the use of physical gestures at a young age is later correlated with higher language scores; new content on how training can help children with dyslexia develop better listening comprehension and word recognition; new cultural diversity coverage discusses how the Piraha people lack language for specific numbers but can still identify quantity; updated Application section on language skills in animals; new Critical Thinking section: "Music Improves Language Skills in Kids."

Module 15: Motivation. New module-opening case example of Erik Weihenmayer to introduce motivation; updated obesity rate for youth and adults in the United States; new content on evolutionary perspective of today's obesity epidemic; new research reports showed brain cell growth in the hypothalamus and less sensitivity to leptin are associated with obesity in rats; updated content on how much exercise raises metabolic rates; new content on how genetic mutations can disrupt appetite regulation; new content about how external cues contribute to obesity; added obesity rates across the globe; revised U.S. content about slim females in media influencing female body image; added Dove's current campaign to embrace nontraditional beauty; new content on emotional eating; new research finds that men are sensitive to women's peaks in sexual hormones; new coverage of how evolutionary theory explains many sexual behaviors; updated research evidence of genetic/biological factors in homosexual orientation; updated stats for adult men and women with sexual dysfunction; updated content on HIV and AIDS; new content on how the need for achievement varies based on cultural factors; updated low-fat or low-carb diet section with new, long-term research; new anorexia case example of 2008 Miss America Kirsten Haglund; updated stats, risk factors, and treatment outcomes for eating disorders; updated Critical Thinking section to reflect recent research findings on Viagra use with women: "Viagra for Men *and Women?*"

Module 16: Emotion. New research findings show that blind and sighted people share universal facial expressions, which supports genetic evidence of universal facial expressions; new content on how our facial expressions help us manage our sensory experiences; new coverage on gender differences in happiness; expanded content on smiling to include cross-cultural research on Russians and Americans; research on Westerners and Cameroon's Mafa farmers suggests that the perception of emotions in music may be a universal human ability; updated research findings on emotional intelligence; included new content about emotional intelligence in romantic relationships; expanded content on the role of mirror neurons in emotional intelligence by discussing autism and people with high empathy skills; new content on how the future of more reliable lie detection may be combining brain scans with clever questioning techniques.

Module 17: Infancy & Childhood. Updated content on how identical twins have genes that are almost indistinguishable; new content on effects of caffeine, nicotine, and lead exposure during pregnancy; new content on how temperament during infancy is associated with mood disorder in adulthood; referred students to Module 18, p. 413, to learn how parenting styles influence the cognitive and emotional development of teenagers; new coverage of egocentric thinking, imaginary audience, and personal fable; new case example of Dave Pelzer, survivor of childhood abuse, to discuss vulnerability and resiliency; reorganized Application section on child abuse; new case example of Teri Hatcher for childhood sexual abuse; added content about stress-regulating gene's contribution to depression in adults who were abused as children; added content about child abuse altering brain area responsible for release of stress hormones leading to increased stress throughout life; new Critical Thinking section: "Who Matters More—Parents or Peers?"

Module 18: Adolescence & Adulthood. New module-opening case example of Charlie Sheen to show that adulthood presents many challenges; updated stats on teens being sexually active; new research shows that watching more sexy TV is correlated with earlier initiation of sexual intercourse and teens who have sex earlier have fewer delinquency and antisocial behaviors years later; new content on how the increased structure and function of the limbic system likely account for a teen's irritability; new research shows that making moral decisions appears to involve unconscious processes; new research shows that physical and mental exercises may help people improve their memory 30–40%; new content on self-esteem of today's adolescents, who think more highly of themselves than teens have in previous generations; updated content on gender roles in the U.S.; expanded "Brain in Love" section by including research using brain scans that shows long-term married couples can feel the same passion and romance as those who only recently found love; new coverage on cohabitation; updated statistics on the number of older adults in the U.S.; updated content on the sexual development of elderly people; updated stats on suicide across the life span; research finds the brains of suicide victims differ from others in several key ways; new content in Critical Thinking article: "Are Teens Too Young to Drive?"

Module 19: Freudian & Humanistic Theories. Included reference to anal expulsive in description of fixation at the anal stage; new scientific data support existence of Oedipus complex; new brain scan research supports that unconscious forces play a role in our decision-making processes; new coverage of how unconscious changes influence behavior; new case example of Lorena Ochoa, world's #1 ranked female pro golfer and humanitarian, to show a person approaching self-actualization; slightly expanded positive regard section to include benefit of pets, who show positive regard, to people; new content on how humanistic theories are becoming more widespread as a result of the relatively recent positive psychology approach; new content on the disadvantage of social cognitive theory.

Module 20: Social Cognitive & Trait Theories. New module-opening case example of Kiran Bedi, India's first female police officer, to illustrate power of determination and differences in personality traits of male/female officers; new research on variability of Big Five across the United States and world; new coverage of the "Big One," proposed to be a general factor similar to Spearman's *g* factor for intelligence; updated Research Focus section on quantum personality changes; updated Cultural Diversity section by focusing on the prevalence of suicide attacks by Palestinian women, added a new case example of a female suicide bomber, and expanded content on what motivates a suicide bomber; clarified that honesty tests are integrity tests; new content on the revision of the MMPI-2, which is now called MMPI-2-RF (Restructured Form).

Module 21: Health, Stress & Coping. New module-opening case example of Brenda Combs to introduce the topic of coping; expanded discussion of mind-body connection by including research on effectiveness of mind-body therapy on various health problems; updated psychoneuroimmunology section with new research showing stress weakens immune system by reducing natural killer cells that battle cancer; new coverage of adjustment disorder; updated stats for people with PTSD and types of situations that commonly lead to PTSD; new coverage of positive stress (eustress); new content on how being hardy helps people see opportunities for growth, which gives them an edge in potentially stressful situations; updated positive psychology section; expanded discussion of social support to include virtual or online group support; expanded buffer against stress section by including new research on benefits of caring touch; new coverage on social conflict; new research on benefits of meditation.

Module 22: Assessment & Anxiety Disorders. Updated stats on number of Americans with fear of flying; added content about current views Americans have toward people with mental illness; new case example on panic disorder; new coverage of PTSD, including case example, symptoms, and treatment; updated content on somatization disorder, including increased health care costs and environmental factors contributing to the disorder; updated Research Focus section on school shootings by including current stats and new case example of Seung-Hui Cho, who committed the deadliest school shooting in history.

Module 23: Mood Disorders & Schizophrenia. New content on role of depressed mothers in children's depression; new data reveal 10% of U.S. population now uses antidepressants, making it the most commonly prescribed medication; new content on how psychotherapy may take longer to begin working, but demonstrates reduced relapse rates compared to drugs; new coverage of transcranial magnetic stimulation; new coverage of borderline personality disorder; updated content about the psychosocial and biological factors involved in antisocial personality disorder; new brain imaging research on visual hallucinations activating visual areas of the brain and auditory hallucinations activating auditory areas of the brain; new content on the role of infections in the development of schizophrenia; new content on the role of glutamate in schizophrenia; updated case example of Jeffrey Ingram, who has dissociative fugue; new case example of Herschel Walker for dissociative identity disorder; brain research shows biological support for the existence of DID; updated Cultural Diversity section by discussing culture-specific mental disorders, including Latah, Bibloqtoq, Susto, and Koro; exercise has an immediate positive effect on mood that lasts for as long as 12 hours.

Module 24: Therapies. New data reveal 26% of Americans are diagnosed with a mental disorder, less than 30% of psychiatric office visits consist of psychotherapy, and 3% of the U.S. population receives psychotherapy; updated content on state legislation allowing clinical psychologists to have prescription privileges; new research supports existence of resistance and transference; updated list of conditions that short-term psychodynamic therapy and cognitive therapy have demonstrated to be effective in treating; added new coverage on cybertherapy; new content on disagreement about whether EMDR is a form of traditional exposure therapy or if it is qualitatively different; new Critical Thinking section: "Can Virtual Reality Be More than Fun & Games?"

Module 25: Social Psychology. New coverage of evolution and physical appearance, including universal attraction, instinctual attraction, and male and female preferences in physical attraction; new content on development of stereotypes; new case example of Harriet Hall to introduce schemas; new case example of Indra Nooyi to introduce attributions and glass ceiling; updated Cultural Diversity content on women's rights in Egypt; referred to Abu Ghraib in discussing implications of results from Milgram's obedience experiment; new case example of Wesly Autrey to introduce prosocial behavior; new coverage of social neuroscience, which includes an overview, methods (PET scan, fMRI, EEG, TMS), and research findings on mirror neurons and racial bias; updated Critical Thinking section on the debate over teen HPV vaccination.

Now that you've read about some of the changes in the 9th edition, we'll discuss the major features of the text.

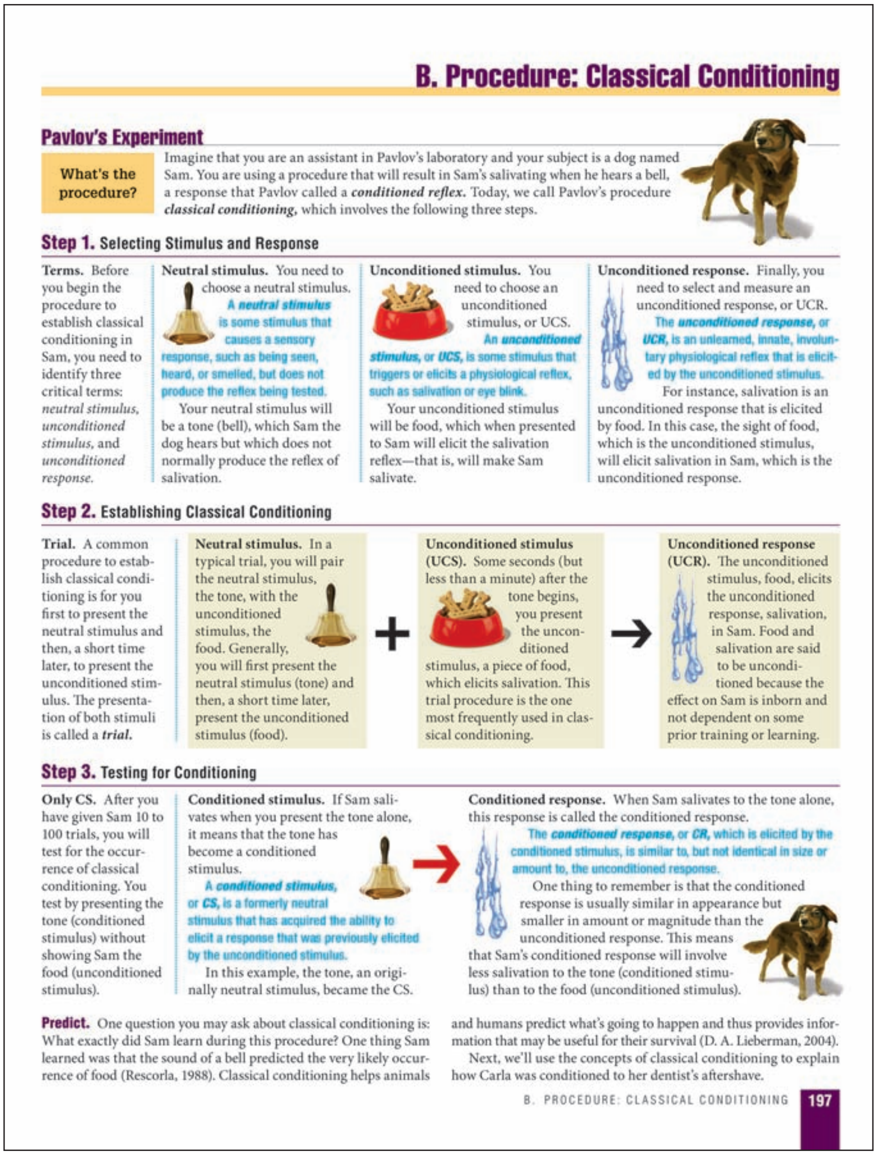
What's Different about This Approach?

One of the first things instructors notice about this textbook is that it looks different from more traditional texts. This book looks different because its method of presenting information is based on well-known principles of learning and memory.

One principle is that if information is presented in an interesting way, then students learn and remember the concepts much more readily. Like previous editions, the 9th edition applies this principle by integrating the text with interesting graphics so that students have visual cues to help them learn and remember. As students often say, "I'm a visual learner, so this text is perfect for me."

Another principle is that if information is organized or "chunked" into smaller units, then students learn and remember the material better. As in previous editions, the 9th edition applies this principle by organizing information into smaller and smaller segments to help students remember the hundreds of terms and concepts. As one reviewer said, "The material is broken down into small, friendly pieces that are easy for students to understand."

Thus, this text looks different because it uses visual learning, which involves the use of ***VISUAL CUES* and *CHUNKING.*** There is a large body of research indicating that chunking helps students better organize and store information and that visual cues help students better retrieve and remember information. The research outcomes on visual learning make complete sense when you consider that our brain is mainly an image processor (much of our sensory cortex is devoted to vision), not a word processor. In fact, the part of the brain used to process words is tiny in comparison to the part that processes visual images. Words are abstract and rather difficult for the brain to retain, whereas visuals are concrete and, as such, more easily remembered (Meier, 2000; Patton, 1991; Schacter, 1966; Shambaugh, 1994; Verdi et al., 1997). It is for these reasons that each page of this textbook has been individually formatted to maximize visual learning.



B. Procedure: Classical Conditioning

Pavlov's Experiment

What's the procedure? Imagine that you are an assistant in Pavlov's laboratory and your subject is a dog named Sam. You are using a procedure that will result in Sam's salivating when he hears a bell, a response that Pavlov called a ***conditioned reflex.*** Today, we call Pavlov's procedure ***classical conditioning,*** which involves the following three steps.

Step 1. Selecting Stimulus and Response

Terms. Before you begin the procedure to establish classical conditioning in Sam, you need to identify three critical terms: *neutral stimulus, unconditioned stimulus,* and *unconditioned response.*

Neutral stimulus. You need to choose a neutral stimulus. A ***neutral stimulus*** is some stimulus that causes a sensory response, such as being seen, heard, or smelled, but does not produce the reflex being tested.

Your neutral stimulus will be a tone (bell), which Sam the dog hears but which does not normally produce the reflex of salivation.

Unconditioned stimulus. You need to choose an unconditioned stimulus, or UCS. An ***unconditioned stimulus,*** or ***UCS,*** is some stimulus that triggers or elicits a physiological reflex, such as salivation or eye blink.

Your unconditioned stimulus will be food, which when presented to Sam will elicit the salivation reflex—that is, will make Sam salivate.

Unconditioned response. Finally, you need to select and measure an unconditioned response, or UCR. The ***unconditioned response,*** or ***UCR,*** is an unlearned, innate, involuntary physiological reflex that is elicited by the unconditioned stimulus.

For instance, salivation is an unconditioned response that is elicited by food. In this case, the sight of food, which is the unconditioned stimulus, will elicit salivation in Sam, which is the unconditioned response.

Step 2. Establishing Classical Conditioning

Trial. A common procedure to establish classical conditioning is for you first to present the neutral stimulus and then, a short time later, to present the unconditioned stimulus. The presentation of both stimuli is called a ***trial.***

Neutral stimulus. In a typical trial, you will pair the neutral stimulus, the tone, with the unconditioned stimulus, the food. Generally, you will first present the neutral stimulus (tone) and then, a short time later, present the unconditioned stimulus (food).

+

Unconditioned stimulus (UCS). Some seconds (but less than a minute) after the tone begins, you present the unconditioned stimulus, a piece of food, which elicits salivation. This trial procedure is the one most frequently used in classical conditioning.

→

Unconditioned response (UCR). The unconditioned stimulus, food, elicits the unconditioned response, salivation, in Sam. Food and salivation are said to be unconditioned because the effect on Sam is inborn and not dependent on some prior training or learning.

Step 3. Testing for Conditioning

Only CS. After you have given Sam 10 to 100 trials, you will test for the occurrence of classical conditioning. You test by presenting the tone (conditioned stimulus) without showing Sam the food (unconditioned stimulus).

Conditioned stimulus. If Sam salivates when you present the tone alone, it means that the tone has become a conditioned stimulus.

A ***conditioned stimulus,*** or ***CS,*** is a formerly neutral stimulus that has acquired the ability to elicit a response that was previously elicited by the unconditioned stimulus.

In this example, the tone, an originally neutral stimulus, became the CS.

→

Conditioned response. When Sam salivates to the tone alone, this response is called the conditioned response.

The ***conditioned response,*** or ***CR,*** which is elicited by the conditioned stimulus, is similar to, but not identical in size or amount to, the unconditioned response.

One thing to remember is that the conditioned response is usually similar in appearance but smaller in amount or magnitude than the unconditioned response. This means that Sam's conditioned response will involve less salivation to the tone (conditioned stimulus) than to the food (unconditioned stimulus).

Predict. One question you may ask about classical conditioning is: What exactly did Sam learn during this procedure? One thing Sam learned was that the sound of a bell predicted the very likely occurrence of food (Rescorla, 1988). Classical conditioning helps animals and humans predict what's going to happen and thus provides information that may be useful for their survival (D. A. Lieberman, 2004).

Next, we'll use the concepts of classical conditioning to explain how Carla was conditioned to her dentist's aftershave.

B. PROCEDURE: CLASSICAL CONDITIONING 197

How Are the Visuals Selected?

Every visual, whether a photo, illustration, concept map, figure, or icon, was carefully selected by the two of us in collaboration with our editorial team. As authors, we are intricately involved in decisions concerning every visual in this textbook. We work collaboratively with our photo researchers and illustrators throughout the revision process. The primary goal of each of our decisions regarding visuals is to improve student learning. If a visual doesn't clearly meet this requirement, we go back to the drawing board with our team to work toward obtaining or creating just the right visual. Based on the many hours of research for only one photo and numerous revisions of a single illustration, we're confident our team agrees that we don't settle for close enough. We believe that the right visuals can help make abstract and difficult concepts more tangible and welcoming, as well as make learning more effective and long lasting.

How Many New Visuals Have Been Added?

We have used feedback from readers and reviewers in revising and adding new photos, figures, and illustrations, which provide effective visual cues for better learning and remembering. In this revision, we added about 200 new photos, updated over 150 figures (e.g., graphs and concept maps), and added nearly 200 original illustrations. Together, there are well over 500 new visuals in this edition! Additionally, we retained hundreds of other effective visuals from the 8th edition.

Integrated Custom Illustrations

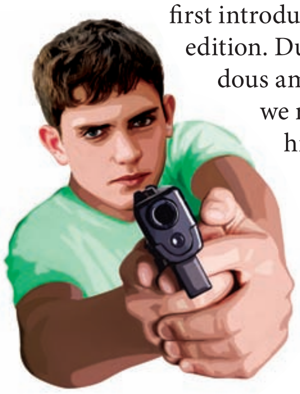
Making a textbook that integrates visuals with every major concept is a massive endeavor. In fact, as authors, we spend as much time on the visual program as we do on the writing. We couldn't do this without the full support of our editorial team and the work of committed and talented photo researchers who won't stop short of finding the perfect photo. Thankfully, we have the privilege of having both.

Threat to survival

Humanistic approach

Because we integrate visuals with written content to aid student learning, many times it is simply impossible to find a photo that clearly conveys a specific concept. Consequently, it is impossible to produce a text that effectively emphasizes visual learning without an extraordinarily talented illustrator, who can literally illustrate *anything* we request. We are truly fortunate to have found Tim Jacobus, an illustrator with phenomenal talent.

Short-term memory

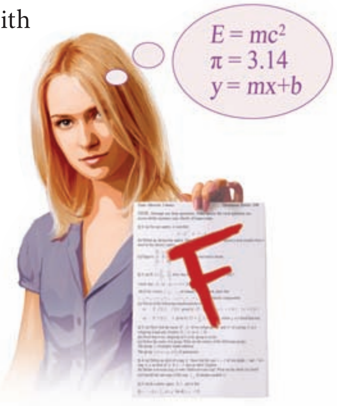


School shooter

Tim Jacobus's work in our textbook was first introduced in the 8th edition. Due to the tremendous amount of praise we received about his work, we asked Tim to join us again and he has in a big way. His illustrations can be found in abundance throughout the 9th edition and include anatomy, faces, animals, objects, conceptual concepts, and so much more! In total, Tim has created over 250 original illustrations specifically for our textbook.

Adaptive theory of sleep

As authors, we work very closely with Tim in making sure each illustration is just right. He makes working on the visual program truly pleasurable. In fact, every Monday morning, he would send a batch of new illustrations, and because of this weekly tradition, Monday mornings became highly anticipated!



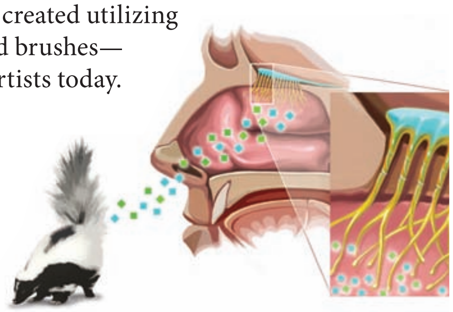
Underachiever

Panic attack

We hope you find Tim's illustrations as amazing as we do. We are confident that your students will not only enjoy them but also learn psychological concepts easier and better because of them. Samples of Tim's illustrations are shown throughout this page, and his biography is below.

Biography of Tim Jacobus

Tim Jacobus began his art career in the early 1980s. He was taught as a traditional artist, and all of his early works were created utilizing pencils, acrylic paint, and brushes—foreign objects to most artists today. Tim's early work was done entirely in the publishing field, designing and creating cover art. Specializing in fantasy and sci-fi work, he began to develop a style that is rich in color and extreme in depth. Tim received his greatest notoriety creating the cover art for the children's series *Goosebumps.*



Olfaction

After hundreds of covers, Tim broadened his scope to include the realm of digital art tools. The use of this medium helped to open a wider scope of work and subject matter, including medical illustration, character distortion, editorial concepts, and web-based animation.

Tim continues to create—unceasingly.

PowerStudy 4.5™
Complete Module

46

Modules. One of the features best liked by both instructors and students is that the text is organized into smaller units called ***modules,*** which are shorter (20–30 pages) and more manageable than traditional chapters (45–50 pages). The 9th edition has 25 ***modules*** (see p. iv), which can easily be organized, omitted, or rearranged into any order. Because individual modules all have the same structure, each one can stand on its own.

Advantage. Instructors said that, compared to longer and more traditional chapters, they preferred the shorter ***modules,*** which allow greater flexibility in planning and personalizing one's course.

Example. The sample page on your left, which is the opening page of Module 3, Brain's Building Blocks, shows that each ***module*** begins with an outline. In this outline, the heads are designated by letter (A. Overview: Human Brain) and provide students with an overview of the entire module.

Outline. Students can use the ***module's*** outline to organize their lecture notes as well as to find and review selected material.

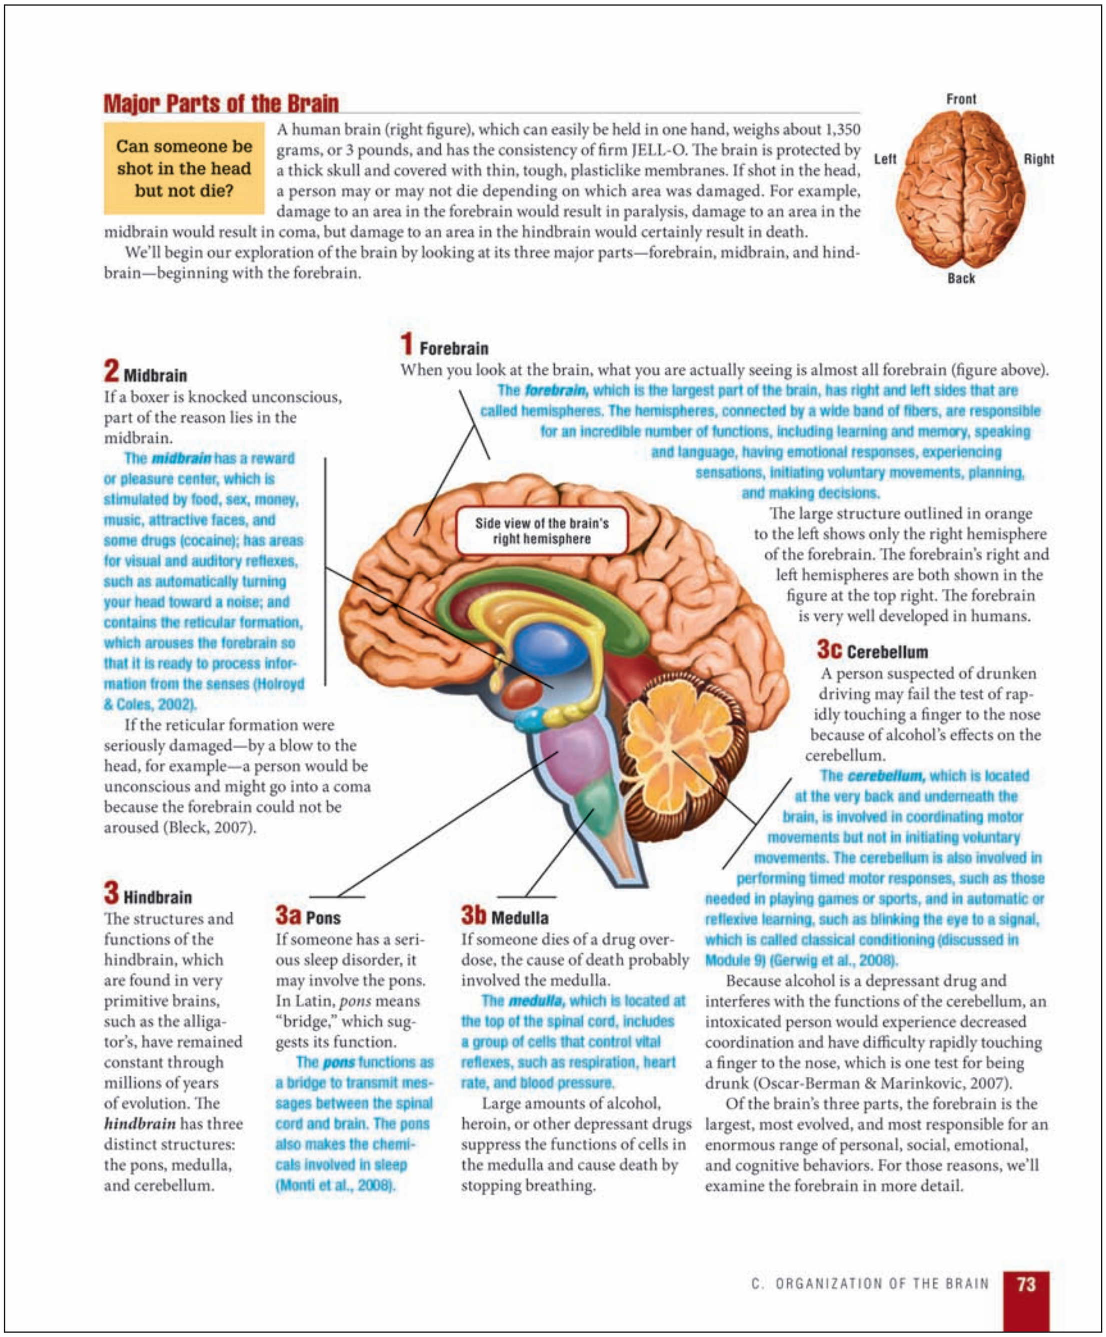
Visual Learning: Text/Graphic Integration and Chunking

Visual learning. Many students who have used this text have commented that they are visual learners and that the visual layout of the text greatly helped them better understand and remember difficult concepts. The visual layout of this text involves two approaches: integrating text and graphics and using "chunking."

Text/graphic integration. Each of the 609 pages of this text has been individually formatted so that text and graphics are always integrated. An example of text/graphic integration is shown in the sample page on the right (Module 4). Students never have to search for a distant figure or graph because the text is always integrated with its related graphic.

Chunking. The second method used to help students better understand and remember the material is to break down difficult or complex concepts into smaller, more manageable "chunks." For example, in this sample page, the relatively complex structure and function of the major parts of the brain are broken down into a series of easily grasped smaller chunks or a series of steps.

Definitions. Finally, the sample page shows that students need never search for definitions because they are always **boldface and printed in blue.** Students need only look for **blue** words to easily find and review definitions.



Major Parts of the Brain

Can someone be shot in the head but not die?

A human brain (right figure), which can easily be held in one hand, weighs about 1,350 grams, or 3 pounds, and has the consistency of firm JELL-O. The brain is protected by a thick skull and covered with thin, tough, plasticlike membranes. If shot in the head, a person may or may not die depending on which area was damaged. For example, damage to an area in the forebrain would result in paralysis, damage to an area in the midbrain would result in coma, but damage to an area in the hindbrain would certainly result in death.

We'll begin our exploration of the brain by looking at its three major parts—forebrain, midbrain, and hindbrain—beginning with the forebrain.

1 Forebrain

When you look at the brain, what you are actually seeing is almost all forebrain (figure above).

The *forebrain,* which is the largest part of the brain, has right and left sides that are called hemispheres. The hemispheres, connected by a wide band of fibers, are responsible for an incredible number of functions, including learning and memory, speaking and language, having emotional responses, experiencing sensations, initiating voluntary movements, planning, and making decisions.

The large structure outlined in orange to the left shows only the right hemisphere of the forebrain. The forebrain's right and left hemispheres are both shown in the figure at the top right. The forebrain is very well developed in humans.

2 Midbrain

If a boxer is knocked unconscious, part of the reason lies in the midbrain.

The *midbrain* has a reward or pleasure center, which is stimulated by food, sex, money, music, attractive faces, and some drugs (cocaine); has areas for visual and auditory reflexes, such as automatically turning your head toward a noise; and contains the reticular formation, which arouses the forebrain so that it is ready to process information from the senses (Holroyd & Coles, 2002).

If the reticular formation were seriously damaged—by a blow to the head, for example—a person would be unconscious and might go into a coma because the forebrain could not be aroused (Bleck, 2007).

3 Hindbrain

The structures and functions of the hindbrain, which are found in very primitive brains, such as the alligator's, have remained constant through millions of years of evolution. The ***hindbrain*** has three distinct structures: the pons, medulla, and cerebellum.

3a Pons

If someone has a serious sleep disorder, it may involve the pons. In Latin, *pons* means "bridge," which suggests its function.

The *pons* functions as a bridge to transmit messages between the spinal cord and brain. The pons also makes the chemicals involved in sleep (Monti et al., 2008).

3b Medulla

If someone dies of a drug overdose, the cause of death probably involved the medulla.

The *medulla,* which is located at the top of the spinal cord, includes a group of cells that control vital reflexes, such as respiration, heart rate, and blood pressure.

Large amounts of alcohol, heroin, or other depressant drugs suppress the functions of cells in the medulla and cause death by stopping breathing.

3c Cerebellum

A person suspected of drunken driving may fail the test of rapidly touching a finger to the nose because of alcohol's effects on the cerebellum.

The *cerebellum,* which is located at the very back and underneath the brain, is involved in coordinating motor movements but not in initiating voluntary movements. The cerebellum is also involved in performing timed motor responses, such as those needed in playing games or sports, and in automatic or reflexive learning, such as blinking the eye to a signal, which is called classical conditioning (discussed in Module 9) (Gerwig et al., 2008).

Because alcohol is a depressant drug and interferes with the functions of the cerebellum, an intoxicated person would experience decreased coordination and have difficulty rapidly touching a finger to the nose, which is one test for being drunk (Oscar-Berman & Marinkovic, 2007).

Of the brain's three parts, the forebrain is the largest, most evolved, and most responsible for an enormous range of personal, social, emotional, and cognitive behaviors. For those reasons, we'll examine the forebrain in more detail.

C. ORGANIZATION OF THE BRAIN 73

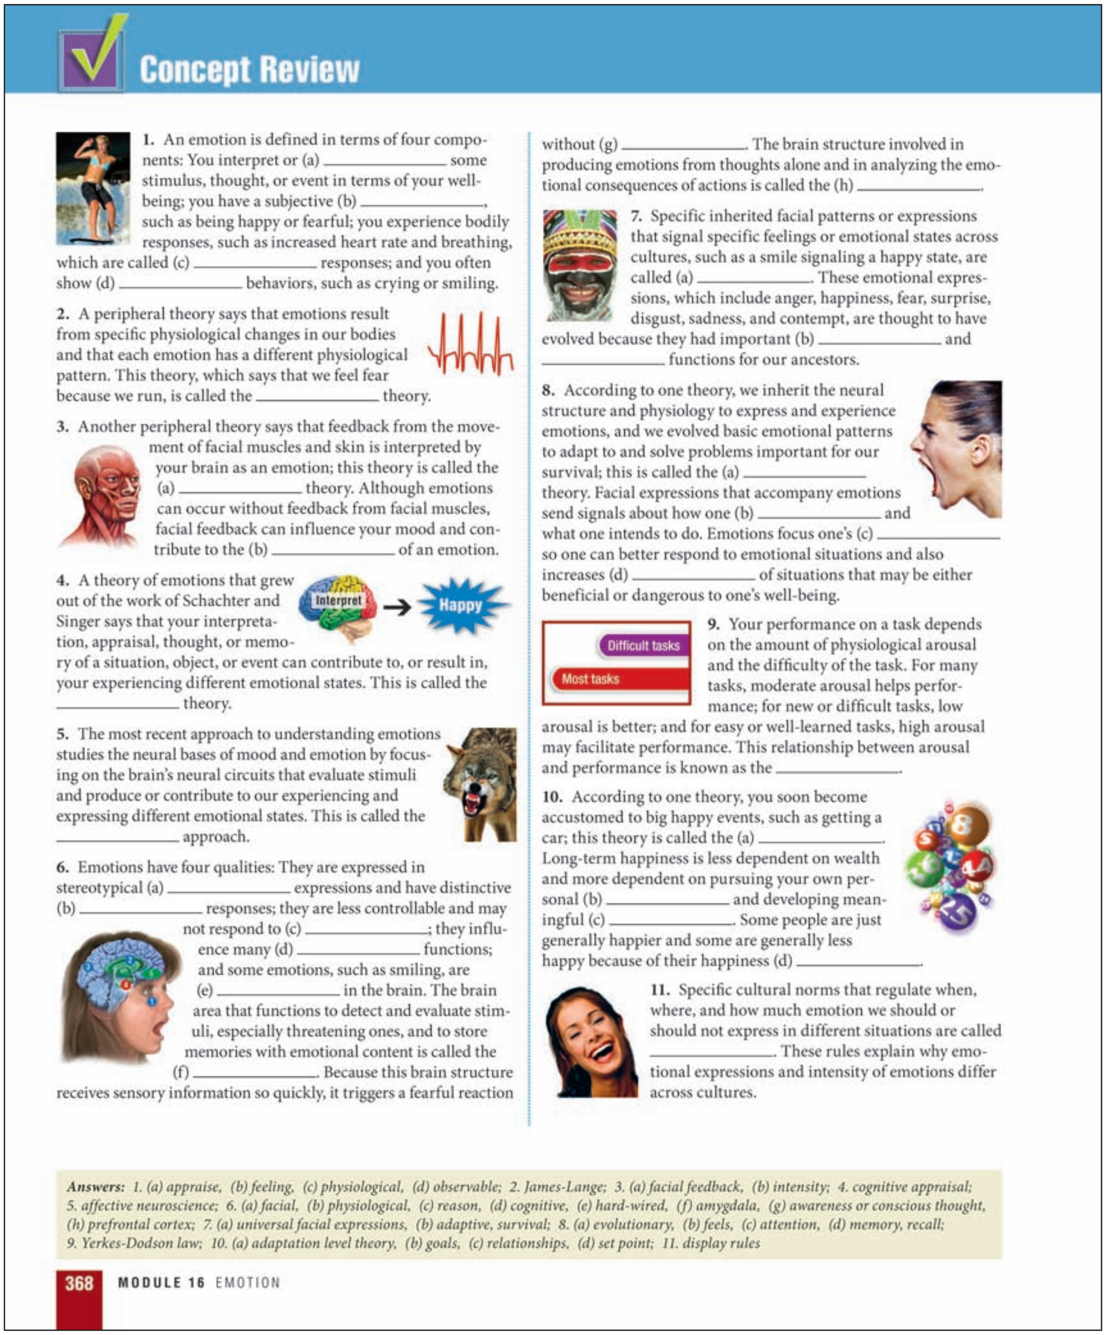
Concept Review: Tests Knowledge of Major Concepts



Concept Review

1. An emotion is defined in terms of four components: You interpret or (a) ________ some stimulus, thought, or event in terms of your well-being; you have a subjective (b) ________, such as being happy or fearful; you experience bodily responses, such as increased heart rate and breathing, which are called (c) ________ responses; and you often show (d) ________ behaviors, such as crying or smiling.

2. A peripheral theory says that emotions result from specific physiological changes in our bodies and that each emotion has a different physiological pattern. This theory, which says that we feel fear because we run, is called the ________ theory.

3. Another peripheral theory says that feedback from the movement of facial muscles and skin is interpreted by your brain as an emotion; this theory is called the (a) ________ theory. Although emotions can occur without feedback from facial muscles, facial feedback can influence your mood and contribute to the (b) ________ of an emotion.

4. A theory of emotions that grew out of the work of Schachter and Singer says that your interpretation, appraisal, thought, or memory of a situation, object, or event can contribute to, or result in, your experiencing different emotional states. This is called the ________ theory.

5. The most recent approach to understanding emotions studies the neural bases of mood and emotion by focusing on the brain's neural circuits that evaluate stimuli and produce or contribute to our experiencing and expressing different emotional states. This is called the ________ approach.

6. Emotions have four qualities: They are expressed in stereotypical (a) ________ expressions and have distinctive (b) ________ responses; they are less controllable and may not respond to (c) ________; they influence many (d) ________ functions; and some emotions, such as smiling, are (e) ________ in the brain. The brain area that functions to detect and evaluate stimuli, especially threatening ones, and to store memories with emotional content is called the (f) ________. Because this brain structure receives sensory information so quickly, it triggers a fearful reaction without (g) ________. The brain structure involved in producing emotions from thoughts alone and in analyzing the emotional consequences of actions is called the (h) ________.

7. Specific inherited facial patterns or expressions that signal specific feelings or emotional states across cultures, such as a smile signaling a happy state, are called (a) ________. These emotional expressions, which include anger, happiness, fear, surprise, disgust, sadness, and contempt, are thought to have evolved because they had important (b) ________ and ________ functions for our ancestors.

8. According to one theory, we inherit the neural structure and physiology to express and experience emotions, and we evolved basic emotional patterns to adapt to and solve problems important for our survival; this is called the (a) ________ theory. Facial expressions that accompany emotions send signals about how one (b) ________ and what one intends to do. Emotions focus one's (c) ________ so one can better respond to emotional situations and also increases (d) ________ of situations that may be either beneficial or dangerous to one's well-being.

9. Your performance on a task depends on the amount of physiological arousal and the difficulty of the task. For many tasks, moderate arousal helps performance; for new or difficult tasks, low arousal is better; and for easy or well-learned tasks, high arousal may facilitate performance. This relationship between arousal and performance is known as the ________.

10. According to one theory, you soon become accustomed to big happy events, such as getting a car; this theory is called the (a) ________. Long-term happiness is less dependent on wealth and more dependent on pursuing your own personal (b) ________ and developing meaningful (c) ________. Some people are just generally happier and some are generally less happy because of their happiness (d) ________.

11. Specific cultural norms that regulate when, where, and how much emotion we should or should not express in different situations are called ________. These rules explain why emotional expressions and intensity of emotions differ across cultures.

Answers: *1. (a) appraise, (b) feeling, (c) physiological, (d) observable; 2. James-Lange; 3. (a) facial feedback, (b) intensity; 4. cognitive appraisal; 5. affective neuroscience; 6. (a) facial, (b) physiological, (c) reason, (d) cognitive, (e) hard-wired, (f) amygdala, (g) awareness or conscious thought, (h) prefrontal cortex; 7. (a) universal facial expressions, (b) adaptive, survival; 8. (a) evolutionary, (b) feels, (c) attention, (d) memory, recall; 9. Yerkes-Dodson law; 10. (a) adaptation level theory, (b) goals, (c) relationships, (d) set point; 11. display rules*

368 **MODULE 16** EMOTION

Often-asked question. How many times have students asked, "What should I study for the test?" One way to answer this question is to tell students to complete the two built-in quizzes that appear in each module. One quiz is the ***Concept Review*** (shown here), and the second is the ***Summary Test*** (shown on p. xxix).

Integrated approach. The sample page on the left shows a ***Concept Review*** (Module 16), which has the unique feature of repeating the graphics that were first linked to the major concepts discussed in the text. This repeated use of visual cues has been shown to increase the learning or encoding of information as well as to promote visual learning.

Reading versus knowing. One reason for including quizzes within the text is that students may think that they know the material because they have read it. However, studies show that students cannot judge how well they actually know the material unless they test their knowledge of specific information. The ***Concept Review*** serves as an interim checkpoint by giving students a chance to test their knowledge of major terms before nearing the end of the module.

Student feedback on the ***Concept Review*** has been very positive. Students like the visual learning approach of having the graphics integrated with the concepts, and they find that the ***Concept Review*** is a great way to test their knowledge.

Cultural Diversity: Opens Students' Minds

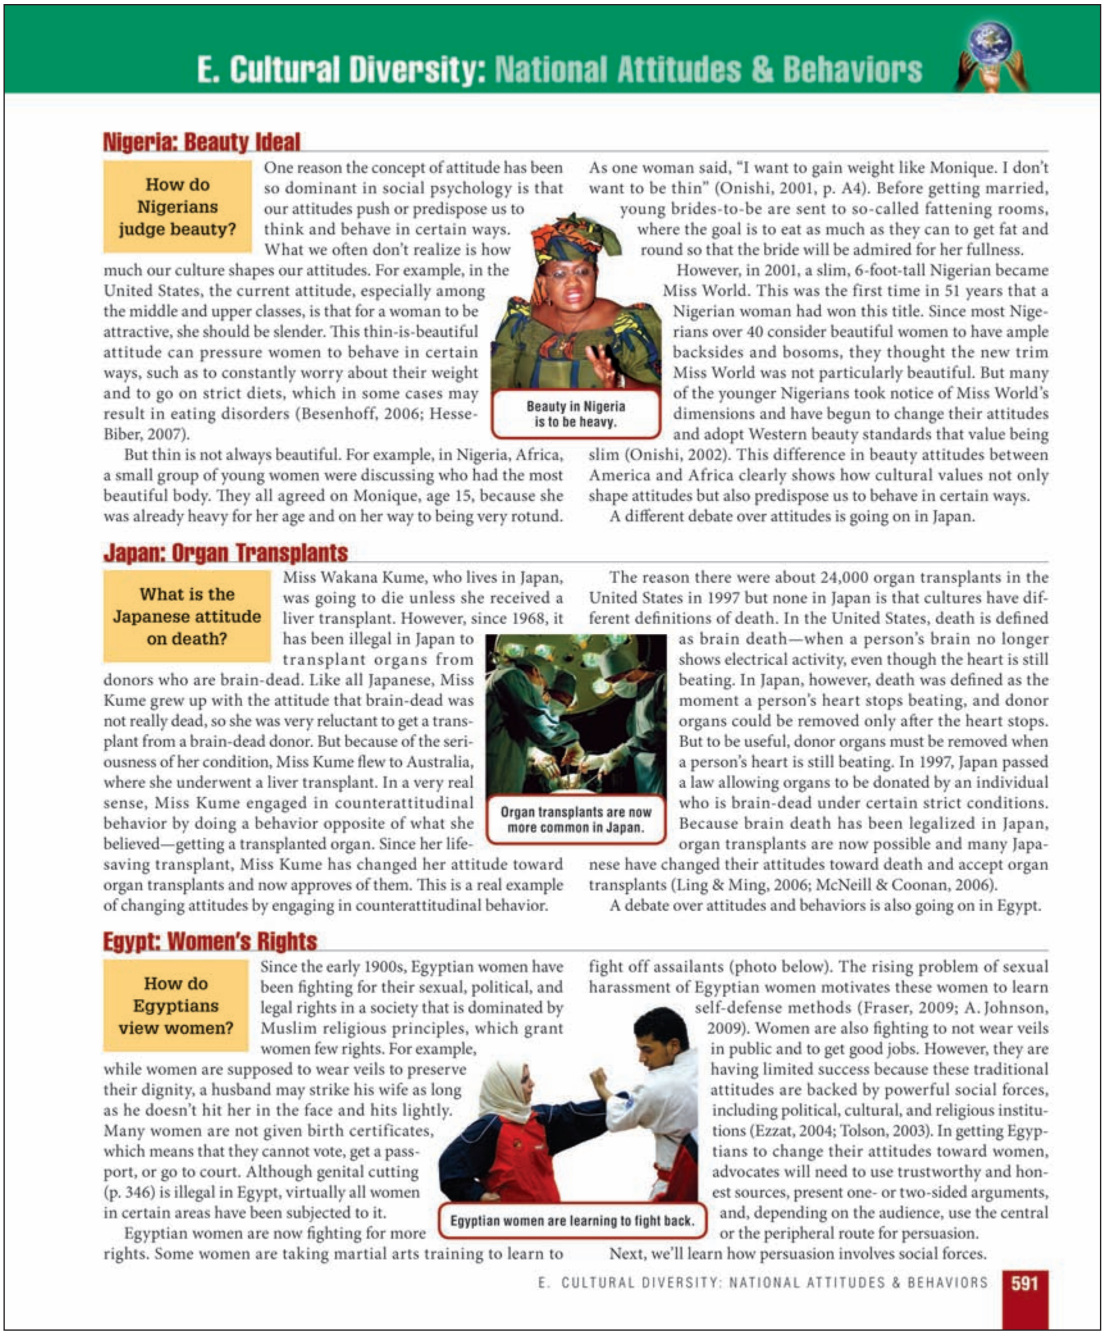
Different viewpoints. One goal of an Introductory Psychology course is to challenge and broaden students' viewpoints by providing information about other cultures. Because of their limited experience of other cultures, students may be unaware that similar behaviors are viewed very differently in other cultures. For this reason, each of the 25 modules includes a ***Cultural Diversity*** feature.

Example. In the sample page on the right, the ***Cultural Diversity*** feature (Module 25) describes the national attitudes and behaviors of three countries: Nigeria, Japan, and Egypt.

Topics. Other ***Cultural Diversity*** topics include:

Module 1: Early Discrimination
Module 2: Use of Placebos
Module 4: Brain Size & Racial Myths
Module 7: Incidence of SAD
Module 8: Alcoholism Rates
Module 9: Conditioning Dental Fears
Module 12: Aborigines Versus White Australians
Module 16: Emotions across Cultures
Module 17: Gender Roles
Module 21: Tibetan Monks
Module 22: An Asian Disorder
Module 24: Different Healer

The ***Cultural Diversity*** feature gives students a chance to see the world through very different eyes.



E. Cultural Diversity: National Attitudes & Behaviors

Nigeria: Beauty Ideal

How do Nigerians judge beauty?

One reason the concept of attitude has been so dominant in social psychology is that our attitudes push or predispose us to think and behave in certain ways. What we often don't realize is how much our culture shapes our attitudes. For example, in the United States, the current attitude, especially among the middle and upper classes, is that for a woman to be attractive, she should be slender. This thin-is-beautiful attitude can pressure women to behave in certain ways, such as to constantly worry about their weight and to go on strict diets, which in some cases may result in eating disorders (Besenhoff, 2006; Hesse-Biber, 2007).

Beauty in Nigeria is to be heavy.

But thin is not always beautiful. For example, in Nigeria, Africa, a small group of young women were discussing who had the most beautiful body. They all agreed on Monique, age 15, because she was already heavy for her age and on her way to being very rotund. As one woman said, "I want to gain weight like Monique. I don't want to be thin" (Onishi, 2001, p. A4). Before getting married, young brides-to-be are sent to so-called fattening rooms, where the goal is to eat as much as they can to get fat and round so that the bride will be admired for her fullness.

However, in 2001, a slim, 6-foot-tall Nigerian became Miss World. This was the first time in 51 years that a Nigerian woman had won this title. Since most Nigerians over 40 consider beautiful women to have ample backsides and bosoms, they thought the new trim Miss World was not particularly beautiful. But many of the younger Nigerians took notice of Miss World's dimensions and have begun to change their attitudes and adopt Western beauty standards that value being slim (Onishi, 2002). This difference in beauty attitudes between America and Africa clearly shows how cultural values not only shape attitudes but also predispose us to behave in certain ways.

A different debate over attitudes is going on in Japan.

Japan: Organ Transplants

What is the Japanese attitude on death?

Miss Wakana Kume, who lives in Japan, was going to die unless she received a liver transplant. However, since 1968, it has been illegal in Japan to transplant organs from donors who are brain-dead. Like all Japanese, Miss Kume grew up with the attitude that brain-dead was not really dead, so she was very reluctant to get a transplant from a brain-dead donor. But because of the seriousness of her condition, Miss Kume flew to Australia, where she underwent a liver transplant. In a very real sense, Miss Kume engaged in counterattitudinal behavior by doing a behavior opposite of what she believed—getting a transplanted organ. Since her life-saving transplant, Miss Kume has changed her attitude toward organ transplants and now approves of them. This is a real example of changing attitudes by engaging in counterattitudinal behavior.

Organ transplants are now more common in Japan.

The reason there were about 24,000 organ transplants in the United States in 1997 but none in Japan is that cultures have different definitions of death. In the United States, death is defined as brain death—when a person's brain no longer shows electrical activity, even though the heart is still beating. In Japan, however, death was defined as the moment a person's heart stops beating, and donor organs could be removed only after the heart stops. But to be useful, donor organs must be removed when a person's heart is still beating. In 1997, Japan passed a law allowing organs to be donated by an individual who is brain-dead under certain strict conditions. Because brain death has been legalized in Japan, organ transplants are now possible and many Japanese have changed their attitudes toward death and accept organ transplants (Ling & Ming, 2006; McNeill & Coonan, 2006).

A debate over attitudes and behaviors is also going on in Egypt.

Egypt: Women's Rights

How do Egyptians view women?

Since the early 1900s, Egyptian women have been fighting for their sexual, political, and legal rights in a society that is dominated by Muslim religious principles, which grant women few rights. For example, while women are supposed to wear veils to preserve their dignity, a husband may strike his wife as long as he doesn't hit her in the face and hits lightly. Many women are not given birth certificates, which means that they cannot vote, get a passport, or go to court. Although genital cutting (p. 346) is illegal in Egypt, virtually all women in certain areas have been subjected to it.

Egyptian women are learning to fight back.

Egyptian women are now fighting for more rights. Some women are taking martial arts training to learn to fight off assailants (photo below). The rising problem of sexual harassment of Egyptian women motivates these women to learn self-defense methods (Fraser, 2009; A. Johnson, 2009). Women are also fighting to not wear veils in public and to get good jobs. However, they are having limited success because these traditional attitudes are backed by powerful social forces, including political, cultural, and religious institutions (Ezzat, 2004; Tolson, 2003). In getting Egyptians to change their attitudes toward women, advocates will need to use trustworthy and honest sources, present one- or two-sided arguments, and, depending on the audience, use the central or the peripheral route for persuasion.

Next, we'll learn how persuasion involves social forces.

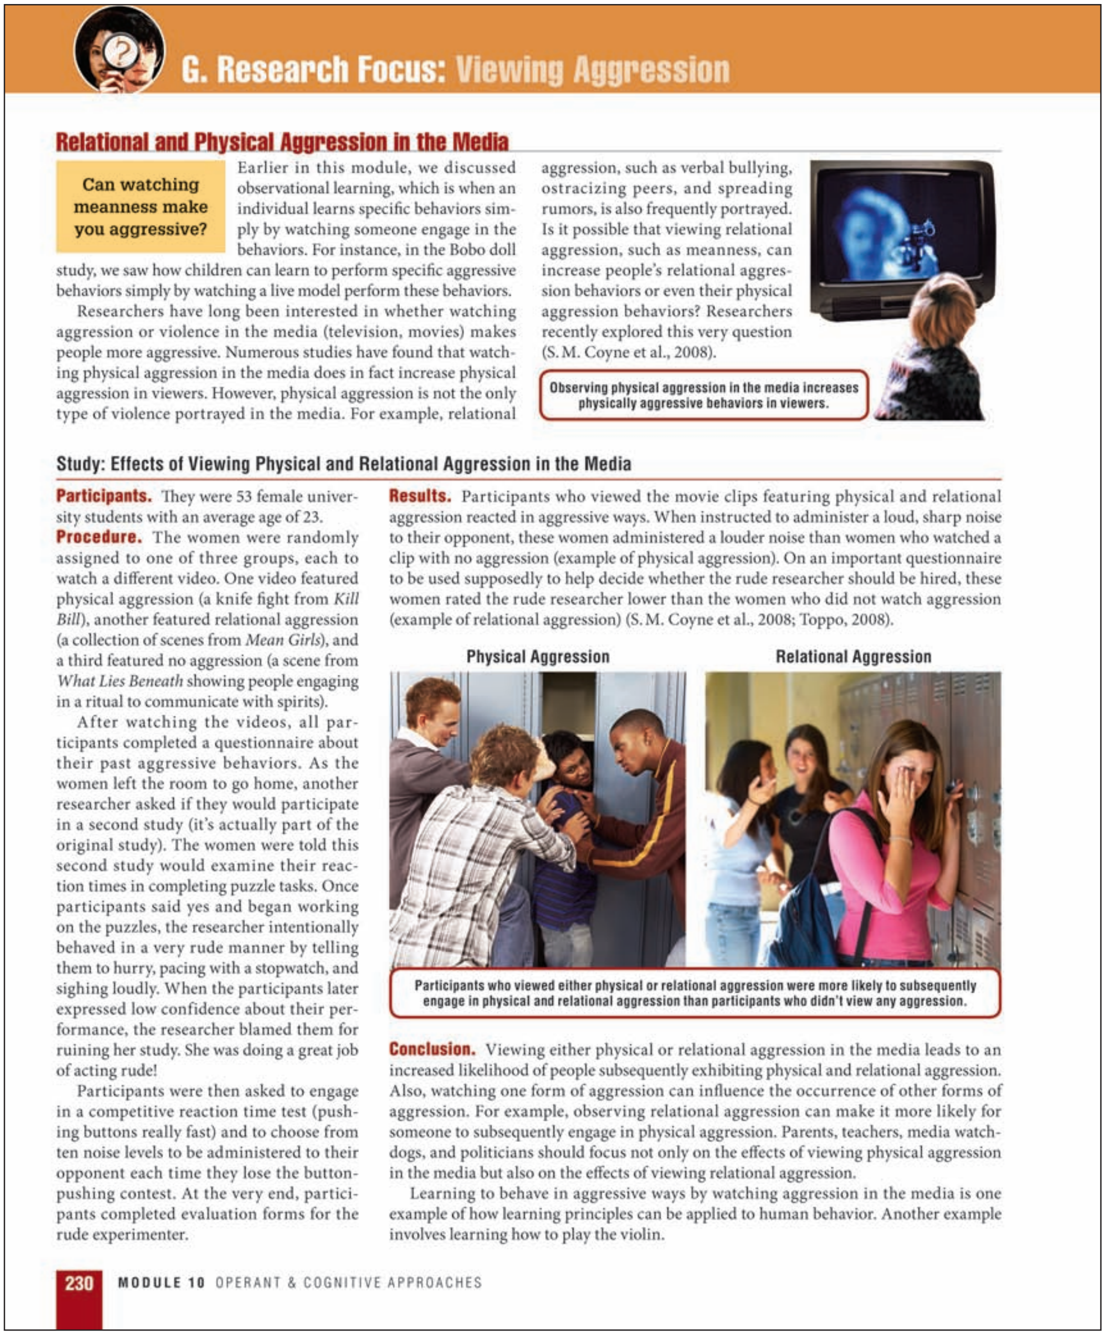
Research Focus: How Psychologists Answer Questions



G. Research Focus: Viewing Aggression

Relational and Physical Aggression in the Media

Can watching meanness make you aggressive?

Earlier in this module, we discussed observational learning, which is when an individual learns specific behaviors simply by watching someone engage in the behaviors. For instance, in the Bobo doll study, we saw how children can learn to perform specific aggressive behaviors simply by watching a live model perform these behaviors.

Researchers have long been interested in whether watching aggression or violence in the media (television, movies) makes people more aggressive. Numerous studies have found that watching physical aggression in the media does in fact increase physical aggression in viewers. However, physical aggression is not the only type of violence portrayed in the media. For example, relational aggression, such as verbal bullying, ostracizing peers, and spreading rumors, is also frequently portrayed. Is it possible that viewing relational aggression, such as meanness, can increase people's relational aggression behaviors or even their physical aggression behaviors? Researchers recently explored this very question (S. M. Coyne et al., 2008).

Observing physical aggression in the media increases physically aggressive behaviors in viewers.

Study: Effects of Viewing Physical and Relational Aggression in the Media

Participants. They were 53 female university students with an average age of 23.

Procedure. The women were randomly assigned to one of three groups, each to watch a different video. One video featured physical aggression (a knife fight from *Kill Bill*), another featured relational aggression (a collection of scenes from *Mean Girls*), and a third featured no aggression (a scene from *What Lies Beneath* showing people engaging in a ritual to communicate with spirits).

After watching the videos, all participants completed a questionnaire about their past aggressive behaviors. As the women left the room to go home, another researcher asked if they would participate in a second study (it's actually part of the original study). The women were told this second study would examine their reaction times in completing puzzle tasks. Once participants said yes and began working on the puzzles, the researcher intentionally behaved in a very rude manner by telling them to hurry, pacing with a stopwatch, and sighing loudly. When the participants later expressed low confidence about their performance, the researcher blamed them for ruining her study. She was doing a great job of acting rude!

Participants were then asked to engage in a competitive reaction time test (pushing buttons really fast) and to choose from ten noise levels to be administered to their opponent each time they lose the button-pushing contest. At the very end, participants completed evaluation forms for the rude experimenter.

Results. Participants who viewed the movie clips featuring physical and relational aggression reacted in aggressive ways. When instructed to administer a loud, sharp noise to their opponent, these women administered a louder noise than women who watched a clip with no aggression (example of physical aggression). On an important questionnaire to be used supposedly to help decide whether the rude researcher should be hired, these women rated the rude researcher lower than the women who did not watch aggression (example of relational aggression) (S. M. Coyne et al., 2008; Toppo, 2008).

Physical Aggression

Relational Aggression

Participants who viewed either physical or relational aggression were more likely to subsequently engage in physical and relational aggression than participants who didn't view any aggression.

Conclusion. Viewing either physical or relational aggression in the media leads to an increased likelihood of people subsequently exhibiting physical and relational aggression. Also, watching one form of aggression can influence the occurrence of other forms of aggression. For example, observing relational aggression can make it more likely for someone to subsequently engage in physical aggression. Parents, teachers, media watchdogs, and politicians should focus not only on the effects of viewing physical aggression in the media but also on the effects of viewing relational aggression.

Learning to behave in aggressive ways by watching aggression in the media is one example of how learning principles can be applied to human behavior. Another example involves learning how to play the violin.

230 **MODULE 10** OPERANT & COGNITIVE APPROACHES

Feature. In teaching Introductory Psychology, an instructor's important but difficult goal is to explain how psychologists use a variety of research methods and techniques to answer questions. To reach this goal, each of the 25 modules includes a ***Research Focus*** that explains how psychologists answer questions through experiments, case studies, self-reports, and surveys.

Example. In the sample page on the left, the ***Research Focus*** (Module 10) explains how psychologists use research methods to examine the effects of viewing physical and relational aggression in the media.

Topics. Other ***Research Focus*** topics include:

Module 2: ADHD Controversies
Module 3: What Is a Phantom Limb?
Module 5: Mind over Body?
Module 7: Circadian Preference
Module 8: Drug Prevention
Module 12: Memory Accuracy
Module 16: Emotional Intelligence
Module 17: Temperament
Module 19: Shyness
Module 20: 180-Degree Change
Module 22: School Shootings
Module 23: Exercise Versus Drugs

Each of the 25 modules includes a Research Focus, which discusses the research methods and techniques that psychologists use to answer questions.

Application: Psychology's Practical Side

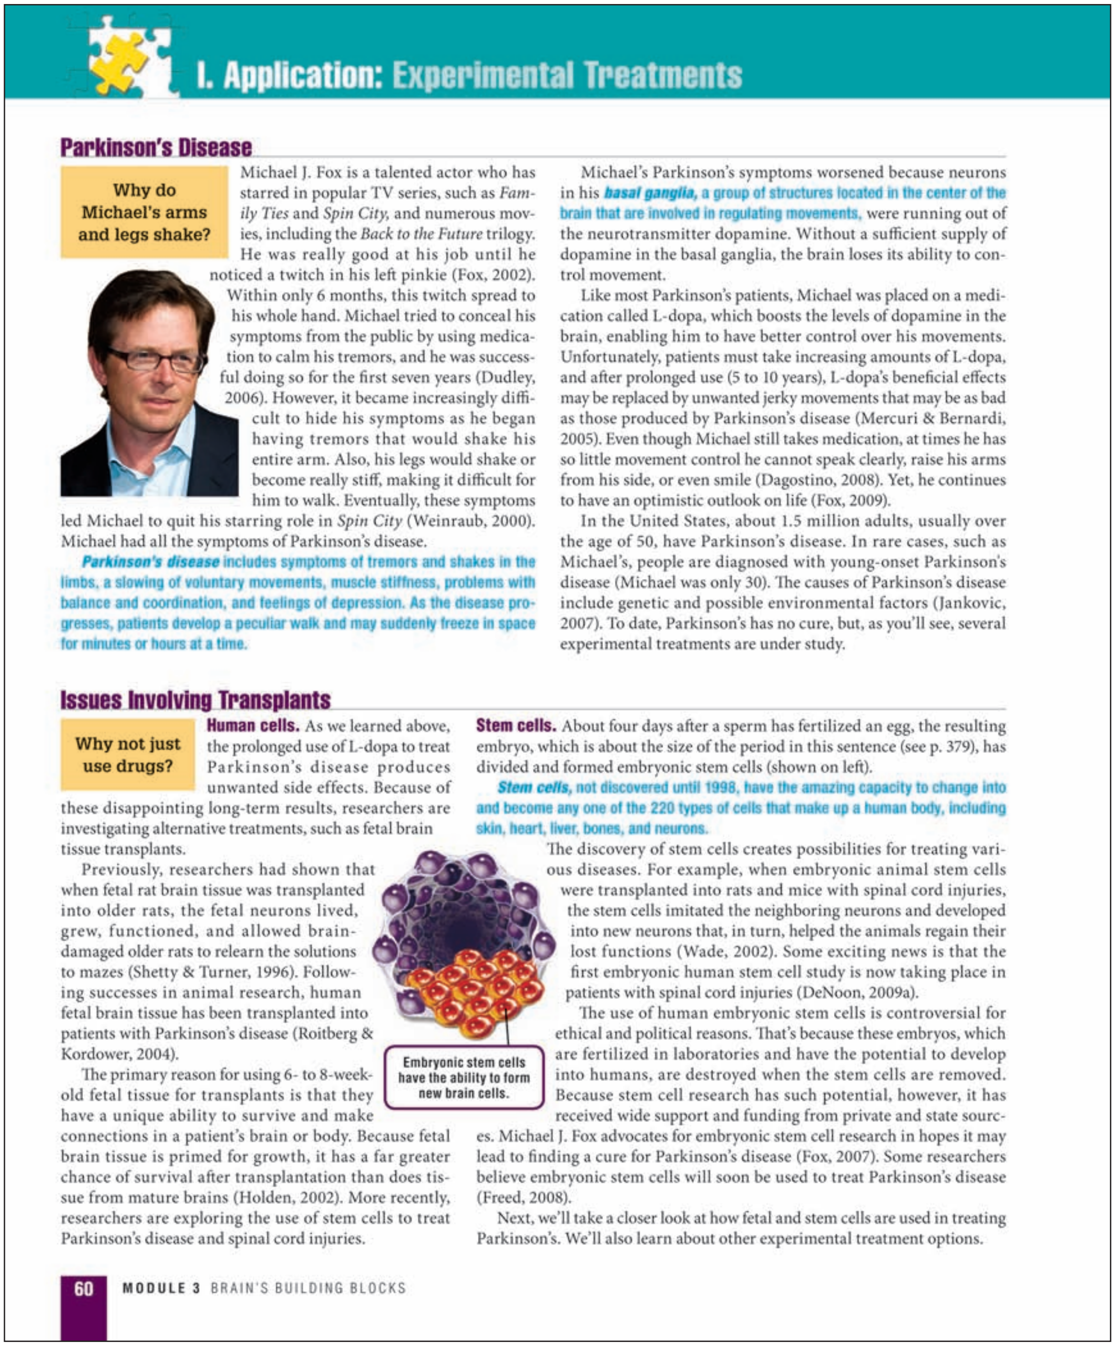
Real world. Students are very interested in how psychologists apply research findings and use basic principles to solve or treat real-life problems.

Example. In the sample page on the right, the ***Application*** (Module 3) describes the various experimental treatments available for Parkinson's disease, which include the use of human stem cells, a stereotaxic procedure to place tissue in the brain, removing part of the thalamus, and deep brain stimulation (pp. 60–61).

Topics. Other ***Application*** topics include:

Module 1: Study Skills
Module 2: Research Concerns
Module 4: Split Brain
Module 5: Artificial Senses
Module 7: Sleep Problems & Treatments
Module 8: Treatment for Drug Abuse
Module 9: Conditioned Fear & Nausea
Module 10: Behavior Modification
Module 11: Unusual Memories
Module 12: Eyewitness Testimony
Module 16: Lie Detection
Module 17: Child Abuse
Module 18: Suicide
Module 21: Stress Management Programs
Module 22: Treating Phobias
Module 23: Dealing with Mild Depression
Module 25: Controlling Aggression

The ***Application*** sections show the practical side of psychology—how psychological principles are applied to real-life situations.



I. Application: Experimental Treatments

Parkinson's Disease

Why do Michael's arms and legs shake?

Michael J. Fox is a talented actor who has starred in popular TV series, such as *Family Ties* and *Spin City,* and numerous movies, including the *Back to the Future* trilogy. He was really good at his job until he noticed a twitch in his left pinkie (Fox, 2002). Within only 6 months, this twitch spread to his whole hand. Michael tried to conceal his symptoms from the public by using medication to calm his tremors, and he was successful doing so for the first seven years (Dudley, 2006). However, it became increasingly difficult to hide his symptoms as he began having tremors that would shake his entire arm. Also, his legs would shake or become really stiff, making it difficult for him to walk. Eventually, these symptoms led Michael to quit his starring role in *Spin City* (Weinraub, 2000). Michael had all the symptoms of Parkinson's disease.

Parkinson's disease includes symptoms of tremors and shakes in the limbs, a slowing of voluntary movements, muscle stiffness, problems with balance and coordination, and feelings of depression. As the disease progresses, patients develop a peculiar walk and may suddenly freeze in space for minutes or hours at a time.

Michael's Parkinson's symptoms worsened because neurons in his ***basal ganglia,*** a group of structures located in the center of the brain that are involved in regulating movements, were running out of the neurotransmitter dopamine. Without a sufficient supply of dopamine in the basal ganglia, the brain loses its ability to control movement.

Like most Parkinson's patients, Michael was placed on a medication called L-dopa, which boosts the levels of dopamine in the brain, enabling him to have better control over his movements. Unfortunately, patients must take increasing amounts of L-dopa, and after prolonged use (5 to 10 years), L-dopa's beneficial effects may be replaced by unwanted jerky movements that may be as bad as those produced by Parkinson's disease (Mercuri & Bernardi, 2005). Even though Michael still takes medication, at times he has so little movement control he cannot speak clearly, raise his arms from his side, or even smile (Dagostino, 2008). Yet, he continues to have an optimistic outlook on life (Fox, 2009).

In the United States, about 1.5 million adults, usually over the age of 50, have Parkinson's disease. In rare cases, such as Michael's, people are diagnosed with young-onset Parkinson's disease (Michael was only 30). The causes of Parkinson's disease include genetic and possible environmental factors (Jankovic, 2007). To date, Parkinson's has no cure, but, as you'll see, several experimental treatments are under study.

Issues Involving Transplants

Why not just use drugs?

Human cells. As we learned above, the prolonged use of L-dopa to treat Parkinson's disease produces unwanted side effects. Because of these disappointing long-term results, researchers are investigating alternative treatments, such as fetal brain tissue transplants.

Previously, researchers had shown that when fetal rat brain tissue was transplanted into older rats, the fetal neurons lived, grew, functioned, and allowed brain-damaged older rats to relearn the solutions to mazes (Shetty & Turner, 1996). Following successes in animal research, human fetal brain tissue has been transplanted into patients with Parkinson's disease (Roitberg & Kordower, 2004).

The primary reason for using 6- to 8-week-old fetal tissue for transplants is that they have a unique ability to survive and make connections in a patient's brain or body. Because fetal brain tissue is primed for growth, it has a far greater chance of survival after transplantation than does tissue from mature brains (Holden, 2002). More recently, researchers are exploring the use of stem cells to treat Parkinson's disease and spinal cord injuries.

Embryonic stem cells have the ability to form new brain cells.

Stem cells. About four days after a sperm has fertilized an egg, the resulting embryo, which is about the size of the period in this sentence (see p. 379), has divided and formed embryonic stem cells (shown on left).

Stem cells, not discovered until 1998, have the amazing capacity to change into and become any one of the 220 types of cells that make up a human body, including skin, heart, liver, bones, and neurons.

The discovery of stem cells creates possibilities for treating various diseases. For example, when embryonic animal stem cells were transplanted into rats and mice with spinal cord injuries, the stem cells imitated the neighboring neurons and developed into new neurons that, in turn, helped the animals regain their lost functions (Wade, 2002). Some exciting news is that the first embryonic human stem cell study is now taking place in patients with spinal cord injuries (DeNoon, 2009a).

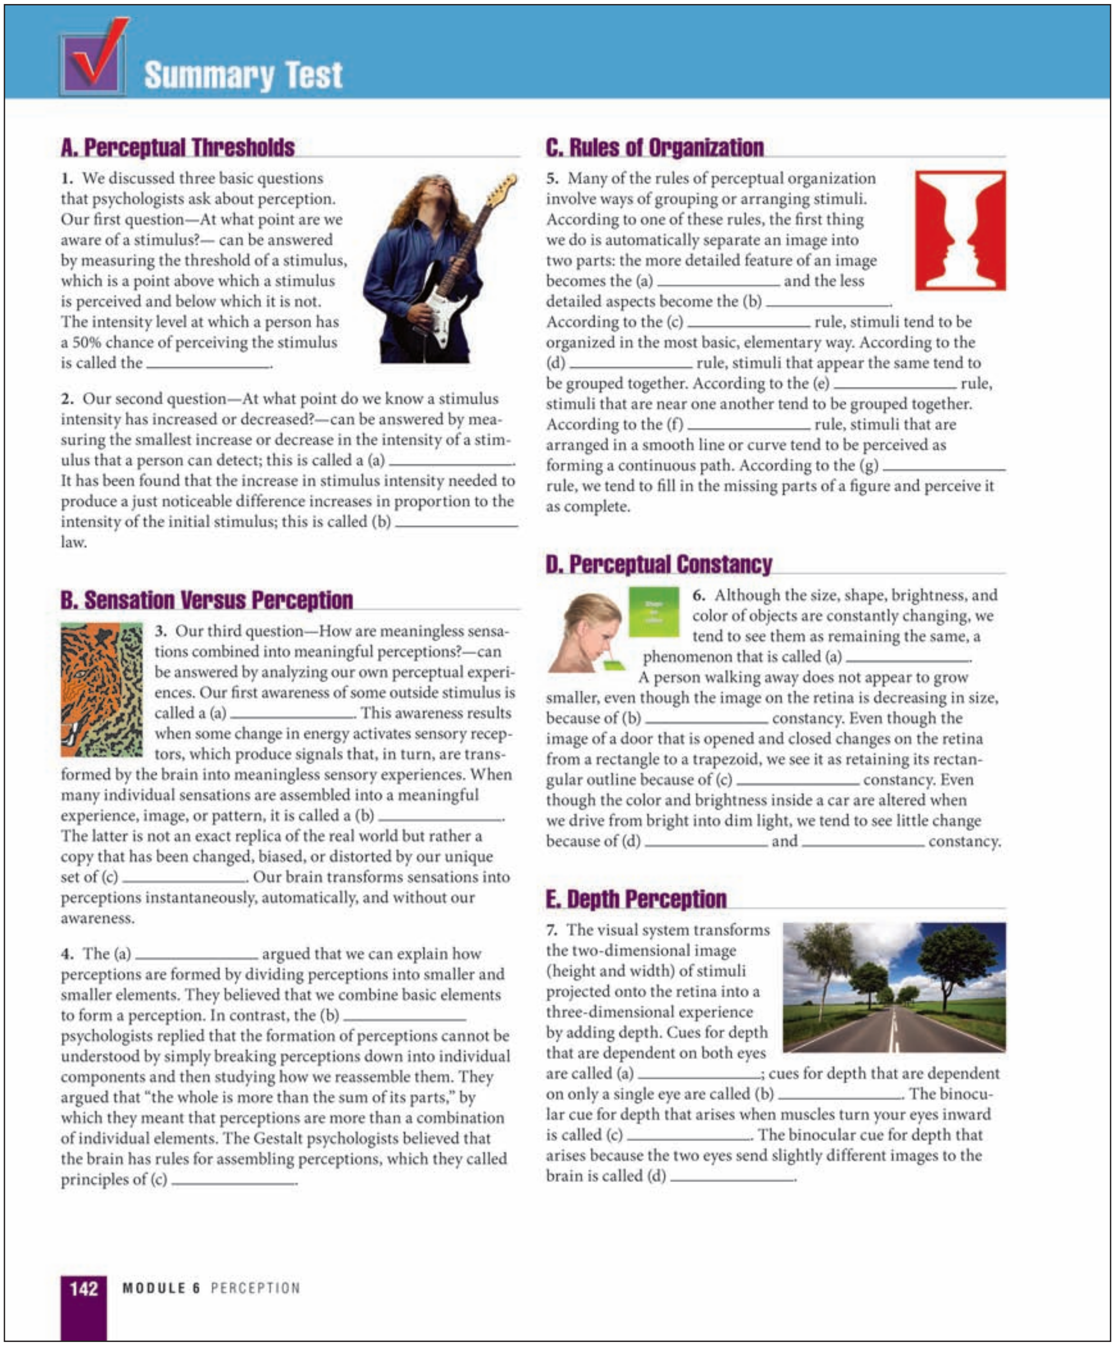
The use of human embryonic stem cells is controversial for ethical and political reasons. That's because these embryos, which are fertilized in laboratories and have the potential to develop into humans, are destroyed when the stem cells are removed. Because stem cell research has such potential, however, it has received wide support and funding from private and state sources. Michael J. Fox advocates for embryonic stem cell research in hopes it may lead to finding a cure for Parkinson's disease (Fox, 2007). Some researchers believe embryonic stem cells will soon be used to treat Parkinson's disease (Freed, 2008).

Next, we'll take a closer look at how fetal and stem cells are used in treating Parkinson's. We'll also learn about other experimental treatment options.

60 MODULE 3 BRAIN'S BUILDING BLOCKS

Photo Credit: © AP Images/Charles Sykes

Summary Test: Review and Test of Complete Module



Summary Test

A. Perceptual Thresholds

1. We discussed three basic questions that psychologists ask about perception. Our first question—At what point are we aware of a stimulus?— can be answered by measuring the threshold of a stimulus, which is a point above which a stimulus is perceived and below which it is not. The intensity level at which a person has a 50% chance of perceiving the stimulus is called the ________.

2. Our second question—At what point do we know a stimulus intensity has increased or decreased?—can be answered by measuring the smallest increase or decrease in the intensity of a stimulus that a person can detect; this is called a (a) ________. It has been found that the increase in stimulus intensity needed to produce a just noticeable difference increases in proportion to the intensity of the initial stimulus; this is called (b) ________ law.

B. Sensation Versus Perception

3. Our third question—How are meaningless sensations combined into meaningful perceptions?—can be answered by analyzing our own perceptual experiences. Our first awareness of some outside stimulus is called a (a) ________. This awareness results when some change in energy activates sensory receptors, which produce signals that, in turn, are transformed by the brain into meaningless sensory experiences. When many individual sensations are assembled into a meaningful experience, image, or pattern, it is called a (b) ________. The latter is not an exact replica of the real world but rather a copy that has been changed, biased, or distorted by our unique set of (c) ________. Our brain transforms sensations into perceptions instantaneously, automatically, and without our awareness.

4. The (a) ________ argued that we can explain how perceptions are formed by dividing perceptions into smaller and smaller elements. They believed that we combine basic elements to form a perception. In contrast, the (b) ________ psychologists replied that the formation of perceptions cannot be understood by simply breaking perceptions down into individual components and then studying how we reassemble them. They argued that "the whole is more than the sum of its parts," by which they meant that perceptions are more than a combination of individual elements. The Gestalt psychologists believed that the brain has rules for assembling perceptions, which they called principles of (c) ________.

C. Rules of Organization

5. Many of the rules of perceptual organization involve ways of grouping or arranging stimuli. According to one of these rules, the first thing we do is automatically separate an image into two parts: the more detailed feature of an image becomes the (a) ________ and the less detailed aspects become the (b) ________. According to the (c) ________ rule, stimuli tend to be organized in the most basic, elementary way. According to the (d) ________ rule, stimuli that appear the same tend to be grouped together. According to the (e) ________ rule, stimuli that are near one another tend to be grouped together. According to the (f) ________ rule, stimuli that are arranged in a smooth line or curve tend to be perceived as forming a continuous path. According to the (g) ________ rule, we tend to fill in the missing parts of a figure and perceive it as complete.

D. Perceptual Constancy

6. Although the size, shape, brightness, and color of objects are constantly changing, we tend to see them as remaining the same, a phenomenon that is called (a) ________. A person walking away does not appear to grow smaller, even though the image on the retina is decreasing in size, because of (b) ________ constancy. Even though the image of a door that is opened and closed changes on the retina from a rectangle to a trapezoid, we see it as retaining its rectangular outline because of (c) ________ constancy. Even though the color and brightness inside a car are altered when we drive from bright into dim light, we tend to see little change because of (d) ________ and ________ constancy.

E. Depth Perception

7. The visual system transforms the two-dimensional image (height and width) of stimuli projected onto the retina into a three-dimensional experience by adding depth. Cues for depth that are dependent on both eyes are called (a) ________; cues for depth that are dependent on only a single eye are called (b) ________. The binocular cue for depth that arises when muscles turn your eyes inward is called (c) ________. The binocular cue for depth that arises because the two eyes send slightly different images to the brain is called (d) ________.

142 MODULE 6 PERCEPTION

Problem. How often have you heard students say, "I read the material three times but still did poorly on the test"? The problem is that students may think they know the material because they have a general idea of what they have read. However, researchers found that students are poor judges of how well they really know material unless they test themselves on specific questions.

Remembering. The sample page on the left shows part of the ***Summary Test*** (Module 6), which gives students a chance to test their knowledge by answering specific questions. The reason the ***Summary Test*** (and the ***Concept Review***) uses fill-in-the-blank questions instead of multiple choice is that fill-in-the-blank questions require recall, while multiple-choice questions require only recognition. Thus, fill-in-the-blank questions are a better test of a student's memory.

Two tests. Each module contains two tests. The first is the ***Concept Review*** (discussed on p. xxv), which occurs toward the end of each module and allows students to test their knowledge of major concepts.

The second is the ***Summary Test,*** which occurs at the end of each module and allows students to check their knowledge of the entire module. Students' comments indicate that they like the ***Summary Test*** because it's a great way to review all the material.

Critical Thinking: Challenges Students' Minds

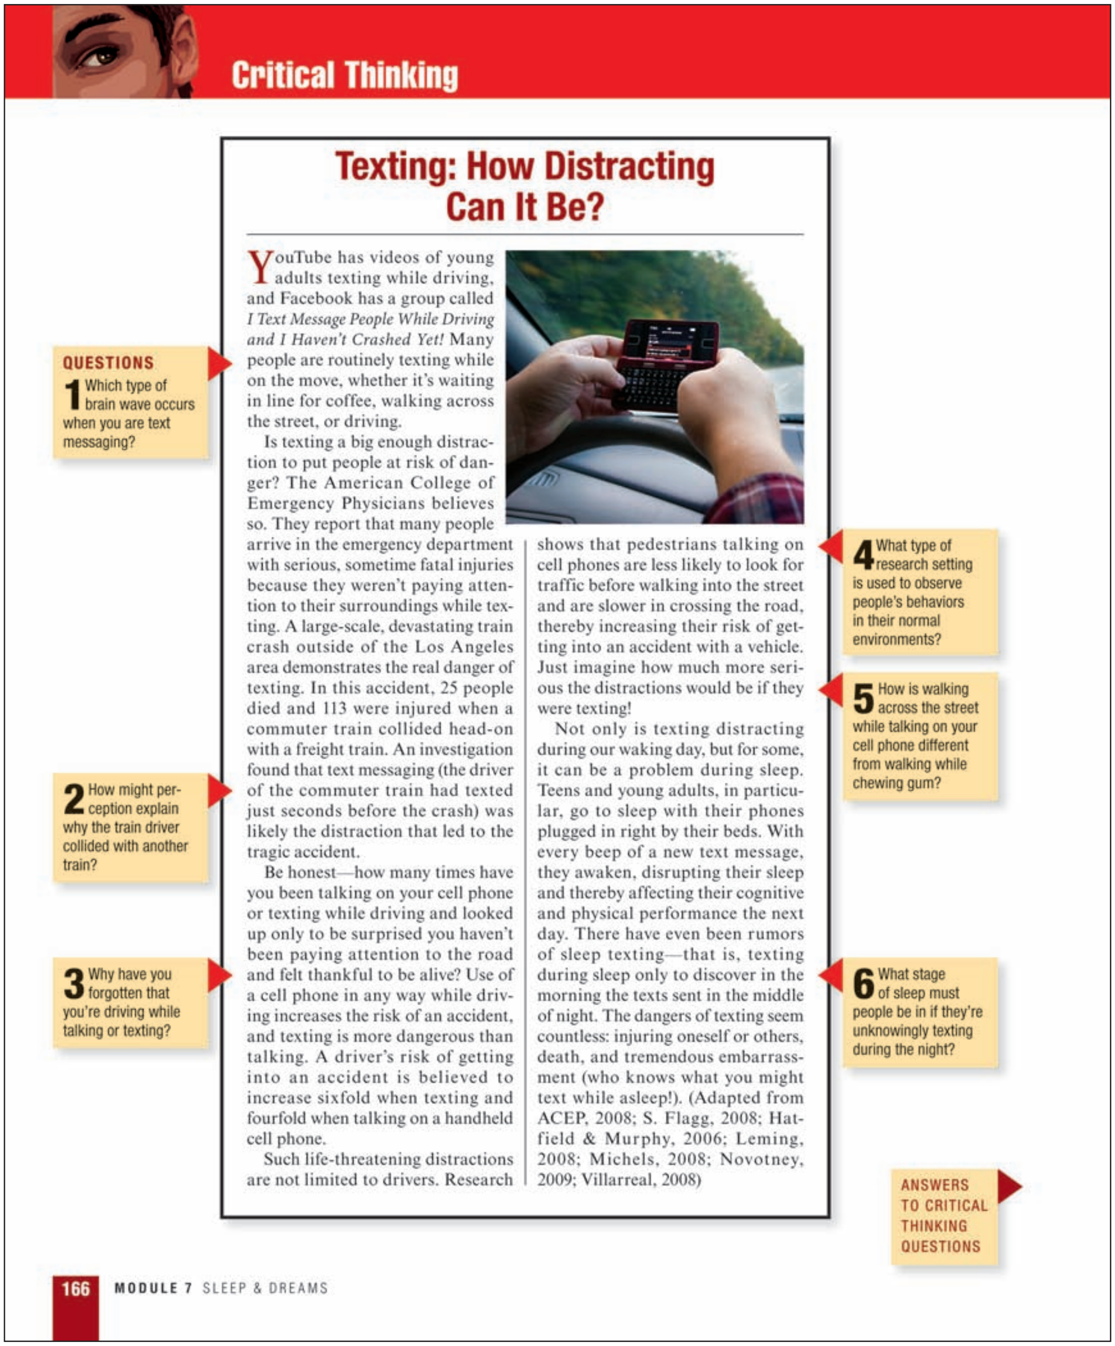
Critical thinking challenge. An important goal of an Introductory Psychology course is to give students practice in critical thinking, which includes using concepts that they have learned in the modules to evaluate information from other sources. To accomplish this goal, we ask students to apply what they have learned by reading and evaluating an interesting and current newspaper article.

Research indicates that newspaper articles are a good way to create interest, nurture curiosity, and stimulate critical thinking and writing.

Example. The sample page on the right shows the ***Critical Thinking*** feature (Module 7), which contains an interesting, current newspaper article that relates to topics discussed in the module (e.g., automatic vs. controlled processes, brain wave activity). Students are asked to think about and evaluate the article by answering six questions that are placed next to it.

Getting started. Because many students need help in thinking about and answering questions, there are brief suggested answers at the bottom of the next page to help them get on the right track. The suggested answers show students how they can use information in the module to evaluate statements in the article.

Class discussions. A newspaper article, which appears at the end of each module, is also great for stimulating class discussions.



Critical Thinking

Texting: How Distracting Can It Be?

YouTube has videos of young adults texting while driving, and Facebook has a group called *I Text Message People While Driving and I Haven't Crashed Yet!* Many people are routinely texting while on the move, whether it's waiting in line for coffee, walking across the street, or driving.

Is texting a big enough distraction to put people at risk of danger? The American College of Emergency Physicians believes so. They report that many people arrive in the emergency department with serious, sometime fatal injuries because they weren't paying attention to their surroundings while texting. A large-scale, devastating train crash outside of the Los Angeles area demonstrates the real danger of texting. In this accident, 25 people died and 113 were injured when a commuter train collided head-on with a freight train. An investigation found that text messaging (the driver of the commuter train had texted just seconds before the crash) was likely the distraction that led to the tragic accident.

Be honest—how many times have you been talking on your cell phone or texting while driving and looked up only to be surprised you haven't been paying attention to the road and felt thankful to be alive? Use of a cell phone in any way while driving increases the risk of an accident, and texting is more dangerous than talking. A driver's risk of getting into an accident is believed to increase sixfold when texting and fourfold when talking on a handheld cell phone.

Such life-threatening distractions are not limited to drivers. Research shows that pedestrians talking on cell phones are less likely to look for traffic before walking into the street and are slower in crossing the road, thereby increasing their risk of getting into an accident with a vehicle. Just imagine how much more serious the distractions would be if they were texting!

Not only is texting distracting during our waking day, but for some, it can be a problem during sleep. Teens and young adults, in particular, go to sleep with their phones plugged in right by their beds. With every beep of a new text message, they awaken, disrupting their sleep and thereby affecting their cognitive and physical performance the next day. There have even been rumors of sleep texting—that is, texting during sleep only to discover in the morning the texts sent in the middle of night. The dangers of texting seem countless: injuring oneself or others, death, and tremendous embarrassment (who knows what you might text while asleep!). (Adapted from ACEP, 2008; S. Flagg, 2008; Hatfield & Murphy, 2006; Leming, 2008; Michels, 2008; Novotney, 2009; Villarreal, 2008)

QUESTIONS

1 Which type of brain wave occurs when you are text messaging?

2 How might perception explain why the train driver collided with another train?

3 Why have you forgotten that you're driving while talking or texting?

4 What type of research setting is used to observe people's behaviors in their normal environments?

5 How is walking across the street while talking on your cell phone different from walking while chewing gum?

6 What stage of sleep must people be in if they're unknowingly texting during the night?

Study Guide and WebTutor

Work through the corresponding module in your Study Guide for tips on how to study effectively and for help learning the material covered in the book. WebTutor (an online Study Tool accessed through your eResources account) provides an interactive version of the Study Guide.

Suggested Answers to Critical Thinking

1. When you are awake and alert, concentrating on your text messaging, you experience brain wave activity called beta waves, which have high frequency and low amplitude.
2. At its simplest, driving requires that the driver perceive what is going on in the driving environment, such as perceiving that a train is rapidly approaching. If the driver's attention is focused on texting, the driver could miss perceiving the train approaching and therefore not take the necessary action to escape the dangerous situation.
3. The problem with talking or texting while driving is that we have the ability to focus all of our attention on only one thing, which is an example of controlled processes. The focused attention required to carry out controlled processes (use of cell phone) interferes with the execution of other ongoing activities (driving).
4. Watching people's behaviors as they cross the street is an example of research in the naturalistic setting, a relatively normal environment in which researchers gather information by observing individuals' behaviors without attempting to change or control the situation.
5. Walking across the street while talking on your cell phone is an example of controlled processes (talking on your cell phone requires most of your attention, leaving little focus on walking across the street). Walking while chewing gum is an example of automatic processes (walking across the street receives most of your attention while you are almost automatically chewing gum, which doesn't interfere with crossing the street).
6. Stage 4 sleep is when you have delta brain waves and your body can move. This is when sleeptalking and sleepwalking may occur. As such, people may be texting (probably incoherent messages) during stage 4 sleep. For people who have REM behavior disorder, it may be possible to text during REM sleep, as the voluntary muscles that should be paralyzed are not.

LINKS TO LEARNING 167

Links to Learning offers students the following opportunities:

Key Terms/Key People allows students to check and review all the important concepts in the module.

PowerStudy 4.5 consists of cross-platform DVDs that contain 40- to 50-minute multimedia presentations with over 40 videos. Each presentation is fully narrated and includes animations, interactive activities, and many quizzes.

PowerStudy 4.5 has complete content and coverage for Modules 2, 3, 4, 6, 7, 8, 9, 10, 11, 12, 17, 21, 22, and 23 and includes interactive tests, quizzes, and critical thinking activities for all the remaining modules. A more detailed description of ***PowerStudy 4.5*** appears on pp. xxxv–xxxvi.

CengageNOW! has a Pre-Test to help students study and a Post-Test to show what they have learned and have yet to master.

Book Companion Website offers learning objectives, Internet exercises, quizzes, flash cards, and a pronunciation glossary.

Study Guide, by Matthew Enos, offers study aids and quizzes.

WebTutor offers students online tutorials and quizzes.

Suggested Answers show students how they can use information they have already learned to evaluate statements in the ***Critical Thinking*** newspaper article on the previous page.

Supplements

The ninth edition of *Introduction to Psychology* is accompanied by a wide array of supplements developed to create the best teaching and learning experience inside as well as outside the classroom, in part by extending the book's visual approach to its supplemental materials. All of the continuing supplements have been thoroughly revised and updated, and some new supplements have been added. Cengage Learning prepared the following descriptions. We invite you to start taking full advantage of the teaching and learning tools available to you by reading this overview. Please note that a guide to Wadsworth's collection of videos for introductory psychology begins on page xxxiii.

PowerStudy for *Introduction to Psychology* 4.5

0-495-90866-5

A cross-platform DVD-ROM, created by Tom Doyle and Rod Plotnik, PowerStudy includes nine 40–50-minute interactive multimedia presentations called SuperModules. These SuperModules accompany the following modules in *Introduction to Psychology,* 9th edition: Module 2: Psychology & Science; Module 3: Brain's Building Blocks; Module 4: Incredible Nervous System; Module 6: Perception; Module 7: Sleep & Dreams; Module 8: Hypnosis & Drugs; Module 9: Classical Conditioning; Module 10: Operant & Cognitive Approaches; Module 11: Types of Memory; Module 12: Remembering & Forgetting; Module 17: Infancy & Childhood; Module 21: Health, Stress & Coping; Module 22: Assessment & Anxiety Disorders; and Module 23: Mood Disorders & Schizophrenia. For all of the book's other modules, the DVD-ROM includes interactive tests and quizzes, a Critical Thinking exercise, key terms, module outlines, and web links.

Instructor's Resource Manual

0-495-90842-8

Written by Gail Knapp of Mott Community College, the manual includes teaching tips for new instructors, module outlines, the Resource Integration Guide, websites, student projects, suggested videos, and films, as well as complete "Active Learning Exercises" and handout masters that simplify course preparation.

Test Bank

0-495-90860-6

Written by Gregory Cutler of Bay de Noc Community College, this test bank includes over 150 multiple-choice, 25 true/false, and 10 short-answer essay questions per module. Thirty test items per module are available to students in the form of online quizzes and are clearly identified as such. Fifteen questions per module are pulled from the Study Guide and the PowerStudy DVD. (These are also clearly identified as such.) Each test item is referenced to the text by page number and topic, is labeled with the question type (applied, conceptual, or factual), and has an indicated level of difficulty. Also available in ExamView electronic format.

PowerLecture with ExamView and JoinIn

0-495-90865-7

The fastest, easiest way to build powerful, customized media-rich lectures, PowerLecture provides a collection of book-specific PowerPoint lectures written by John Phelan, Western Oklahoma State College, and class tools to enhance the educational experience. Featuring automatic grading, ExamView® allows you to create, deliver, and customize tests and study guides (both print and online) in minutes. The DVD-ROM also includes the JoinIn™ Student Response System that lets you pose topic-specific polling questions, video polling questions, and book-specific questions and display students' answers seamlessly within the PowerPoint® slides of your own lecture in conjunction with the "clicker" hardware of your choice.

Study Guide

0-495-90840-1

Written by Matthew Enos of Harold Washington College, the Study Guide includes module outlines, effective student tips, key terms, learning objectives, language development tools, The Big Picture questions, PowerStudy 4.5 integration, and true/false, matching, essay, and multiple-choice questions. It also includes a "How English Works" section, written by John Thissen of Harold Washington College. Answers to all testing items are found on the last page of the Study Guide module.

CengageNOW Printed Access Card

0-538-49322-4

CengageNOW for *Introduction to Psychology* includes a personalized study system that provides a pre-test and a post-test for each chapter, written by Paul Kochmanski of Erie Community College. CengageNOW Personalized Study is a diagnostic tool consisting of a chapter-specific Pre-Test, Study Plan, and Post-Test that utilize valuable text-specific assets to empower students to master concepts, prepare for exams, and be more involved in class. CengageNOW features a variety of valuable assets including an integrated e-book, videos, simulations, and animations that help students gain a deeper understanding of important concepts.

WebTutor on WebCT or Blackboard

Printed Access Card for WebCT: 0-538-49181-7
Printed Access Card for Blackboard: 0-538-49180-9

Jump-start your course with customizable, rich, text-specific content within your Course Management System.

- **Jump-start**—Simply load a WebTutor cartridge into your Course Management System.
- **Customizable**—Easily blend, add, edit, reorganize, or delete content.
- **Content**—Rich, text-specific content, media assets, quizzes, web links, discussion topics, interactive games and exercises, and more.

Book Companion Website
0-495-90867-3
When you adopt *Introduction to Psychology,* you and your students will have access to a rich array of teaching and learning resources that you won't find anywhere else. This outstanding site features tutorial quizzing, glossary, flash cards, crossword puzzles, and more!

***The Psychology Major's Handbook,* 2nd Edition**
ISBN-10: 0-534-53387-6
ISBN-13: 9-780-534533-878
By Tara L. Kuther, Western Connecticut State University, this brief book offers undergraduate students the information they need to make informed decisions about whether to pursue psychology as a major and career and how to succeed in psychology. The author encourages the student to become an active learner and take control of his or her education and future.

***Cross-Cultural Perspectives in Introductory Psychology,* 4th Edition** 0-534-54653-6
By William F. Price, North Country Community College, and Richley H. Crapo, Utah State University, this book contains 27 articles on cultural groups around the globe and is an ideal companion volume to any introductory psychology text. Each cross-cultural reading or vignette enriches the traditional material of the course. These articles were specifically chosen to increase student understanding of the similarities and differences among the peoples of the world as they relate to psychological principles, concepts, and issues. Available at a discounted package price with the text.

***Challenging Your Preconceptions: Thinking Critically About Psychology,* 2nd Edition** 0-534-26739-4
By Randolph A. Smith, Ouachita Baptist University, this is an ideal supplement for any introductory psychology text. The book covers critical thinking within the context of research methods and statistics, biological bases of behavior, sensation and perception, altered states of consciousness, learning, memory, testing, motivation, therapy, and abnormal and social psychology.

***Critical Thinking in Psychology: Separating Sense from Nonsense,* 2nd Edition**
ISBN-10: 0-534-63459-1
ISBN-13: 9-780-534-63459-9
Do your students have the tools to distinguish the true science of human thought and behavior from pop psychology? This engaging, brief book, written by John Ruscio of Elizabethtown College, provides a tangible and compelling framework for making that distinction. Because we are inundated with "scientific" claims, the author does not merely differentiate science and pseudoscience, but goes further to teach the fundamentals of scientific reasoning on which students can base their evaluation of information.

Guide to Wadsworth Videos for Introductory Psychology

Wadsworth offers qualified adopters a rich collection of videos for use in their courses.

ABC® DVD: Introduction to Psychology
Volume 1: 0-495-50306-1
Volume 2: 0-495-59637-X
Volume 3: 0-495-60490-9
ABC Videos feature short, high-interest clips from current news events as well as historic raw footage going back 40 years. Perfect to start discussion or to enrich your lectures and spark interest in the material in the text, these brief videos provide students with a new lens through which to view the past and present, one that will greatly enhance their knowledge and understanding of significant events and open up new dimensions in learning. Clips are taken from such programs as "World News Tonight," "Good Morning America," "This Week," "PrimeTime Live," "20/20," and "Nightline," as well as numerous ABC News specials and material from the Associated Press Television News and British Movietone News collections.

Wadsworth Psychology: Research in Action
Volume 1: 0-495-60490-9
Volume 2: 0-495-59813-5
The *Research in Action* video collections feature the work of research psychologists to give students an opportunity to learn about cutting-edge research—not just who is doing it, but also how it is done, and how and where the results are being used. By taking students into the laboratories of both established and up-and-coming researchers, and by showing research results being applied outside of the laboratory, these videos offer insight into both the research process and the many ways in which real people's lives are affected by research in the fields of psychology and neuroscience.

Psych in Film
0-618-27530-4
PSYCH IN FILM® DVD contains 35 clips from Universal Studios films, illustrating key concepts in psychology. Clips from films like *Schindler's List, Snow Falling on Cedars,* and many others are combined with commentary and discussion questions to help bring psychology alive for students and demonstrate its relevance to contemporary life and culture. Teaching tips are correlated with specific text chapters and concepts and are available on the instructor website.

Wadsworth Guest Lecture Series
0-547-00401-X
The Guest Lecture Series features many talented teachers sharing their teaching tips and best practices on a wide range of topics, including: Rational Emotive Behavior Theory, Blogging as an Effective Tool, Demonstrations on Taste, Dramatizing Perspectives in Psychology, How to Teach Writing in Psychology, and more.

Ordering options for student supplements are flexible. Please consult your local Wadsworth | Cengage Learning sales representative or visit us at **www.cengage.com** for more information, including ISBNs; to receive examination copies of any of these instructor or student resources; or for product demonstrations. Print and e-book versions of this text, as well as many of its supplemental materials, are available for students to purchase at a discount at **www.CengageBrain.com.**

To the Student: A Different Kind of Textbook

Looks different. This textbook looks different because it uses visual learning techniques, such as breaking material into smaller units and integrating text and graphics. Every definition is boldface and printed in **blue** so that you can identify it easily.

Concept Review. This is a test of how well you remember some of the key concepts. As you fill in the blanks of the Concept Review, you'll be learning important terms and concepts.

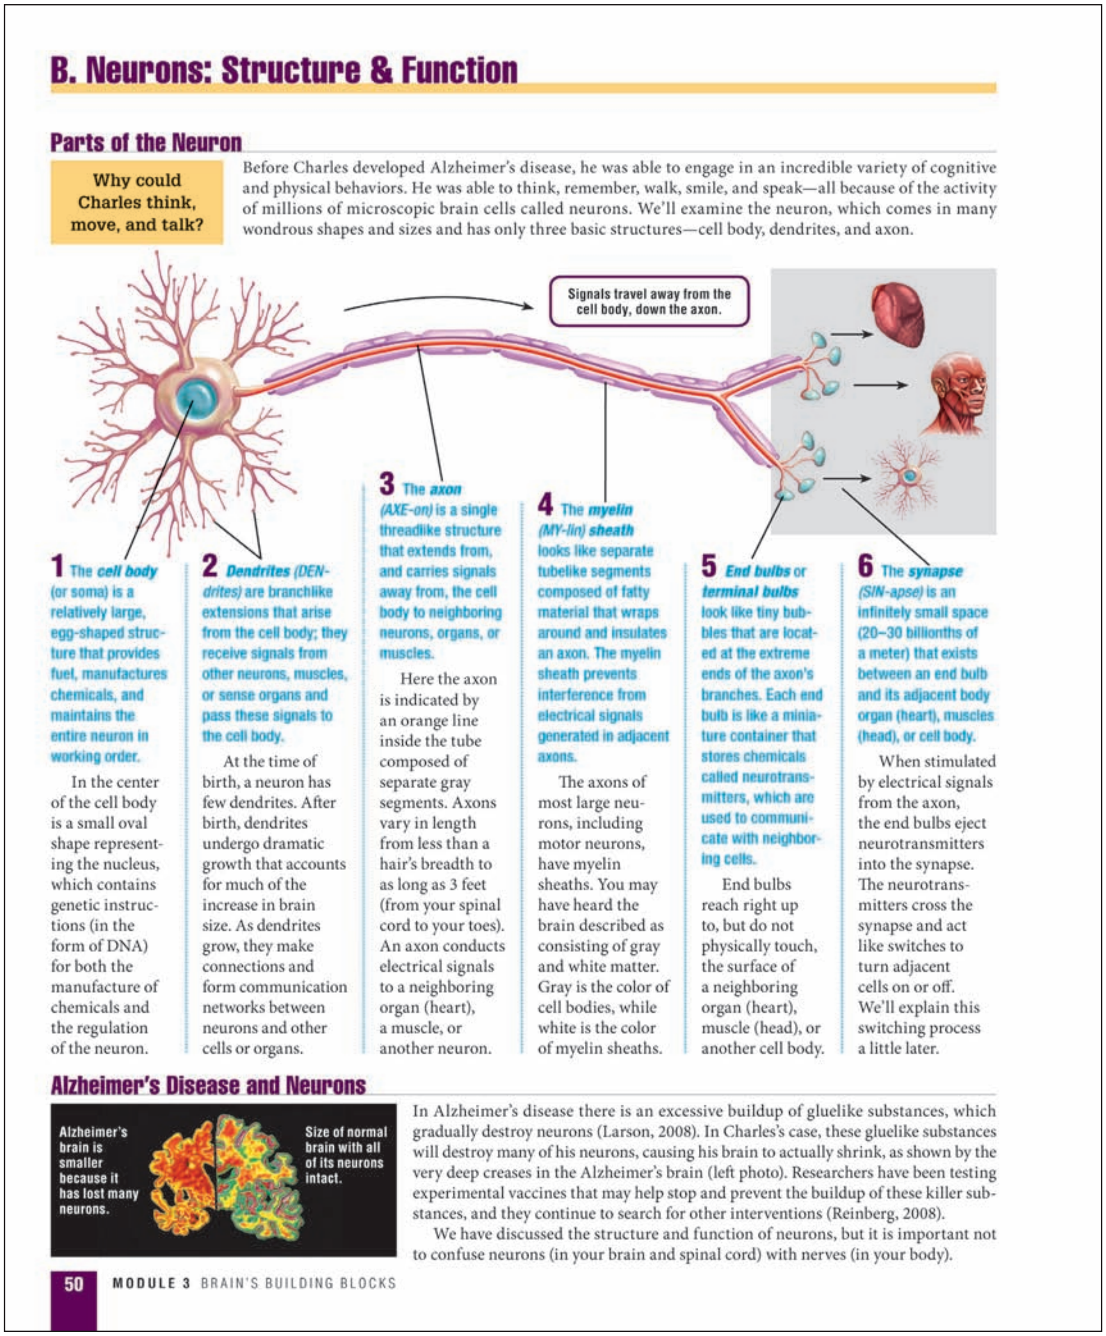
Summary Test. This lets you check how well you remember the material from the entire module. Taking the Summary Test is also an excellent way to review all the major terms discussed in the module.

Critical Thinking. At the end of each module are several Critical Thinking activities, including study questions and questions about an interesting newspaper article.

Key Terms/Key People. There's a list of key terms/people (with page numbers) at the end of each module.

Study Guide. To give you additional help in mastering a module, the ***Study Guide*** contains outlines of each module plus a variety of questions (multiple-choice, true/false, matching) that give you many chances to test your mastery of the material.

PowerStudy 4.5. Available on DVD, this multimedia resource contains narrated lectures, interactive tests, and over 40 videos—an exciting way to learn.



B. Neurons: Structure & Function

Parts of the Neuron

Why could Charles think, move, and talk?

Before Charles developed Alzheimer's disease, he was able to engage in an incredible variety of cognitive and physical behaviors. He was able to think, remember, walk, smile, and speak—all because of the activity of millions of microscopic brain cells called neurons. We'll examine the neuron, which comes in many wondrous shapes and sizes and has only three basic structures—cell body, dendrites, and axon.

Signals travel away from the cell body, down the axon.

1 The ***cell body*** (or soma) is a relatively large, egg-shaped structure that provides fuel, manufactures chemicals, and maintains the entire neuron in working order.

In the center of the cell body is a small oval shape representing the nucleus, which contains genetic instructions (in the form of DNA) for both the manufacture of chemicals and the regulation of the neuron.

2 ***Dendrites*** *(DEN-drites)* are branchlike extensions that arise from the cell body; they receive signals from other neurons, muscles, or sense organs and pass these signals to the cell body.

At the time of birth, a neuron has few dendrites. After birth, dendrites undergo dramatic growth that accounts for much of the increase in brain size. As dendrites grow, they make connections and form communication networks between neurons and other cells or organs.

3 The ***axon*** *(AXE-on)* is a single threadlike structure that extends from, and carries signals away from, the cell body to neighboring neurons, organs, or muscles.

Here the axon is indicated by an orange line inside the tube composed of separate gray segments. Axons vary in length from less than a hair's breadth to as long as 3 feet (from your spinal cord to your toes). An axon conducts electrical signals to a neighboring organ (heart), a muscle, or another neuron.

4 The ***myelin*** *(MY-lin)* ***sheath*** looks like separate tubelike segments composed of fatty material that wraps around and insulates an axon. The myelin sheath prevents interference from electrical signals generated in adjacent axons.

The axons of most large neurons, including motor neurons, have myelin sheaths. You may have heard the brain described as consisting of gray and white matter. Gray is the color of cell bodies, while white is the color of myelin sheaths.

5 ***End bulbs*** or ***terminal bulbs*** look like tiny bubbles that are located at the extreme ends of the axon's branches. Each end bulb is like a miniature container that stores chemicals called neurotransmitters, which are used to communicate with neighboring cells.

End bulbs reach right up to, but do not physically touch, the surface of a neighboring organ (heart), muscle (head), or another cell body.

6 The ***synapse*** *(SIN-apse)* is an infinitely small space (20–30 billionths of a meter) that exists between an end bulb and its adjacent body organ (heart), muscles (head), or cell body.

When stimulated by electrical signals from the axon, the end bulbs eject neurotransmitters into the synapse. The neurotransmitters cross the synapse and act like switches to turn adjacent cells on or off. We'll explain this switching process a little later.

Alzheimer's Disease and Neurons

Alzheimer's brain is smaller because it has lost many neurons.

Size of normal brain with all of its neurons intact.

In Alzheimer's disease there is an excessive buildup of gluelike substances, which gradually destroy neurons (Larson, 2008). In Charles's case, these gluelike substances will destroy many of his neurons, causing his brain to actually shrink, as shown by the very deep creases in the Alzheimer's brain (left photo). Researchers have been testing experimental vaccines that may help stop and prevent the buildup of these killer substances, and they continue to search for other interventions (Reinberg, 2008).

We have discussed the structure and function of neurons, but it is important not to confuse neurons (in your brain and spinal cord) with nerves (in your body).

Complete Text

Introduction

A. Perceptual Thresholds
- Becoming Aware of a Stimulus
- Weber's Law
- Just Noticeable Difference (JND)

B. Sensation versus Perception
- Basic Differences
- Changing Sensations into Perceptions

C. Rules of Organization
- Structuralists versus Gestalt Psychologists
- Evidence for Rules
- Organizational Rules

D. Perceptual Constancy
- Size, Shape, Brightness, & Color Constancy

E. Depth Perception
- Binocular Depth Cues
- Monocular Depth Cues

F. Illusions
- Strange Perceptions
- Learning from Illusions

G. Research Focus: Influencing Perception
- Can "Unsensed Messages" Change Behavior

H. Cultural Diversity: Influence on Perceptions
- What Do Cultural Influences Do?
- Definition and Controversy

I. ESP: Extrasensory Perception
- Trickery and Magic
- ESP Experiment
- Status of ESP and TV Psychics

J. Application: Creating Perceptions
- Creating Movement
- Creating Movies
- Creating Virtual Reality
- Crating First Impressions

K. Learning Activities
- Quizzes
- Web Sites
- Key Terms
- Critical Thinking

Featuring 14 fully narrated, 40- to 50-minute **SuperModules** that allow you to hear and see multimedia presentations on their topics as well as 11 additional interactive modules, the ***PowerStudy 4.5 DVD-ROM*** was developed to work with every module in this textbook, so its organization mirrors that of the book. All modules include helpful study tools such as interactive versions of the book's Summary Test and Critical Thinking activities, quizzes, key terms, chapter outlines, and links to relevant websites. Overall, ***PowerStudy 4.5***'s instructive, colorful multimedia presentations actively involve you in your own learning in ways that lead to greater understanding of the material, better retention, ***and*** better grades on exams!

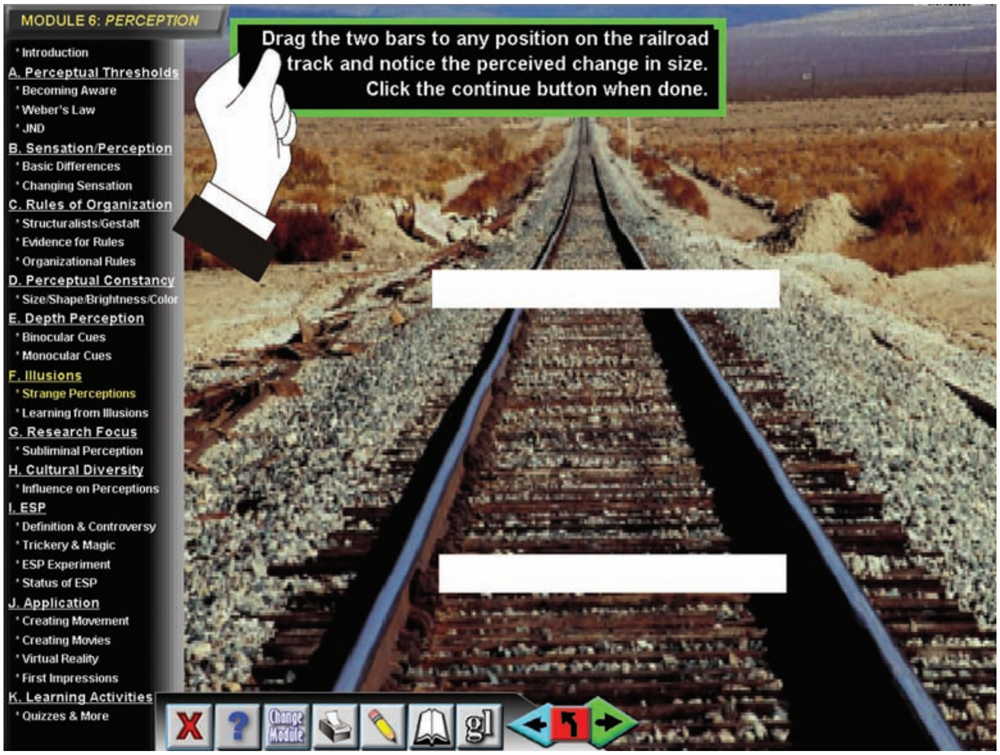
The opening screen for each module displays the module outline.

A Closer Look

You'll learn interactively by *doing!*

With ***PowerStudy 4.5,*** you are actively involved in your own learning—building and reinforcing your understanding of psychology's important concepts interactively. For example, in **SuperModule 6** (shown here), you have an opportunity to experience what is known as Linear Perspective by moving bars along a railroad track.

Throughout ***PowerStudy 4.5,*** you'll have plenty of opportunities to learn by doing—especially in the program's 14 **SuperModules:**



Drag the two bars to any position on the railroad track and notice the perceived change in size. Click the continue button when done.

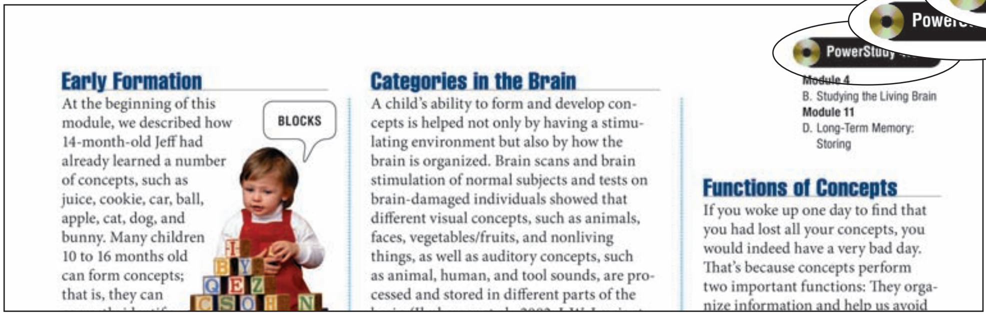
Video segments show you what psychologists do!

Video segments are included within all ***PowerStudy 4.5* SuperModules.** Many of the these videos show psychologists in clinical settings and discussing their work, so you get a real-world understanding of the *science* of psychology and its vital work in actual practice. For example, the video you see in the screen here presents research that includes a split-brain demonstration.

PowerStudy 4.5™



Early Formation

At the beginning of this module, we described how 14-month-old Jeff had already learned a number of concepts, such as juice, cookie, car, ball, apple, cat, dog, and bunny. Many children 10 to 16 months old can form concepts; that is, they can

Categories in the Brain

A child's ability to form and develop concepts is helped not only by having a stimulating environment but also by how the brain is organized. Brain scans and brain stimulation of normal subjects and tests on brain-damaged individuals showed that different visual concepts, such as animals, faces, vegetables/fruits, and nonliving things, as well as auditory concepts, such as animal, human, and tool sounds, are processed and stored in different parts of the

Acknowledgments and Many Thanks

After more than 20 years of working on my own, I have decided that it was time to cut back on my workload and take on a coauthor. The coauthor I chose has such unique qualifications that if I had told you about them, you might have thought I made them up. For that reason, I will let my coauthor, Haig Kouyoumdjian, tell you his own story and, after reading it, you will understand why he is so ideally and perfectly suited for this project (even though I still have trouble pronouncing his name).

—Rod Plotnik

When I took my first college psychology class at Diablo Valley College, I used *Introduction to Psychology* by Rod Plotnik. I can still recall the many conversations I had with peers and family members sharing the fascinating stories I read about and my overall enthusiasm for the textbook. For the first time ever, I did the unimaginable; that is, I began reading ahead because I was impatient to read the next great story and learn the next interesting concept. Plotnik's text sparked my interest in psychology, and I went on to pursue a Bachelor of Science degree at Saint Mary's College of California, a liberal arts college in the San Francisco Bay Area.

My interest in psychology continued to deepen while in college, and I went on to receive a Master of Arts degree in psychology at San Diego State University, where I had the unique experience of working closely with Rod Plotnik, who at that time was a professor in the department and supervisor of the graduate teaching associates training program. Under Plotnik's close supervision, I began teaching Introduction to Psychology courses at the university using his textbook.

Following my education and training at San Diego State University, I attended University of Nebraska–Lincoln, where I received a PhD in Clinical Psychology. While there, I continued to teach Introduction to Psychology courses using Plotnik's text.

After receiving my PhD, I worked as a psychologist in an outpatient medical center, providing mental health services to youths, adults, and families, and continued to teach undergraduate psychology courses. Currently, I am an Assistant Professor at Mott Community College in Flint, Michigan.

My teaching experiences have strengthened my interest in the practice and study of teaching. I especially enjoy stimulating students by using visual learning approaches, such as breaking educational content into small, meaningful chunks of information and presenting visual cues to help students better process, retrieve, and remember information.

Rod Plotnik's influence on my interest in psychology began when I read his textbook as an undergraduate and developed as he trained me in how to become an effective instructor and later carefully guided me through the 8th edition revision of this text. It is with much appreciation and pleasure that I help to continue his vision in *Introduction to Psychology.*

—Haig Kouyoumdjian

In revising the 9th edition, I worked with a remarkable group of creative and talented people, each of whom deserves special thanks.

Senior Acquisitions Editor. This edition benefited from the addition of Jaime Perkins, who believed in the vision of this textbook and supported a major design and content update to make this edition the best it could possibly be. This textbook would not be where it is now without the past support from Vicki Knight.

Senior Developmental Editor. Also new to the team is Renee Deljon, who coordinated many aspects of this revision, but more important, she provided much needed encouragement and supported my vision while making valuable contributions that took the textbook beyond my aim. Her fun sense of humor also lightened the stress that comes along with any revision.

Designers. As always, Vernon Boes does excellent work as our art director. Roger Knox is the creative person who did the wonderful cover image, and Gary Hespenheide did a fantastic cover design and new interior design, which so nicely captures the personality of the textbook.

Concept Illustrators. Once again Tim Jacobus had a vital role in making this textbook visually breathtaking. He is incredibly talented and knows exactly what this textbook needs.

Photo Researchers. Kathleen Olson is new to the team and handled the challenging task of photo research and permissions amazingly well. She worked at lightning speeds while maintaining the highest standards, always remaining committed to finding just the right photo. In previous editions, Linda Rill had this role and her markings are evident throughout the book. During this revision, she kindly contributed as a consultant for some of the module-opening photos.

Manuscript Editor. We had the best manuscript editor ever in Carol Reitz, whose editorial skills really did improve the book.

Production: Part 1. The job of Nancy Shammas at New Leaf Publishing Services was to make sure that every page was perfect and ready for print. This textbook looks so polished because of her great efforts. Keeping track of everything at Cengage Learning was Pat Waldo, Senior Content Project Manager, who made sure that everything got done on time and was where it should be. Her feedback, support, and constant availability are much appreciated.

Production: Part 2. Paige Larkin and Ed Scanlon of LaurelTech made sure the individual pages were turned into a complete book. Paige is new to the team and did a superb job. She kept track of 2,000+ visuals and had the tough job of checking and correcting all of the files. She has a great visual eye, which helped to make this book so visually appealing.

Sales. Liz Rhoden makes sure that all sales representatives know what the book is about and how to describe it to potential adopters. She is really committed to make this book a success.

Study Guide. Matthew Enos at Harold Washington College uses his friendly and helpful teaching skills to write the *Study Guide,* whose previous editions are highly praised by students. John Thissen at Harold Washington College did a great job on the *Study Guide*'s language workout section.

Supplements. Paige Leeds, assistant editor, was responsible for organizing and keeping track of all the many supplements. Once again, Gail Knapp at Mott Community College used her creative talents to revise the *Instructor's Resource Manual* and make it one of the best ever. Greg Cutler at Bay de Noc Community College continued to use his critical thinking skills to write the *Test Bank,* which has always received high marks. John Phelan at Western Oklahoma State College developed the PowerPoints on *PowerLecture.* Paul Kochmanski at SUNY Erie Community College wrote self-assessment questions on *CengageNOW* that help students determine what they know and what they should learn.

PowerStudy 4.5. Professor Tom Doyle at Cuyamaca College is one of the brightest and most creative people we know. No one is as talented as Tom when it comes to developing *PowerStudy,* an interactive multimedia presentation for students. Lauren Keyes, Technology Project Manager, assisted Tom in the development of *PowerStudy 4.5.*

Cengage Learning. Thank you to Sean Wakely, Michelle Julet, Linda Schreiber, and Jon-David Hague, who supported the nontraditional look of the 9th edition and the continued development of the revolutionary learning tool, *PowerStudy.*

And finally... There is absolutely no way I could have revised this textbook without lots and lots of help from family. During this revision process, my wife and I welcomed the birth of our daughter, Sosi. In the peak of my exhaustion or frustration, I could always count on Sosi to brighten my mood by making me smile and laugh. Thank you to my parents who often had to watch Sosi while I worked on this revision. And thank you to my wife, Zepure, for her unwavering confidence, endless patience, and graceful support—all while going through her own challenging medical career.

—Haig Kouyoumdjian

Reviewers and Many Thanks

We especially want to thank the many reviewers who put in an amazing amount of time and energy to consider and comment on various aspects of this textbook.

We would like to explain why we were not able to include all your valuable suggestions.

Sometimes your suggestions were great but required inserting material for which there simply was no room.

Other times, one reviewer might suggest changing something that another reviewer really liked, so we tried to work out the best compromise.

Still other times, reviewers forcefully argued for entirely different points so that we felt like the proverbial starving donkey trying to decide which way to turn between two stacks of hay.

For all these reasons, we could not make all your suggested changes but we did give them a great deal of thought and used as many as we possibly could.

We do want each reviewer to know that his or her efforts were invaluable in the process of revising and developing a textbook. If it were within our power, we would triple your honorariums and give you each a year-long sabbatical.

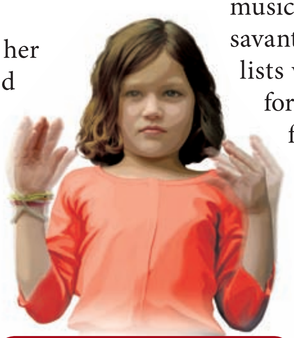
Growing Up in a Strange World

Why does Donna flap her hands?

When Donna was about 3 years old, she ate lettuce because she liked rabbits and they ate lettuce. She ate jelly because it looked like colored glass and she liked to look at colored glass.

She was told to make friends, but Donna had her own friends. She had a pair of green eyes named Willie, which hid under her bed, and wisps, which were tiny, transparent spots that hung in the air around her.

When people spoke, their words were strange sounds with no meaning, like mumble jumble. Donna did learn the sounds of letters and how they fit together to make words. Although she didn't learn the meanings of words, she loved their sounds when she said them out loud. As a child, she was tested for deafness because she did not use language like other children. She did not learn that words had meaning until she was a teenager.



Some autistic children show rapid hand flapping.

When people talked to Donna, especially people with loud or excited voices, she heard only "blah, blah, blah." Too much excited talk or overstimulation caused Donna to stare straight ahead and appear to be frozen. Donna later called this state "involuntarily anesthetized."

Donna was in and out of many schools because she failed her exams, refused to take part in class activities, walked out of classes she didn't like, and sometimes threw things.

When Donna did make a friend, she tried to avoid getting a friendly hug, which made her feel as if she were burning up inside and going to faint. Eventually she learned to tolerate being hugged but never liked it (D. Williams, 1992). Donna Williams had all the symptoms of autism.

Although relatively rare (1 in 150), autism affects 3 to 4 times as many boys as girls, occurs in all parts of the world, and is thought to be 10 times more prevalent now than it was 20 years ago (Fombonne, 2005; NICHD, 2005). Some parents blamed the increase in autism on childhood vaccinations, but after a thorough investigation, a U.S. federal court ruled this is not true (USCFC, 2009). Researchers believe the increase in autism is due, in part, to better diagnosis in recent years as well as to various environmental and genetic factors (C. Kalb, 2008; Kraft, 2006). Researchers are making great strides in understanding the genetic links to autism and have identified a number of genes involved in autism (Arking et al., 2008; Morrow et al., 2008; Weiss et al., 2008).

Some autistic children avoid social interactions.

Autism is marked by especially abnormal or impaired development in social interactions, such as hiding to avoid people, not making eye contact, not wanting to be touched. Autism is marked by difficulties in communicating, such as grave problems in developing spoken language or in initiating conversations. Individuals with autism are characterized by having very few activities and interests, spending long periods repeating the same behaviors (hand flapping), or following the same rituals. Signs of autism usually appear when a child is 2 or 3 years old (American Psychiatric Association, 2000).

A very small percentage of individuals with autism are called *savants* because they have incredible math skills, spatial abilities, musical talent, or near picture-perfect memory. For example, one savant memorized 7,600 books; another plays 7,000 songs; another lists world events that happened on any given day; another performs amazing calculations, such as doubling 8,388,628 twenty-four times in only seconds (answer: 140,737,488,355,328) (D. S. Fox, 2009; Treffert, 2006; Treffert & Wallace, 2002).

Donna Williams (1992) is an example of a savant who developed exceptional language skills. At age 25, in four almost-nonstop weeks, she wrote a 500-page book that described what it was like to be autistic. In this and her three other autobiographies (D. Williams, 1994, 1999, 2004), Donna describes how common sights, sounds, and images become strangely distorted, which makes getting through an ordinary day like finding one's way out of a terribly complex maze.

As we describe Donna's experiences, you'll see how psychologists try to answer questions about complex behaviors, such as autism, as well as countless other behaviors discussed throughout this text. For example, one question that psychologists have studied involves a problem that you may be interested in—test anxiety.

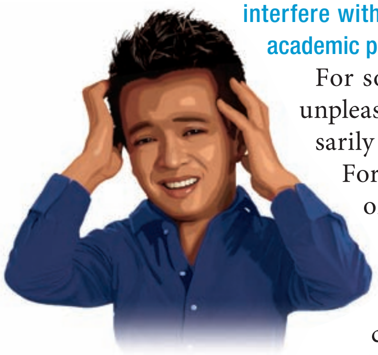
Test Anxiety

Why are your hands sweating?

If you're like many other students, you probably experience some degree of test anxiety.

Test anxiety refers to a combination of physiological, emotional, and cognitive components that are caused by the stress of taking exams and may interfere with one's concentration, planning, and academic performance (Flippo et al., 2009).

For some students, test anxiety is an unpleasant experience but doesn't necessarily interfere with exam performance. For other students, test anxiety not only is an unpleasant experience but also seriously interferes with doing well on exams. We'll discuss what psychologists have discovered about test anxiety, such as its different components, why students differ in how much test anxiety they feel, and, perhaps most important, how to decrease test anxiety.



There are several ways to decrease test anxiety.

What's Coming

In this module, we'll explore the goals of psychology, the major approaches that psychologists use to understand behavior and answer questions, the historical roots of psychology, current research areas, and possible careers in the broad field of psychology. Let's begin with how psychologists study complex problems, such as Donna's autistic behaviors.

A. Definition & Goals

Definition of Psychology

What do psychologists study?

When you think of psychology, you may think of helping people with mental problems. However, psychologists study a broad range of behaviors, including Donna's autistic behaviors and students' test anxiety, as well as hundreds of other behaviors. For this reason, we need a very broad definition of psychology.

Psychology **is the systematic, scientific study of behaviors and mental processes.**

What's important about this definition is that each of its terms has a broad meaning. For example, *behaviors* refers to observable actions or responses in both humans and animals. Behaviors might include eating, speaking, laughing, running, reading, and sleeping. *Mental processes,* which are not directly observable, refer to a wide range of complex mental processes, such as thinking, imagining, studying, and dreaming. The current broad definition of psychology grew out of discussions and heated arguments among early psychologists, who defined psychology much more specifically, as we'll discuss later in this module.

Although the current definition of psychology is very broad, psychologists usually have four specific goals in mind when they study some behavior or mental process, such as Donna's autistic experiences.

Goals of Psychology

What are some of Donna's unusual behaviors?

Donna (photo below) knows that she has some unusual behaviors. For example, she says that she doesn't like to be touched, held, or hugged, doesn't like to make eye contact when speaking to people, hates to talk to someone who has a loud voice, and really dislikes meeting strangers. If you were a psychologist studying Donna's unusual behaviors, you would have the following four goals in mind: to describe, explain, predict, and control her behavior.

Psychology's goals are to describe, explain, predict, and control Donna's autistic behaviors.

1 Describe

Donna says that when she was a child, she wondered what people were saying to her because words were just lists of meaningless sounds. When people or things bothered her, she would endlessly tap or twirl her fingers to create movements that completely held her attention and helped her escape from a world that often made no sense.

The first goal of psychology is to describe the different ways that organisms behave.

As psychologists begin to describe the behaviors and mental processes of autistic children, such as difficulties in learning language, they begin to understand how autistic children behave. After describing behavior, psychologists try to explain behavior, the second goal.

2 Explain

Donna's mother believed that autism was caused by evil spirits. Donna thinks her autism may result from metabolic imbalance.

The second goal of psychology is to explain the causes of behavior.

The explanation of autism has changed as psychologists learn more about this complex problem. In the 1950s, psychologists explained that children became autistic if they were reared by parents who were cold and rejecting (Blakeslee, 2000). In the 1990s, researchers discovered that autism is caused by genetic and biological factors that result in a maldeveloped brain (Courchesne et al., 2003). Being able to describe and explain behavior helps psychologists reach the third goal, which is to predict behavior.

3 Predict

Donna says that one of her biggest problems is being so overloaded by visual sensations that she literally freezes in place. She tries to predict when she will freeze up by estimating how many new stimuli she must adjust to.

The third goal of psychology is to predict how organisms will behave in certain situations.

However, psychologists may have difficulty predicting how autistic children will behave in certain situations unless they have already described and explained their behaviors. For example, from the first two goals, psychologists know that autistic children are easily overwhelmed by strange stimuli and have difficulty paying attention. Based on this information, psychologists can predict that autistic children will have difficulty learning in a school environment because there are too many activities and stimuli in the classroom (Heflin & Alaimo, 2006; M. Pittman, 2007). However, if psychologists can predict behavior, then they can often control behavior.

4 Control

Donna knows one reason she fears meeting people is that social interactions cause a tremendous sensory overload that makes her freeze up. She controls her social fear by making a rule to meet only one person at a time.

For some psychologists, the fourth goal of psychology is to control an organism's behavior. However, the idea of control has both positive and negative sides. The positive side is that psychologists can help people, such as Donna, learn to control undesirable behaviors by teaching better methods of self-control and ways to deal with situations and relationships (Eikeseth et al., 2007; Hall, 2008). The negative side is the concern that psychologists might control people's behaviors without their knowledge or consent. In Module 2, we'll discuss the strict guidelines that psychologists have established to prevent potential abuse of controlling behavior and to protect the rights and privacy of individuals, patients, and participants in experiments.

Because many behaviors, such as autism, are enormously complex, psychologists use a combination of different approaches to reach the four goals of describing, explaining, predicting, and controlling behavior. To reach these goals, psychologists may use one or a combination of the following seven approaches.

Answering Questions

How do psychologists answer questions?

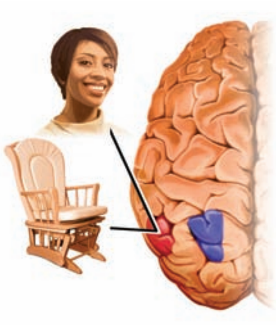
Psychologists have many questions about Donna's unusual behaviors. For example, why did Donna believe that objects were alive and made their own sounds? "My bed was my friend; my coat protected me and kept me inside; things that made noise had their own unique voices, which said vroom, ping, or whatever. I told my shoes where they were going so they would take me there" (Blakely, 1994, p. 14).

Why did Donna initially hear words as meaningless sounds that people were constantly saying to her? Why did she develop her own signaling system, such as scrunching her toes to signal that no one could reach her? Why did she freeze up when staring at soap bubbles in the sink? In trying to answer questions about Donna's strange and intriguing behaviors, psychologists would use a combination of approaches.

Donna would tell her shoes where she was going so they would take her there.

An ***approach*** refers to a focus or perspective, which may use a particular research method or technique.

The approaches to understanding behavior include the ***biological, cognitive, behavioral, psychoanalytic, humanistic, cross-cultural,*** and, most recently, ***evolutionary.*** We'll summarize these seven approaches and then discuss them in more detail on the following pages.



1 As a child, was Donna unable to learn that words had meaning because of some problem with the development of her brain?

The ***biological approach*** focuses on how our genes, hormones, and nervous system interact with our environments to influence learning, personality, memory, motivation, emotions, and coping techniques.

2 How was Donna able to develop her own signaling system that involved gestures instead of words?

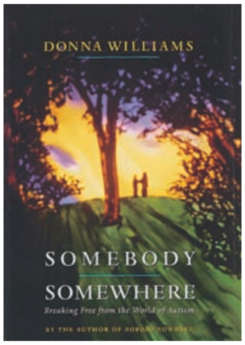
The ***cognitive approach*** examines how we process, store, and use information and how this information influences what we attend to, perceive, learn, remember, believe, and feel.

3 Why did Donna make it a rule to avoid leaving soap bubbles in the sink?

The ***behavioral approach*** studies how organisms learn new behaviors or modify existing ones, depending on whether events in their environments reward or punish these behaviors.

4 Why did Donna develop alternate personalities, such as Willie, who had "hateful glaring eyes, a rigid corpselike stance, and clenched fists"?

The ***psychoanalytic approach*** stresses the influence of unconscious fears, desires, and motivations on thoughts, behaviors, and the development of personality traits and psychological problems later in life.

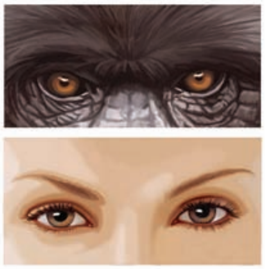


5 How was Donna able to overcome her early language problems and write a book in four weeks?

The ***humanistic approach*** emphasizes that each individual has great freedom in directing his or her future, a large capacity for personal growth, a considerable amount of intrinsic worth, and enormous potential for self-fulfillment.

6 Why did her mother believe autism was caused by evil spirits? What do other peoples and cultures believe causes it?

The ***cross-cultural approach*** examines the influence of cultural and ethnic similarities and differences on the psychological and social functioning of a culture's members.



7 How might Donna's unique behaviors help her to adapt to the environment? How did autism evolve during the course of our human ancestry?

The ***evolutionary approach*** studies how evolutionary ideas, such as adaptation and natural selection, explain human behaviors and mental processes.

By using one or more of these seven approaches, psychologists can look at autism from different viewpoints and stand a better chance of reaching psychology's four goals: to describe, explain, predict, and control behavior. The first six approaches are well-established and commonly used approaches to understanding behavior. We'll use the problems of autism and test anxiety to show how each of these six approaches examines these problems from a different perspective. Then, we'll provide more information about the relatively recent and increasingly popular evolutionary approach.

B. Modern Approaches

PowerStudy 4.5™

Module 4
A. Genes & Evolution
B. Studying the Living Brain

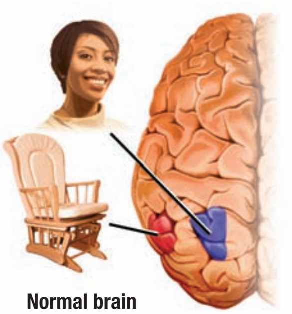
Biological Approach

Are their brains different?

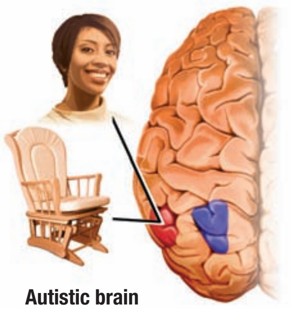
As Donna explains, autism has a huge effect on all parts of her life. "Autism makes me feel everything at once without knowing what I am feeling. Or it cuts me off from feeling anything at all" (D. Williams, 1994, p. 237). Donna's description of how autism so drastically affects her life raises questions about whether her brain has not developed normally or functions differently. To answer these questions, researchers use the biological approach.

The ***biological approach*** examines how our genes, hormones, and nervous system interact with our environments to influence learning, personality, memory, motivation, emotions, and other traits and abilities.

Autism is thought to originate in early brain development. In children with autism, brain cells appear to connect irregularly, leading to abnormal functioning in brain areas responsible for thoughts, movement, and emotions. These abnormalities may explain why these children seem uninterested in their environment and in social interaction. Brain imaging research has shown that children with autism show different brain activity than other children while looking at faces (D. S. Fox, 2009). For example, the top figure shows that the normal brain uses one area (blue—fusiform gyrus) to process ***faces*** of people and a different area (red—inferior temporal gyrus) to process inanimate ***objects,*** such as a chair. The bottom figure shows that the autistic brain uses the area that processes inanimate objects (red—inferior temporal gyrus) to also process human faces (R. T. Schultz et al., 2000). This study uses the biological approach to look inside the brain to explain why people with autism show little interest in looking at a person's face during social interactions or in identifying facial emotional expressions.



Normal brain



Autistic brain

Psychobiologists, researchers who use the biological approach, have shown that genetic factors influence a range of human behaviors, which we'll discuss throughout this text. The genes (p. 68) use a chemical alphabet to write instructions for the development of the brain and body and the manufacture of chemicals that affect mental health, learning, emotions, and everything we do (Rutter & Silberg, 2002). For example, it is known that autism runs in families, and this genetic involvement is supported by the finding that if one identical twin has autism, then there is as high as a 90% chance the other twin will have signs of autism (M. H. Lewis & Lazoritz, 2005). Researchers recently identified a number of genes involved in autism (Arking et al., 2008; Weiss et al., 2008) and are now using genetic screening to help identify the causes of autism (Cai et al., 2008).

Also using the biological approach, researchers found that social problems associated with autism are linked to less activity in brain cells responsible for human empathy (mirror neurons). These cells allow us to put ourselves in other people's shoes and experience how they feel. Reduced activity in these cells helps explain why children with autism misunderstand verbal and nonverbal cues suggesting different emotions felt by others, including joy, sadness, and anger, and why they have difficulty empathizing with others (Dapretto et al., 2006; Iacoboni, 2008).

Essentially, psychobiologists study how the brain affects the mind, and vice versa. They may study an experience that many students are familiar with, called test anxiety.

Biological Approach to Test Anxiety

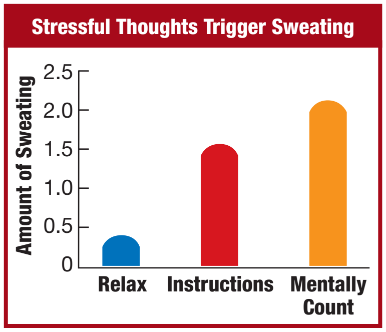
Why do my hands sweat?

You've probably experienced one component of test anxiety, called the emotional component. This component includes a variety of physiological responses, such as increased heart rate, dry mouth, and sweaty palms. An interesting feature of sweaty palms, called palmar sweating, is that it is caused by stressful feelings and is not related to changes in room temperature (L. A. Goldsmith, 2008). In fact, palmar sweating is one of the measures used in the lie detector test, which we'll discuss in Module 16.

Sweaty hands often indicate stress.

As you take an exam—or even think about taking one—your stressful thoughts trigger the emotional component, which can interfere with processing information and increase your chances of making mistakes (Cassady & Johnson, 2002).

The graph on the right shows how easily your stressful thoughts can trigger palmar sweating, which is one measure of the emotional component of test anxiety. As subjects listened to instructions telling them to do mental arithmetic, which involved them counting backward from 100 in steps of 7, there was a significant increase in palmar sweating. Then, once subjects started to actually do the mental arithmetic, their palmer sweating increased even more (Kobayashi et al., 2003). If simply listening to instructions about having to do a simple task of counting backward increased palmar sweating, a sign of physiological and emotional arousal, imagine the increased arousal that occurs while taking an exam!



In fact, symptoms of test anxiety may include shaky legs, racing heart, physical illness, or even crying during an exam (Strauss, 2004). In Module 21, we'll describe several methods of controlling stress that will be useful in controlling the emotional component of test anxiety.

Figure/Text Credit: Graph data from "Arithmetic calculation, deep inspiration or handgrip exercise-mediated pre-operational active palmar sweating responses in humans," by Masayoshi Kobayashi, Noriko Tomioka, Yoshihisa Ushiyama and Toshio Ohhashi *Autonomic Neuroscience*, Volume 104, Issue 1, pp. 58–65.

PowerStudy 4.5™
Module 10
E. Cognitive Learning

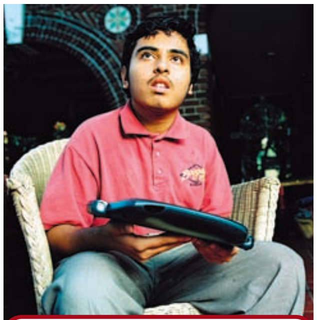
Cognitive Approach

Was Donna an unusual autistic?

Individuals with autism usually have difficulty developing language skills. For example, Donna writes, "Autism makes me hear other people's words but be unable to know what the words mean. Autism stops me from finding and using my own words when I want to. Or makes me use all the words and silly things I do not want to say" (D. Williams, 1994, p. 237). Although Donna did not understand words until she was an adolescent, she eventually learned to both speak and write, has written several creative books (D. Williams, 1992, 1994, 1999, 2004), and has learned French and German. Because of her remarkable language abilities, Donna is said to be a high-functioning autistic, or *savant*. To discover why individuals with autism differ in their language and social skills, psychologists use the cognitive approach.

The ***cognitive approach*** focuses on how we process, store, and use information and how this information influences what we attend to, perceive, learn, remember, believe, and feel.

Unlike Donna Williams, who speaks fluently and is considered a high-functioning autistic, the photo on the right shows Tito Mukhopadhyay, a teenager with severe autism who often seems overcome by various movements, whose speech is virtually unintelligible, but who has the unusual ability to answer questions or explain what he's thinking or doing by writing or typing on the keyboard he is holding. For example, when Tito was being tested in a laboratory, he repeatedly stopped and started bursts of activity, standing and spinning, making loud smacking noises, or flapping his fingers. When asked why he does this, Tito didn't answer verbally but wrote, "I am calming myself. My senses are so disconnected I lose my body, so I flap. If I don't do this, I feel scattered and anxious" (Blakeslee, 2002, p. D1). Tito has written books inviting others to share in his inner life (Mukhopadhyay, 2000, 2003, 2008). In his writings, he explains that his brain has difficulty processing different senses at the same time, such as sound, sight, and touch. This is the reason he avoids eye contact when talking with people, as he usually chooses to focus on hearing (McEdwards, 2008). Thus, there is a cognitive difference between normal individuals who can respond simultaneously to more than one sensory input, such as seeing and hearing, and individuals with autism who are limited to concentrating on one sense at a time.



Tito is severely autistic but can type answers to questions.

Some cognitive researchers combine the study of cognitive skills with identifying their corresponding areas in the brain. This exciting new approach is called cognitive neuroscience (Purves et al., 2008).

Cognitive neuroscience involves taking pictures and identifying the structures and functions of the living brain during performance of a variety of mental or cognitive processes, such as thinking, planning, naming, and recognizing objects.

For example, when listening to a conversation, 95% of right-handers use primarily the left sides of their brains and very little of the right sides to process this verbal information. In contrast, researchers found that individuals with autism used primarily the right sides of their brains and very little of the left sides when listening to a conversation (E. J. Flagg et al., 2005). This reversing of brain sides as well as difficulties in processing verbal information may help explain why autistic individuals have problems acquiring cognitive, language, and communication skills.

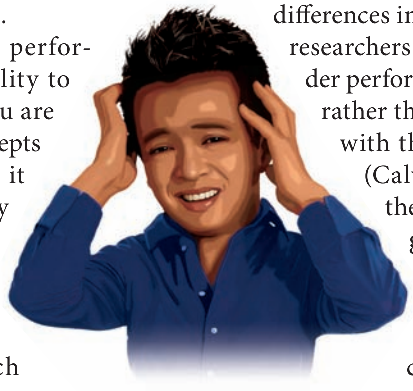
Recently, the cognitive approach and its newer relative, cognitive neuroscience, have become popular because they have proved useful in answering questions about emotions, personality, cognitive skills, and social behaviors (Cacioppo et al., 2005; Harmon-Jones & Winkielman, 2007). For example, the cognitive approach has much to say about test anxiety, especially about worrying too much.

Cognitive Approach to Test Anxiety

Can you worry too much?

Students who experience test anxiety must deal with two components. The first component, which we already described, is increased physiological arousal, which is the emotional component. The second component is the cognitive component, which is excessive worrying, usually about doing poorly on exams.

Excessive worrying about your performance can interfere with your ability to read accurately, understand what you are reading, and identify important concepts (Cassady & Johnson, 2002). Thus, it is easy to see how excessive anxiety and worrying can decrease students' confidence and impair their studying and academic performance (Cassady, 2004; Flippo et al., 2009; Miesner & Maki, 2007). Research measuring students' test anxiety in elementary school, college, and graduate school shows that females report significantly greater test anxiety than males (Chapell et al., 2005; Lynch, 2008; Reteguiz, 2006). Even though females report greater test anxiety, there is no difference in their academic performance when compared to males (Chapell et al. 2005).



The reason females report greater worry and anxiety than males, yet demonstrate the same academic performance, may have something to do with differences in how the sexes channel their worry and anxiety. For instance, researchers found that the cognitive component could either help or hinder performance. Students who channeled their worry into complaining rather than studying performed poorly because their worry interfered with their reading and caused them to make more reading errors (Calvo & Carreiras, 1993). In contrast, students who channeled their worry into studying performed better and achieved higher grades because they were better prepared (Endler et al., 1994).

These studies indicate that the cognitive component of test anxiety—excessive worrying—may either help or hinder cognitive performance, depending on how students channel their worries.

B. Modern Approaches

PowerStudy 4.5™

Module 10
A. Operant Conditioning
E. Cognitive Learning

Behavioral Approach

No leaving soap suds in the sink!

Why have a "no soap suds" rule?

If Donna happened to leave soap suds in the sink, she might see a rainbow of colors reflected in the bubbles. She would become so completely absorbed in looking at the brilliant colors that she could not move; she would be in a state of temporary paralysis. Donna made her "no soap suds" rule to prevent the environment from triggering an autistic behavior—temporary paralysis. Donna and her husband, who is also autistic, have developed many rules to control some of their unwanted behaviors. Here are some of their rules: *No lining feet up with furniture; No making the fruit in the bowl symmetrical; No reading newspaper headlines in gas stations or at newsstands* (Blakely, 1994, p. 43). These rules, which help Donna and her husband avoid performing repetitive and stereotyped behaviors, illustrate the behavioral approach.

Seeing a dazzling rainbow in soap suds stopped Donna in her tracks.

The *behavioral approach* analyzes how organisms learn new behaviors or modify existing ones, depending on whether events in their environments reward or punish these behaviors.

Donna and her husband's rules are examples of a basic behavioral principle: Rewards or punishments can modify, change, or control behavior. Psychologists use behavioral principles to teach people to be more assertive or less depressed, to toilet train young children, and to change many other behaviors. Psychologists use behavioral principles to train animals to press levers, to use symbols to communicate, and to perform behaviors on cue in movies and television shows.

Largely through the creative work and original ideas of B. F. Skinner (1989), the behavioral approach has grown into a major force in psychology. Skinner's ideas stress the study of observable behaviors, the importance of environmental reinforcers (reward and punishment), and the exclusion of mental processes. His ideas, often referred to as strict behaviorism, continue to have an impact on psychology. In Module 10, we'll explain how Skinner's ideas were integrated into a program that taught autistic children new social behaviors that enabled them to enter and do well in public grade schools.

However, some behaviorists, such as Albert Bandura (2001a), disagree with strict behaviorism and have formulated a theory that includes mental or cognitive processes in addition to observable behaviors. According to Bandura's *social cognitive approach,* our behaviors are influenced not only by environmental events and reinforcers but also by observation, imitation, and thought processes. In Module 10, we'll discuss how Bandura's ideas explain why some children develop a fear of bugs.

Behaviorists have developed a number of techniques for changing behaviors that can be applied to both animals and humans. Next, you will see how they have used self-management skills to reduce the cognitive component of test anxiety.

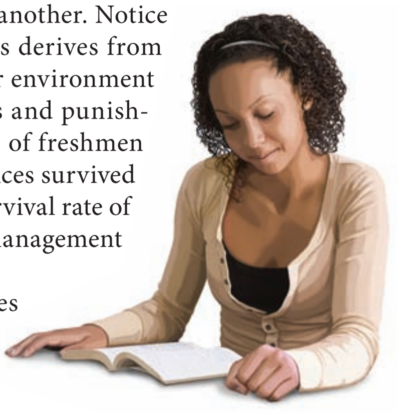
Behavioral Approach to Test Anxiety

Can I redirect my worrying?

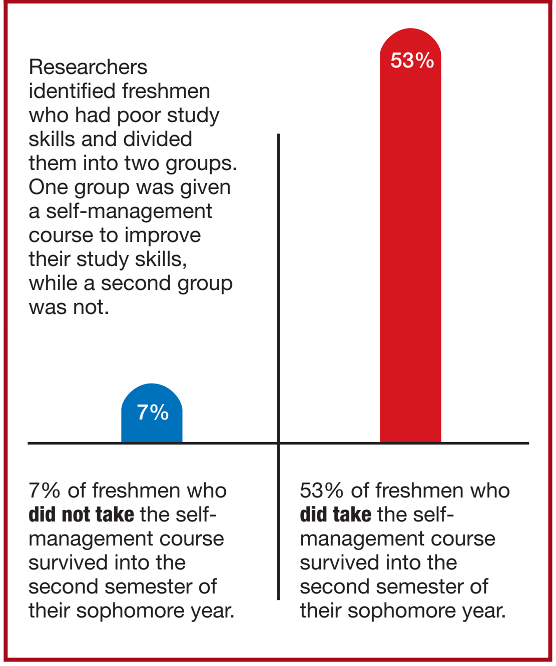
We discussed how excessive worrying, which is the cognitive component of test anxiety, can improve test performance if you can channel your worry into studying for exams. One method to redirect worry into studying more is to use a system of *self-management* based on a number of behavioral principles (D. V. Kennedy & Doepke, 1999).

Researchers found that the following self-management practices are related to increasing studying time and achieving better grades: (1) select a place that you use exclusively for study; (2) reward yourself for studying; (3) keep a record of your study time; (4) establish priorities among projects; (5) specify a time for each task; and (6) complete one task before going on to another. Notice that each of these self-management practices derives from our basic behavioral principle: Events in your environment can modify your behaviors through rewards and punishments. As the graph on the right shows, 53% of freshmen who learned and used self-management practices survived into their sophomore year compared to the survival rate of only 7% of freshmen who did not learn self-management practices (Long et al., 1994).

In later modules, we'll give many examples of how behavioral principles can be used to modify a wide range of behaviors and thought patterns.



Effectiveness of Self-Management



Researchers identified freshmen who had poor study skills and divided them into two groups. One group was given a self-management course to improve their study skills, while a second group was not.

7% of freshmen who **did not take** the self-management course survived into the second semester of their sophomore year.

53% of freshmen who **did take** the self-management course survived into the second semester of their sophomore year.

Psychoanalytic Approach

How was Donna's childhood?

Donna had an alcoholic and verbally abusive mother and a mostly absent father.

When she was about 3 years old, Donna faced a number of personal problems: having an alcoholic mother who hit and verbally abused her, having a father who was often gone, and being sent to a "special needs" school. Apparently in trying to deal with these problems, Donna developed other personalities. One personality was Willie, a child with "hateful glaring eyes, a pinched-up mouth, rigid corpselike stance, and clenched fists," who stamped and spit but also did well in school. The other was Carol, a charming, cooperative little girl who could act normal and make friends (S. Reed & Cook, 1993). Why Donna developed other personalities to deal with difficult childhood experiences would be carefully looked at in the psychoanalytic approach (Lanyado & Horne, 1999).

The *psychoanalytic approach* is based on the belief that childhood experiences greatly influence the development of later personality traits and psychological problems. It also stresses the influence of unconscious fears, desires, and motivations on thoughts and behaviors.

In the late 1800s, Sigmund Freud, a physician, treated a number of patients with psychological problems. On the basis of insights from therapy sessions, Freud proposed some revolutionary ideas about the human mind and personality development. For example, one hallmark of Sigmund Freud's psychoanalytic approach is the idea that the first five years have a profound effect on later personality development. According to the psychoanalytic approach, Donna's first five years with a verbally abusive mother and mostly absent father would profoundly affect her later personality development.

In addition, Freud reasoned that thoughts or feelings that make us feel fearful or guilty, that threaten our self-esteem, or that come from unresolved sexual conflicts are automatically placed deep into our unconscious. In turn, these unconscious, threatening thoughts and feelings give rise to anxiety, fear, or psychological problems. Because Freud's patients could not uncover their unconscious fears, he developed several techniques, such as dream interpretation, to bring hidden fears to the surface. Freud's belief in an unconscious force that influenced human thought and behavior was another of his revolutionary ideas (Fayek, 2005).

Many of Freud's beliefs, such as the existence of unconscious feelings and fears, have survived, while other ideas, such as the all-importance of a person's first five years, have received less support. Many of Freud's terms, such as *id, ego, superego,* and *libido,* have become part of our everyday language. We'll discuss Freud's theory of personality in Module 19.

Unlike the biological, cognitive, and behavioral approaches, the psychoanalytic approach would search for hidden or unconscious forces underlying test anxiety.

Psychoanalytic Approach to Test Anxiety

Is test anxiety related to procrastination?

We discussed two components of test anxiety—excessive worrying and increased physiological responses—that can impair a student's performance on exams. Researchers also found that students with high test anxiety are much more likely to procrastinate than students with low test anxiety (N. A. Milgram et al., 1992).

***Procrastination* refers to the tendency to always put off completing a task to the point of feeling anxious or uncomfortable about one's delay.**

Researchers estimate that about 20% of adults are chronic procrastinators and from 80 to 95% of students procrastinate or deliberately delay completing assignments or studying for exams (Gura, 2008b; E. Hoover, 2005; Steel, 2007). Some of the more obvious reasons students give for procrastinating include being lazy or undisciplined, lacking motivation, and not knowing how to organize their time or set deadlines (Ariely & Wertenbroch, 2002).

The best thing for you to do is to put off doing anything for a few more days.

However, the psychoanalytic approach would look beneath these obvious reasons and try to identify unconscious personality problems that may underlie procrastination and test anxiety. Because unconscious reasons for procrastination and test anxiety are difficult to uncover, psychologists use a variety of standard personality tests in their research.

Based on personality tests, researchers concluded that students who are regular procrastinators may have low self-esteem, are too dependent on others, or have such a strong fear of failure that they do not start the task (Blunt & Pychyl, 2000). Personality tests also show that neuroticism (persistent anxiety; see p. 463) and an external locus of control (feeling little control over events; see p. 459) are associated with test anxiety (Carden et al., 2004; Chamorro-Premuzic et al., 2008). Thus, the psychoanalytic approach points to underlying personality problems as the probable cause of procrastination and test anxiety.

The psychoanalytic approach would also study how childhood experiences may have led to procrastination. For instance, researchers found that procrastinators tend to be raised by authoritarian parents who stress overachievement, set unrealistic goals for their children, or link achievement to giving parental love and approval. A child who is raised by parents like these may feel anxious when he or she fails at some task and will be tempted to put off such tasks in the future (Pychyl et al., 2002).

Psychologists know that ingrained personality characteristics, such as procrastination, remain relatively stable and persist across time unless a person makes a deliberate effort to change them. In Modules 21, 23, and 24, we'll discuss several methods that psychologists have developed to change personality characteristics.

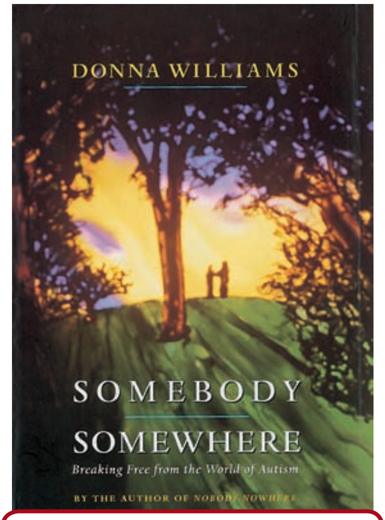
B. Modern Approaches

Humanistic Approach

What was Donna's potential?

Donna says that one reason she wrote her books was to escape her prison of autism. Autism has trapped her in a world where she sometimes blinks compulsively, switches lights on and off for long periods of time, rocks back and forth, freezes up, stares off into space without being able to stop herself, hates to be touched, cannot stand to enter public places, and hates to make eye contact with others (D. Williams, 1992).

Even though Donna has serious life challenges, she strives toward reaching her potential, and her achievements are impressive. She has published autobiographies and textbooks on autism. Her creative paintings and sculptures can be seen at exhibits. Donna is also a singer–songwriter who has released two incredible albums. Also, she married a man she refers to as a "diamond of a person" (D. Williams, 2009).



DONNA WILLIAMS
SOMEBODY SOMEWHERE
Breaking Free from the World of Autism
BY THE AUTHOR OF NOBODY NOWHERE

Although the majority of people with autism have difficulty with language, Donna has an amazing ability for written and spoken language.

Donna's struggle to free herself from autism, develop close personal relationships, and reach her potential characterizes the humanistic approach.

The ***humanistic approach*** emphasizes that each individual has great freedom in directing his or her future, a large capacity for achieving personal growth, a considerable amount of intrinsic worth, and enormous potential for self-fulfillment.

Donna echoes the humanistic approach when she writes, "Autism tried to rob me of life, of friendship, of caring, of sharing, of showing interest, of using my intelligence . . . it tries to bury me alive. . . ." The last words in her book are "I CAN FIGHT AUTISM. . . . I WILL CONTROL IT. . . . IT WILL NOT CONTROL ME" (D. Williams, 1994, p. 238).

Humanists believe that, like Donna, we may have to struggle to reach our potential, but we have control of our fate and are free to become whatever we are capable of being. The humanistic approach emphasizes the positive side of human nature, its creative tendencies, and its inclination to build caring relationships. This concept of human nature—freedom, potential, creativity—is the most distinctive feature of the humanistic approach and sets it far apart from the behavioral and psychoanalytic approaches (Giorgi, 2005).

The humanistic approach officially began in the early 1960s with the publication of the *Journal of Humanistic Psychology*. One of the major figures behind establishing the journal and the humanistic approach was Abraham Maslow, who had become dissatisfied with the behavioral and psychoanalytic approaches. To paraphrase Maslow (1968), the humanistic approach was to be a new way of perceiving and thinking about the individual's capacity, freedom, and potential for growth. Many of humanism's ideas have been incorporated into approaches for counseling and psychotherapy.

Because of its free-will concept of human nature and lack of experimental methods, many behaviorists regard the humanistic approach as more of a philosophy of life than a science of human behavior.

The humanistic approach also applies to dealing with a student's problems, such as test anxiety and procrastination.

Humanistic Approach to Test Anxiety

How can students reach their potentials?

The first year of college can be a difficult adjustment for many students, since it is more demanding and stressful than high school. Researchers wanted to learn which specific factors lead to high academic performance and successful adjustment among first-year college students. They found that students who were confident in their academic abilities performed significantly better than students who were less confident, and they adjusted better to college. Also, students who had higher expectations for academic success, such as performing well in courses, received better grades (Chemers et al., 2001). Based on these findings, it is evident that believing in one's abilities and potential is an important factor in being a successful student. These results may be useful for educators in helping students who do poorly in school to not give up but rather try to develop their academic potential.

Psychologists have also studied students whose academic performance ranged from poor to very good in order to develop a profile of a successful student. Studies showed that successful students share a number of similar characteristics: they feel competent about meeting the demands of their classes; they believe they can handle test situations; they are very good at organizing their study time and leisure time; they prepare themselves for tests and do not procrastinate (Kleijn et al., 1994).

Based on studies of students' performances, the humanistic approach would say that just as successful students found ways to reach their academic potential, all students should search for ways to reach their own potentials. The humanistic approach emphasizes that students have the capacity to choose, that each is unique or special, and that students should have faith in their personal or subjective feelings (Hansen, 2000).

PowerStudy 4.5™

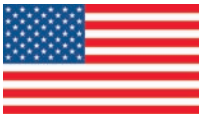
Module 10

I. Application: Behavior Modification

Cross-Cultural Approach

How is autism perceived in other cultures?

Autism is believed to exist in every culture (Grinker 2007). Let's look at how different cultures perceive autism.



United States. A psychologist in the United States first described the symptoms of autism almost 70 years ago (L. Kanner, 1943). Then autism was thought to be caused by environmental factors, such as having "cold" parents. In the 1960s, the focus changed to searching for biological causes (Rimland, 1964). Today, researchers believe the probable causes of autism include environmental and genetic factors (C. Kalb, 2008; Kraft, 2006).

There are between 1 million and 1.5 million Americans with autism (ASA, 2008). Early diagnosis is a priority in the United States. While the diagnosis of autism usually occurs between ages 2 and 3, the American Academy of Pediatrics (2007) is now recommending screening as early as 18 months, recognizing the importance of early intervention. Treatment is provided by psychiatrists and other physicians, psychologists, teachers, speech therapists, play therapists, and other professionals who understand autism.

South Korea. The number of people with autism in South Korea is unknown, as the disorder has a terrible stigma and children with autism are often kept at home hidden from the public. Parents in South Korea may fear that their family will lose face if people know someone with autism lives there and that marriage prospects for their other children will be negatively affected as a result of having a child with an abnormality.

Physicians in South Korea usually diagnose what would be considered autism in the United States as reactive attachment disorder (see p. 377), which they interpret as "lack of love." This is a less stigmatizing diagnosis, as parents believe they can help their child by providing more love. Also, it doesn't negatively harm the family as much as a genetic disease might. The unfortunate result, however, is that children with autism do not get the treatment they need. Within only the past few years, the perceptions of autism have begun to positively change in South Korea. Some children with autism are now going to school and even walking out in public with their families (Grinker, 2007).

The differences in how autism is perceived in the United States and South Korea show the influence of cultural factors and the use of the cross-cultural approach in psychology (Matsumoto & Juang, 2008; Shiraev & Levy, 2009).

The ***cross-cultural approach*** studies the influence of cultural and ethnic similarities and differences on psychological and social functioning.

There are also differences in how other cultures experience test anxiety.

Cross-Cultural Approach to Test Anxiety

How do other cultures deal with test anxiety?

Culture plays an important role in determining the intensity and expression of test anxiety, and test anxiety has been examined in countries across the globe (Bodas & Ollendick, 2005).

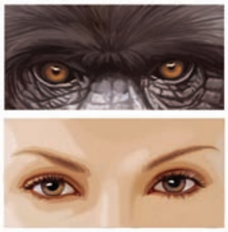
This symbol indicates a cultural diversity topic.

The development and severity of test anxiety appear to be different between Asian and non-Asian students. For example, students in India experience heightened test anxiety due to several factors, including the cultural emphasis on academic achievement, parental and social pressures to perform, and the stressful, competitive nature of exams. In contrast, American students don't experience as much test anxiety, in part because parents are less involved with their children's schoolwork and they promote independence and personal responsibility. A related cross-cultural difference is how children express test anxiety. Indian students express their anxiety through physical symptoms, whereas American students experience more cognitive symptoms, such as excessive worrying (Bodas & Ollendick, 2005; Verma et al., 2002).

This research shows how the cross-cultural approach provides different and interesting answers to the same question (Shiraev & Levy, 2009). In each module, we will highlight a cross-cultural study, which will be indicated by the cultural diversity symbol shown above.

Evolutionary Approach

The most recent modern approach to psychology emerges out of evolutionary theory and is called the evolutionary approach.



The ***evolutionary approach*** studies how evolutionary ideas, such as adaptation and natural selection, explain human behaviors and mental processes.

Although the evolutionary approach is relatively new, research has already examined how evolution influences a variety of behaviors and mental processes, such as aggression, mate selection, fears, depression, and decision making (Buss, 2004, 2007, 2009). We'll discuss the evolutionary approach again in Module 4 (p. 69) and include some of the exciting research resulting from this approach throughout the text.

Eclectic Approach

Rather than strictly focusing on one of the seven approaches, most of today's psychologists use an ***eclectic approach***, which means they use different approaches to study the same behavior. By combining information from the biological, cognitive, behavioral, psychoanalytic, humanistic, cross-cultural, and evolutionary approaches, psychologists stand a better chance of reaching their four goals of describing, explaining, predicting, and controlling behavior.

We have discussed the approaches used by modern psychologists so you can compare them with the different approaches used by early psychologists. As you compare early and modern approaches, you can appreciate how much psychology has changed in the past 100 years.

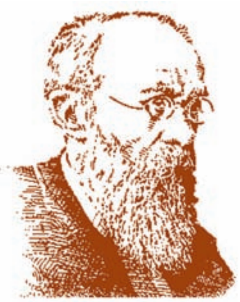
C. Historical Approaches

How did psychology begin?

Imagine living in the late 1800s and early 1900s, when the electric light, radio, and airplane were being invented and the average human life span was about 30 years. This was the time when psychology broke away from philosophy and became a separate field of study. As they developed this new area, early psychologists hotly debated its definition, approach, and goals (Benjamin, 2000). We'll highlight those early psychologists whose ideas and criticisms shaped the field. We'll begin with the person considered to be the father of psychology, Wilhelm Wundt.

Structuralism: Elements of the Mind

Who established the first lab?



Wilhelm Wundt
1832–1920

There were no bands or celebrations when Wilhelm Wundt established the first psychology laboratory in 1879, in Leipzig, Germany. In fact, his laboratory was housed in several rooms in a shabby building that contained rather simple equipment, such as platforms, various balls, telegraph keys, and metronomes. The heavily bearded Wundt, now considered the father of psychology, would ask subjects to drop balls from a platform or listen to a metronome (figure below) and report their own sensations. Wundt and his followers were analyzing their sensations, which they thought were the key to analyzing the structure of the mind (Hergenhahn, 2009). For this reason they were called structuralists and their approach was called structuralism.

Structuralism **was the study of the most basic elements, primarily sensations and perceptions, that make up our conscious mental experiences.**

Just as you might assemble hundreds of pieces of a jigsaw puzzle into a completed picture, structuralists tried to combine hundreds of sensations into a complete conscious experience. Perhaps Wundt's greatest contribution was his method of introspection.

Introspection **was a method of exploring conscious mental processes by asking subjects to look inward and report their sensations and perceptions.**

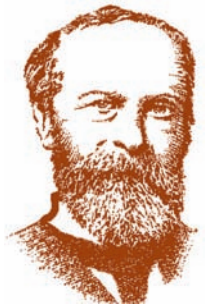
For example, after listening to a beating metronome, the subjects would be asked to report whether their sensations were pleasant, unpleasant, exciting, or relaxing. However, introspection was heavily criticized for being an unscientific method because it was solely dependent on subjects' self-reports, which could be biased, rather than on objective measurements. Although Wundt's approach was the first, it had little impact on modern psychology. The modern-day cognitive approach also studies mental processes, but with different scientific methods and much broader interests than those of Wundt.

It wasn't long before Wundt's approach was criticized for being too narrow and subjective in primarily studying sensations. These criticisms resulted in another new approach, called functionalism.

Can you describe each sensation you hear?

Functionalism: Functions of the Mind

Who wrote the first textbook?



William James
1842–1910

For twelve years, William James labored over a book called *The Principles of Psychology*, which was published in 1890 and included almost every topic that is now part of psychology textbooks: learning, sensation, memory, reasoning, attention, feelings, consciousness, and a revolutionary theory of emotions.

For example, why do you feel fear when running from a raging wolf? You might answer that an angry wolf (figure below) is a terrifying creature that causes fear and makes you run—fear makes you run. Not so, according to James, who reasoned that the act of running causes a specific set of physiological responses that your brain interprets as fear—running makes you afraid. According to James, emotions were caused by physiological changes; thus, running produced fear. You'll find out if James's theory of emotions was correct in Module 16.

Unlike Wundt, who saw mental activities as composed of basic elements, James viewed mental activities as having developed through ages of evolution because of their adaptive functions, such as helping humans survive. James was interested in the goals, purposes, and functions of the mind, an approach called functionalism.

Functionalism, **which was the study of the function rather than the structure of consciousness, was interested in how our minds adapt to our changing environment.**

Functionalism did not last as a unique approach, but many of James's ideas grew into current areas of study, such as emotions, attention, and memory (Hergenhahn, 2009). In addition, James suggested ways to apply psychological principles to teaching, which had a great impact on educational psychology. For all these reasons, James is considered the father of modern psychology.

Notice that James disagreed with Wundt's structural approach and pushed psychology toward looking at how the mind functions and adapts to our ever-changing world. About the same time that James was criticizing Wundt's structuralism, another group also found reasons to disagree with Wundt; this group was the Gestalt psychologists.

Does running from an angry wolf cause fear?

PowerStudy 4.5™
Module 10
A. Operant Conditioning

Gestalt Approach: Sensations Versus Perceptions

Who said, "Wundt is wrong"?

Max Wertheimer
1883–1943

When you see a road hazard sign like the one in the photo below, you think the lights forming the arrow are actually moving in one direction. This motion, however, is only an illusion; the lights are stationary and are only flashing on and off.

The illusion that flashing lights appear to move was first studied in 1912 by three psychologists: Max Wertheimer, Wolfgang Köhler, and Kurt Koffka. They reported that they had created the perception of movement by briefly flashing one light and then, a short time later, a second light. Although the two bulbs were fixed, the light actually appeared to move from one to the other. They called this the *phi phenomenon;* today it is known as *apparent motion.*

Wertheimer and his colleagues believed that the perception of apparent motion could not be explained by the structuralists, who said that the movement resulted from simply adding together the sensations from two fixed lights. Instead, Wertheimer argued that perceptual experiences, such as perceiving moving lights, resulted from analyzing a "whole pattern," or, in German, a *Gestalt.*

The ***Gestalt approach*** emphasized that perception is more than the sum of its parts and studied how sensations are assembled into meaningful perceptual experiences.

Why do blinking lights seem to move?

In our example, Gestalt psychologists would explain that your experience of perceiving moving traffic lights is much more than and very different from what is actually happening—fixed lights flashing in sequence. These kinds of findings could not be explained by the structuralists and pointed out the limitations of their approach (D. P. Schultz & Schultz, 2008).

After all these years, many principles of the Gestalt approach are still used to explain how we perceive objects. We'll discuss many of the Gestalt principles of perception in Module 6.

Behaviorism: Observable Behaviors

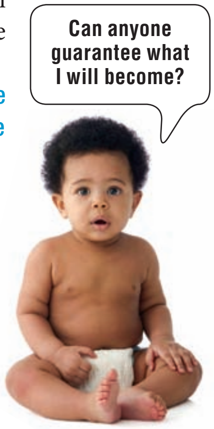
Who offered a guarantee?

John B. Watson
1878–1958

"Give me a dozen healthy infants, well-formed, and my own special world to bring them up in and I'll guarantee to take any one at random and train him to become any type of specialist I might select—doctor, lawyer, artist . . ." (Watson, 1924).

These words come from John B. Watson, who published a landmark paper in 1913 titled "Psychology as a Behaviorist Views It." In it, he rejected Wundt's structuralism and its study of mental elements and conscious processes. He rejected introspection as a psychological technique because its results could not be scientifically verified by other psychologists. Instead, John Watson boldly stated that psychology should be considered an objective, experimental science, whose goal should be the analysis of observable behaviors and the prediction and control of those behaviors (Harzem, 2004). It is a small step from these ideas to Watson's boast, "Give me a dozen healthy infants . . . ," which illustrates the behavioral approach.

The ***behavioral approach*** emphasized the objective, scientific analysis of observable behaviors.



Can anyone guarantee what I will become?

From the 1920s to the 1960s, behaviorism was the dominant force in American psychology. Part of this dominance was due to the work of B. F. Skinner and other behaviorists, who expanded and developed Watson's ideas into the modern-day behavioral approach, which is fully discussed in Module 10. However, beginning in the 1970s and continuing into the present, behaviorism's dominance was challenged by the cognitive approach, whose popularity now surpasses behaviorism (Evans, 1999; Glassman & Hadad, 2004).

Survival of Approaches

Which approaches survived?

The survival of each approach—structuralism, functionalism, Gestalt, and behaviorism—depended on its ability to survive its criticisms. Criticisms of Wundt's structural approach gave rise to the functional approach of James and the Gestalt approach of Wertheimer, Köhler, and Koffka. Criticisms of all three approaches—structural, functional, and Gestalt—gave rise to Watson's behavioral approach. Another approach, Sigmund Freud's psychoanalytic approach (see p. 9), which emphasized the influence of unconscious processes, disagreed with Watson's strict behavioral approach and developed largely in parallel with these other approaches. These disagreements in approaches resulted in heated debates among early psychologists, but they helped psychology develop into the scientific field it is today (Evans, 1999).

Although early American psychologists differed in their approaches, they shared one underlying theme that was a sign of their times. They discriminated against women and minorities in both academic and career settings. Such discriminatory practices were widespread in early times, and we'll examine that issue next.

Photo Credits: right, © Image Source Black/Alamy; left, © Tony Freeman/PhotoEdit

D. Cultural Diversity: Early Discrimination

Because psychologists focus on studying and understanding human behavior, you would expect them to be among the first to recognize the mistreatment of and discrimination against other groups. However, psychologists are human and, being human, they knowingly or unknowingly adopted and carried out the discriminatory practices that were operating at the time. This means that, for the first 75 of its more than 100 years of existence, the academic policies and career opportunities of American psychology were determined by White males, who both intentionally and unintentionally discriminated against women and people of color. Here are just a few examples.

Women in Psychology

Why couldn't she enter graduate school?

The reason Mary Calkins (below) could not enter graduate school was that she was a woman, and many universities (Johns Hopkins, Harvard, Columbia) would not admit women. Since Calkins was a faculty member and had established a laboratory in psychology at Wellesley College in 1891, she petitioned and was allowed to take seminars at Harvard. There, she completed all requirements for a PhD and was recommended for a doctorate by her professors, but the Harvard administration declined to grant it because she was a woman (Furumoto, 1989). It was not until 1908 that a woman, Margaret Washburn, was awarded a PhD in psychology.

Mary Calkins was not given a PhD because she was a woman.

Even after women began obtaining doctorates, the only positions open to them were teaching jobs at women's colleges or normal schools, which trained high school teachers (Furumoto & Scarborough, 1986). During the past 35 years, women have made great progress in the field. In 1970, about 20% of graduate students receiving PhDs were women, and by 2005, the number had increased to about 70%. However, even though women currently earn more PhDs in psychology than men, female psychologists earn less than male psychologists, and fewer women are editors of psychology journals (APA, 2007b; Cynkar, 2007). Not only did women face discrimination in psychology, but so did people of color.

Minorities in Psychology

Why so few minority students?

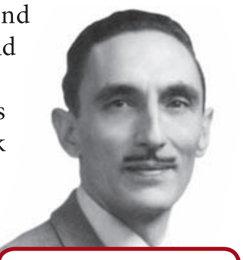
Inez Prosser was the first Black woman to get a PhD in 1933.

In psychology's early days, only a few northern White universities accepted Black students, while all southern White universities denied admission to Black students.

The first African American woman to receive a PhD in psychology was Inez Prosser (on left), who graduated from the University of Cincinnati in 1933. Her career was spent teaching at Black colleges and helping Black students obtain financial aid to attend college (Benjamin, 2008).

Between 1920 and 1966, only 8 PhDs in psychology were awarded to Black students, compared to 3,767 doctorates to Whites (R. V. Guthrie, 1976). In 1996, 168 PhDs were awarded to African Americans, 183 to Hispanics, 23 to Native Americans, 131 to Asians, and 2,939 to Whites (Rabasca, 2000b).

During the early 1900s, few degrees were awarded to Hispanics. One exception was George Sanchez (photo below), who conducted pioneering work on the cultural bias of intelligence tests given to minority students. Sanchez criticized the claim that Mexican Americans were mentally inferior, saying the claim was based solely on intelligence tests. He showed that intelligence tests contained many questions that were biased against minorities and thus resulted in their lower scores (R. V. Guthrie, 1976).



George Sanchez found intelligence tests were culturally biased.

From the founding of the American Psychological Association in 1892 to 1990, its cumulative membership was 128,000. Of those members, only 700 were African American, 700 were Latino, and 70 were Native American. The numbers of ethnic minority members are rising; however, they are still low (1.9% African American, 2.0% Asian American, 2.2% Latino, and 0.2% Native American) (APA, 2007a). Psychology must continue to focus on recruiting minorities and ensuring their academic and career success (Maton et al., 2006).

Righting the Wrongs

How much success?

Today, people of color are still underrepresented in academic departments and in graduate programs in psychology, although their numbers and influence are increasing (APA, 2008a).

The American Psychological Association (APA) recognized the need to recruit more ethnic minorities and formed a special group to reach this goal. The group established numerous journals to promote the causes of women and ethnic minorities (DeAngelis, 1966) and sponsored a program to visit high schools and teach minority students about careers in psychology (APA, 2009b). The APA has an official policy supporting equal opportunities "for persons regardless of race, gender, age, religion, disability, sexual orientation and national origin" (Tomes, 2000).

In the late 1990s, several states banned affirmative action programs, which had helped minority students enter college. As a result, university enrollments of minority students in these states dropped (J. Steinberg, 2003). Psychology departments are actively searching for ways to recruit minority students (M. R. Rogers & Molina, 2006).

Concept Review

1. The systematic, scientific study of behaviors and mental processes is called __________.

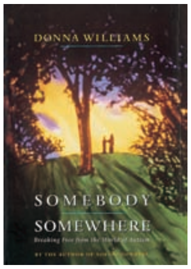
2. The four goals of psychology are to (a) __________ what organisms do, to (b) __________ the causes of behavior, to (c) __________ behavior in new situations, and to (d) __________ behavior, which has both positive and negative aspects.

3. The approach that focuses on how one's nervous system, hormones, and genes interact with the environment is called the __________ approach.

4. The approach that studies how people think, solve problems, and process information is called the __________ approach.

5. The approach that analyzes how environmental rewards and punishments shape, change, or motivate behavior is called the __________ approach.

6. The approach that stresses the influence of unconscious feelings, fears, or desires on the development of behavior, personality, and psychological problems is called the (a) __________ approach. This approach also emphasizes the importance of early (b) __________ experiences.



7. The approach that emphasizes freedom of choice, self-fulfillment, and attaining one's potential is called the (a) __________ approach. Many of this approach's concepts have been taken up and used in (b) __________.

8. The approach that focuses on cultural and ethnic influences on behavior is called the __________ approach.

9. Wundt studied the elements that made up the conscious mind and called this approach (a) __________. Subjects were asked to observe the workings of their minds, a technique that Wundt called (b) __________. Modern-day psychologists who study mental activities with more objective and scientific methods are said to use the (c) __________ approach.

10. William James disagreed with Wundt's structuralism and instead emphasized the functions, goals, and purposes of the mind and its adaptation to the environment; he called this approach (a) __________. James also applied the principles of psychology to teaching, so his approach had a great effect on the field of (b) __________ psychology.

11. Some psychologists disagreed with Wundt's approach of structuralism and instead believed that perceptions are more than the sum of many individual (a) __________. These psychologists called their approach the (b) __________ approach, which studied how sensations were assembled into meaningful (c) __________.

12. John Watson disagreed with Wundt's approach, which was called (a) __________, and disagreed with Wundt's technique of studying the mind, which was called (b) __________. Instead, Watson emphasized the objective, scientific analysis of observable behaviors, which was known as the (c) __________ approach. Later, this approach became a dominant force in psychology through the work of behaviorist (d) __________.

Answers: *1. psychology; 2. (a) describe, (b) explain, (c) predict, (d) control; 3. biological; 4. cognitive; 5. behavioral; 6. (a) psychoanalytic, (b) childhood; 7. (a) humanistic, (b) counseling or psychotherapy; 8. cross-cultural; 9. (a) structuralism, (b) introspection, (c) cognitive; 10. (a) functionalism, (b) educational; 11. (a) sensations, (b) Gestalt, (c) perceptions; 12. (a) structuralism, (b) introspection, (c) behavioral, (d) B. F. Skinner*

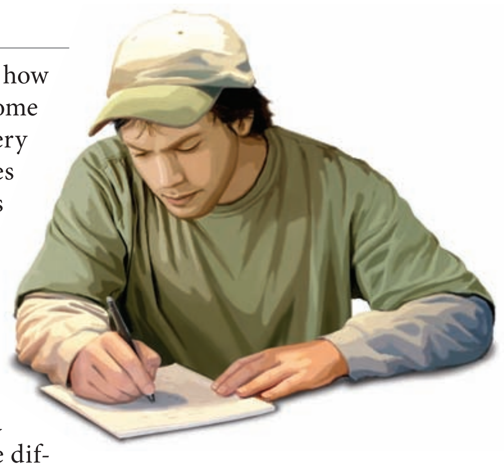
E. Research Focus: Taking Class Notes

Best Strategy for Taking Class Notes?

How good are your class notes?

As you listen to lectures in class, you'll probably be taking notes. But how do you know if you're using the best system or strategy? To research some particular behavior, such as note-taking, psychologists first ask a very specific research question: Which system or strategy for taking notes results in the best performance on tests? One researcher answered this question by using a combination of behavioral and cognitive approaches (A. King, 1992). As we describe this interesting study, notice how it involves the four goals of psychology, beginning with the first goal, describing behavior.



1st Goal: Describe Behavior

The researcher divided college students into three different groups. Each group was given a different method or strategy for taking notes. As described below, students practiced three different strategies for taking notes: review notes, summarize notes, and answer questions about notes.

A. Review Notes

The strategy that most students use is to try to write down as much as possible of what the professor says. Then, before exams, students review their notes, hoping they took good class notes.

B. Summarize Notes

Students took notes as usual but, after the lecture, used their notes to write a summary of the lecture in their own words.

Students were shown how to identify a main topic and, in their own words, write a sentence about it. Then they identified a subtopic and wrote a sentence that related it to the main topic. When linked together, these sentences created a summary of the lecture, written in the students' own words.

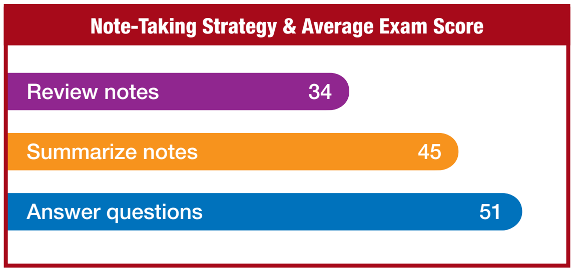
C. Answer Questions about Notes

Students took notes as usual but, after the lecture, used their notes to ask and answer questions about the lecture material. Students were given a set of 13 general questions, such as: **What is the main idea of . . . ? How would you use . . . to . . . ? What is a new example of . . . ? What is the difference between . . . and . . . ?** Students answered each of these questions using their class notes.

After practicing one of these three note-taking strategies, students watched a videotaped lecture and used their particular strategy for taking notes.

2nd Goal: Explain Behavior

A week after each group had watched a videotaped lecture, they were given an exam. The graph on the right shows that the group who used the strategy of taking notes plus answering questions scored significantly higher than the other two groups. The researcher explained that students who took notes and then answered questions about their notes retained more information than students who employed the other two strategies (A. King, 1992).



3rd Goal: Predict Behavior

On the basis of these results, the researcher predicts that students who use the strategy that combines note-taking with answering questions are likely to retain more information and perform better on exams than students who use traditional note-taking methods, such as writing as much as they can and then reviewing their notes before exams.

4th Goal: Control Behavior

Students can increase their chances of getting better grades by taking the time to learn a better note-taking strategy. This new strategy involves taking notes and then answering, in their own words, a series of general questions about the lecture material. Although this new note-taking strategy takes a little time to learn, the payoff will be better performance on exams. This and other research show the connection between good note-taking skills and higher test performance (Peverly et al., 2003).

Purpose of the Research Focus

This study shows how psychologists answered a very practical and important question about how best to take lecture notes. We'll use the Research Focus to show how psychologists use different approaches and research techniques to answer a variety of interesting questions about human behavior.

Each time you see this symbol, it will indicate a Research Focus, which occurs in each module.

Although a large percentage of psychologists engage in research, you'll see next how many others work in a variety of career settings that may or may not involve research.

F. Careers in Psychology

Psychologist Versus Psychiatrist

What's a psychologist?

Many students think psychologists are primarily counselors and therapists, even though degrees in psychology are awarded in many areas. Obtaining an advanced degree in psychology requires that one finish college and spend two to three years in postgraduate study to obtain a master's degree or four to five years in postgraduate study to obtain a PhD. Some careers or work settings require a master's degree, while others require a PhD. Many students are confused about the difference between a psychologist, a clinical or counseling psychologist, and a psychiatrist.

A ***psychologist*** is usually someone who has completed 4 to 5 years of postgraduate education and has obtained a PhD, PsyD, or EdD in psychology.

It usually takes about 4 to 5 years after college to become a psychologist.

A ***clinical psychologist*** has a PhD, PsyD, or EdD, has specialized in a clinical subarea, and has spent an additional year in a supervised therapy setting to gain experience in diagnosing and treating a wide range of abnormal behaviors.

Similar to clinical psychologists are ***counseling psychologists,*** who provide similar services but usually work with different problems, such as those involving marriage, family, or career counseling.

Until recently no psychologists in the United States have been able to prescribe drugs. Now, psychologists in New Mexico and Louisiana who complete special medical training can prescribe drugs as psychiatrists do. Several other states may pass similar legislation in the near future, giving psychologists the right to prescribe medication (Munsey, 2008a, 2008b).

A ***psychiatrist*** is a medical doctor (MD) who has spent several years in clinical training, which includes diagnosing possible physical and neurological causes of abnormal behaviors and treating these behaviors, often with prescription drugs.

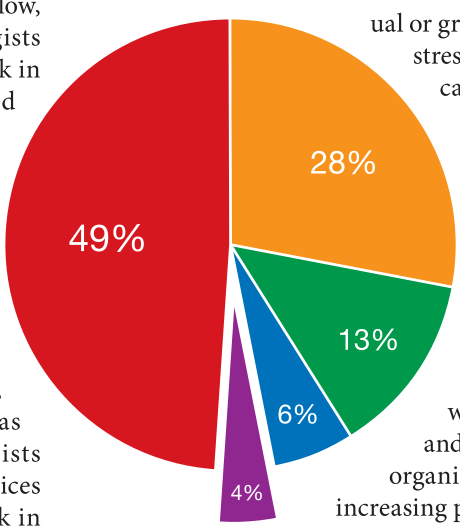
Psychologists can work in the following career settings.

Many Career Settings

Are psychologists usually therapists?

As you can see in the pie chart below, the majority (49%) of psychologists are therapists, while the rest work in four other settings. In the United States and Canada, most psychologists have a PhD, PsyD, or EdD, which requires four to five years of study after college. In many other countries, most psychologists have a college degree, which requires four to five years of study after high school (Helmes & Pachana, 2005). Since the 1950s, there has been an increase in psychologists who provide therapy/health services and a decline in those who work in academic/research settings.

The U.S. Department of Labor predicts that employment opportunities for psychologists will grow much faster than the average for other occupations in the coming years (U.S. Dept. of Labor, 2006). Here's a breakdown of where psychologists in the United States currently work (D. Smith, 2002).



Figure/Text Credit: Pie chart data from "Psychological Science Around the World," by M. R. Rosenzweig, 1992, *American Psychologist, 47,* 718–22.

49% The largest percentage (49%) of psychologists work as clinical or counseling psychologists in either a *private practice* or *therapy setting,* such as a psychological or psychiatric clinic; a mental health center; a psychiatric, drug, or rehabilitation ward of a hospital; or a private office.

The duties of clinical or counseling psychologists might involve doing individual or group therapy; helping patients with problems involving drugs, stress, weight, family, or career; or testing patients for psychological problems that developed from some neurological problem.

28% The second largest percentage (28%) of psychologists work in the *academic settings* of universities and colleges. Academic psychologists often engage in some combination of classroom teaching, mentoring or helping students, and doing research in their areas of interest.

13% The third largest percentage (13%) of psychologists work in a variety of other kinds of jobs and *career settings.*

6% The fourth largest percentage (6%) of psychologists work in *industrial settings,* such as businesses, corporations, and consulting firms. These psychologists, often called industrial/organizational psychologists, may work at selecting personnel, increasing production, or improving job satisfaction.

4% The smallest percentage (4%) work in *secondary schools and other settings.* For example, school psychologists conduct academic and career testing and provide counseling for a variety of psychological problems (learning disabilities, attention-deficit/hyperactivity disorder).

If you are thinking of entering the field of psychology today, you have a wide and exciting range of career choices. Your career choices are almost limitless! For example, in addition to the many work settings discussed above, psychologists are working in the Department of Defense, Department of Homeland Security, and National Institutes of Health. They are also working with attorneys, engineers, physicians, and computer scientists (DeAngelis, 2008). For those who decide to engage in research, we'll next discuss popular research areas that psychologists choose.

G. Research Areas

Areas of Specialization

Which area should I choose?

As you proceed through your introductory psychology course, you'll find that the world of psychology has been divided into at least eight general areas. And, if you go on and enter graduate school in psychology, you'll be expected to specialize in one of these areas. Students often find it difficult to choose only one special area of psychology, since they may be interested in two or three. The reason graduate students are asked to choose one area is that there is such an enormous amount of information that it takes great effort to master even one area. As you read about each research area, think about which one you might prefer.

Clinical/Counseling

Which type of therapy is most effective?

How do people develop phobias?

MELACHRI
20p 90c
GREECE

You would be asking these kinds of questions if you were a clinical or counseling psychologist.

Clinical and counseling psychology includes the assessment and treatment of people with psychological problems, such as grief, anxiety, or stress.

Some clinical and counseling psychologists work with a variety of populations, whereas others may specialize in specific groups like children or the elderly. They may work in hospitals, community health centers, private practice, or academic settings.

Social

How does being in a group affect one's behavior?

How can people make a good impression on others?

These kinds of questions interest social psychologists.

Social psychology involves the study of social interactions, stereotypes, prejudices, attitudes, conformity, group behaviors, aggression, and attraction.

Many social psychologists work in academic settings, but some work in hospitals and federal agencies as consultants and in business settings as personnel managers.

Developmental

Why do some babies cry more than others?

What happens to our sex drive as we age?

You would be asking these kinds of questions if you were a developmental psychologist.

Developmental pschology examines moral, social, emotional, and cognitive development throughout a person's entire life.

Some developmental psychologists focus on changes in infancy and childhood, while others trace changes through adolescence, adulthood, and old age. They work in academic settings and may consult on day care or programs for the aging.

Experimental

Why does an animal press a bar to obtain food?

Can learning principles be used to discipline children?

These kinds of questions interest experimental psychologists.

Experimental psychology includes the areas of sensation, perception, learning, human performance, motivation, and emotion.

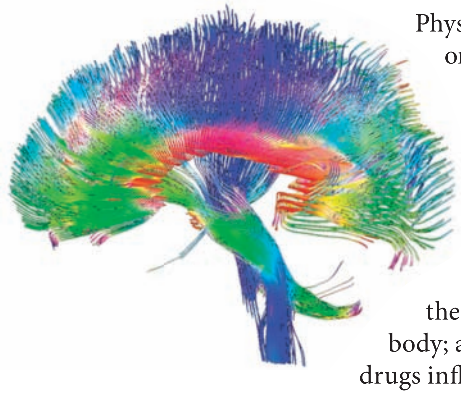
Experimental psychologists conduct much of their research under carefully controlled laboratory conditions, with both animal and human subjects. Most work in academic settings, but some also work in business, industry, and government.

Photo Credits: top right, © Andy Sacks/Getty Images; top left, © Zigy Kaluzny/Getty Images; bottom right, © Frans Lanting/Corbis; bottom left, © Oleksiy Maksymenko/Alamy

Biological

How do brain cells change during Alzheimer's disease?

How do genes affect your intelligence?



Physiological psychologists or psychobiologists study the biological basis of learning and memory; the effects of brain damage; the causes of sleep and wakefulness; the basis of hunger, thirst, and sex; the effects of stress on the body; and the ways in which drugs influence behavior.

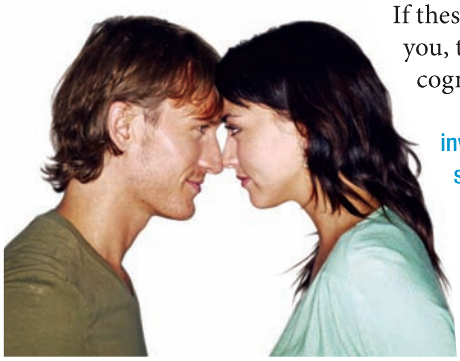
Biological psychology or ***psychobiology*** **involves research on the physical and chemical changes that occur during stress, learning, and emotions, as well as how our genetic makeup, brain, and nervous system interact with our environments and influence our behaviors.**

Psychobiologists work in academic settings, hospitals, and private research laboratories.

Cognitive

What's the best way to learn new information?

Do men and women think differently?



If these questions interest you, think about being a cognitive psychologist.

Cognitive psychology **involves how we process, store, and retrieve information and how cognitive processes influence our behaviors.**

Cognitive research includes memory, thinking, language, creativity, and decision making. Earlier we discussed a relatively new area that combines cognitive and biological approaches and is called cognitive neuroscience.

Psychometrics

What do college entrance tests show?

What career best fits my abilities?

These questions introduce an area called psychometrics, which involves the construction, administration, and interpretation of psychological tests.

Psychometrics **focuses on the measurement of people's abilities, skills, intelligence, personality, and abnormal behaviors.**

To accomplish their goals, psychologists in this area focus on developing a wide range of psychological tests, which must be continually updated and checked for usefulness and cultural biases. Some of these tests are used to assess people's skills and abilities, as well as to predict their performance in certain careers and situations, such as college or business.

Industrial/Organizational

How can we increase the productivity of workers?

How can we select employees who will be successful?

If you have an interest in psychology and business, you may wish to consider becoming an industrial/organizational psychologist.

Industrial/organizational psychology **examines the relationships of people and their work environments.**

These psychologists may be involved in personnel selection, help improve employee relationships, or increase employee job satisfaction. Industrial/organizational psychologists usually work in businesses, industry, and academic settings.

Making Decisions

What should I do?

If you decide to become a psychologist, you will need to make a series of decisions. The first is whether to obtain a master's degree or a PhD. The next decision involves which setting to work in: choosing among private practice, clinic or hospital setting, academic research and/or teaching, industry/business, or counseling and testing in a school setting. You'll also need to specialize in one of the eight areas described above. After making these decisions, you are on your way to an interesting and exciting career.

Next, we're going to use research findings from several research areas, including experimental and cognitive, and give you tips on how to improve your study skills.

H. Application: Study Skills

Improving Study Habits

What study problems do most freshmen report?

In a survey of college freshmen, only 16% reported they had very good study habits and only 24% said they were very good at managing their time (HRSDC, 2007). We'll discuss ways you can improve your study habits and time management to help you be a successful college student.

Common complaint. The most common student complaint we hear after exams is, "I read the book and went over my notes three times and still got a C." This complaint points to the most common mistake students make in studying for exams. Because students read the material and go over their notes several times, they may have a general feeling they know the material. For example, you have just read about the modern approaches, the historical approaches, and the differences between a psychologist and psychiatrist. Having read this material, you may generally feel that you know it. However, researchers have discovered a startling fact: There is almost no relationship between how well students think they know material and how well they perform on an exam (Eva et al., 2004; Tousignant & DesMarchais, 2002).

How do I know when I've studied enough to take a test?

Poor judges. The reason students tend to be poor judges of what they know is that they base their judgments more on what they *generally* know than on what they *specifically* remember (Glenberg et al., 1987). For example, you might generally remember the modern approaches. However, on an exam you will be asked for specific information, such as names and definitions. One way to judge how prepared you are for an exam is to test yourself and get feedback from answering specific questions. For instance, can you list the modern approaches and define each one? Because answering specific questions is one way to judge your learning, we built specific questions and answers into this text. You can test yourself by answering questions in the Concept Review in each module and in the Summary Test at the end of each module.

Reducing distractions. When we ask students about their study habits, we often learn they listen to music, watch TV, answer phone calls, or use the Internet while studying. These study habits can lead to lower exam scores (Gurung, 2005). One way students can improve their study habits is by eliminating distractions.

Time management. A common problem students have is managing their time. As a result, students often fall behind in classes and then must cram for exams. Intense studying before an exam may help you pass, but your time could be much better spent. Did you know that spreading out your studying can help you better remember information? In fact, dividing your studying into two sessions with time between them has been shown to result in twice as much learning as one study session of the same length! This is because your brain remembers information longer if it has time to process what you've learned (Aamodt & Wang, 2008). Next, we'll discuss another useful way to better manage your time.

Remember:
To judge how well prepared you are for an exam, ask yourself specific questions about the material. You can do that by taking the tests built into each module—Concept Review and Summary Test.

Setting Goals

What's the best kind of goal to set?

Another way to better manage your study time is to set the right goals, which can vary from studying for a certain period of time to studying until you feel you are well prepared (Flippo & Caverly, 2000, 2009). Which of the following goals do you think would make your study time more efficient and improve your test performance?

1 Set a **time goal,** such as studying 10 hours a week or more, and then keep track of your study time during the semester.

2 Set a **general goal,** such as trying to study hard and stay on schedule; then, try to reach this goal during the semester.

3 Set a **specific performance goal,** such as answering at least 80% of the Summary Test questions correctly for each module.

Should my goal be to study 10 hours a week?

To determine which of these three goals leads to more effective studying, researchers told three different groups of students to set time goals, general goals, or specific performance goals when they studied on their own. The researchers found that students who set specific performance goals did significantly better on the final exam than students who set time or general goals (M. Morgan, 1985). Thus, if you want to improve your study skills, you should think less about the total time you study and concentrate more on reaching a specific performance goal every week. For example, the first week your goal might be to correctly answer 80% of the Summary Test questions. Once you have reached this goal, you could aim to answer 90% of the questions correctly. Following a study plan based on specific performance goals is the key to better time management (Wolters, 2003).

As you'll see next, one way to motivate yourself to reach your performance goals is to reward yourself at the right times.

Remember:
One way to make your study time more efficient is to set a specific performance goal and keep track of your progress.

Photo Credit: © Hangarter/Photolibrary

Rewarding Yourself

What if you reach a goal?

One problem many students have is getting and staying motivated. One reliable solution is to give yourself a reward when you reach a specific goal, such as answering 80% of the questions correctly. The reward may be a special treat (such as a CD, meal, movie, or time with friends) or a positive statement (such as "I'm doing really well" or "I'm going to get a good grade on the test"). Giving yourself a reward (self-reinforcement) is an effective way to improve performance (Allgood et al., 2000).

Motivate yourself with rewards.

Remember:
Immediately after you reach a specific goal, give yourself a reward, which will both maintain and improve your motivation.

Taking Notes

Another way to improve your performance is to take great notes. Students generally make two kinds of mistakes in taking notes. One is to try to write down everything the instructor says, which is impossible and leads to confusing notes. The other is to mechanically copy down terms or concepts that they do not understand but hope to learn by memorization, which is difficult. Researchers have four suggestions for taking good notes (Armbruster, 2000, 2009):

1 Write down the information in your own words. This approach will ensure that you understand the material and will increase your chances of remembering it.

2 Use headings or an outline format. This method will help you better organize and remember the material.

3 Try to associate new lecture or text material with material that you already know. It's easier to remember new information if you can relate it to your existing knowledge. That is the reason we have paired terms in the Concept Review section with illustrations, drawings, and photos that you are familiar with from earlier in the text.

4 As we discussed in the Research Focus (p. 16), you can improve your note-taking by asking yourself questions, such as: What is the main idea of . . . ? What is an example of . . . ? How is . . . related to what we studied earlier? Writing the answers in your own words will give you a better chance of remembering the material (A. King, 1992).

Even though you may take great notes and set performance goals, if you procrastinate and put off getting started, as about 70% of students report doing, your best-laid plans will come to nothing (E. Hoover, 2005). We already discussed some of the reasons behind procrastination (p. 9), and here we'll look at ways to overcome it.

Remember:
Go through your lecture notes, ask questions, and write down answers in your own words.

Stopping Procrastination

How do you get started?

Some students find the task of reading assignments, studying for exams, or writing papers so difficult that they cannot bring themselves to start. If you have problems with procrastinating, here are three things you should do to get started (Ariely & Wertenbroch, 2002; Blunt & Pychyl, 2000):

1 *Stop thinking about the final goal*—reading 30 pages or taking two midterm exams—which may seem too overwhelming.

2 Break the final assignment down into *smaller goals* that are less overwhelming and easier to accomplish. Work on the first small goal, and when you finish it, go on to the next small goal. Continue until you have completed all the small goals. Thinking about study tasks in specific ways makes you feel like the tasks can be completed sooner and reduces procrastination (S. M. McCrea et al., 2008). Setting smaller goals is a way to think of tasks in a specific way.

3 Write down a *realistic schedule* for reaching each of your smaller goals. This schedule should indicate the time and place for study and what you will accomplish that day. Use a variety of self-reinforcements to stay on your daily schedule and accomplish your specific goals.

Everyone procrastinates a little, but it becomes a problem if you continually put off starting important projects that have deadlines, such as exams and papers. Take the advice of professionals on stopping procrastination: get organized, set specific goals, and reward yourself (Ariely & Wertenbroch, 2002).

These 3 steps helped me overcome procrastination!

If you adopt these tested methods for improving your study skills, you'll greatly increase your chances of being a successful student (Flippo & Caverly, 2009).

Remember:
One of the most effective ways to start a large assignment is to break it down into a series of smaller goals and work on each goal separately.

Unusual Excuses for Missing Exams

- ✔ I can't be at the exam because my cat is having kittens and I'm her coach.
- ✔ I want to reschedule the final because my grandmother is a nun.
- ✔ I can't take the exam on Monday because my mom is getting married on Sunday and I'll be too drunk to drive back to school.
- ✔ I couldn't be at the exam because I had to attend the funeral of my girlfriend's dog.
- ✔ I can't take the test Friday because my mother is having a vasectomy. (D. A. Bernstein, 1993, p. 4)

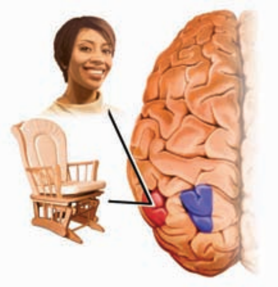
Summary Test

A. Definitions & Goals

1. The broad definition of psychology is the systematic, scientific study of (a) ________ and (b) ________. The term in (a) refers to observable responses of animals and humans, and the term in (b) refers to processes that are not directly observable, such as thoughts, ideas, and dreams.

2. All psychologists agree that the first three goals of psychology are to (a) ________ what organisms do, to (b) ________ how organisms behave as they do, and to (c) ________ how they will respond in the future and in different situations. Some psychologists add a fourth goal, which is to (d) ________ behavior and thus curb or eliminate psychological and social problems.

B. Modern Approaches



3. Because behavior is often so complex, psychologists study it using seven different approaches. The approach that focuses on how a person's genetic makeup, hormones, and nervous system interact with the environment to influence a wide range of behaviors is called the ________ approach.

4. The approach that studies how organisms learn new behaviors or change or modify existing ones in response to influences from the environment is called the (a) ________ approach. There are two versions of this approach. One that primarily studies observable behaviors and excludes mental events is called (b) ________ and is best expressed by the ideas of B. F. Skinner; the other, which includes observable behaviors plus cognitive processes, is called the (c) ________ approach and is expressed by the ideas of Albert Bandura and his colleagues.

5. An approach that examines how our unconscious fears, desires, and motivations influence behaviors, thoughts, and personality and cause psychological problems is called the ________ approach. Sigmund Freud developed this approach, as well as the technique of dream interpretation, to bring unconscious ideas to the surface.

6. The approach that investigates how people attend to, store, and process information and how this information affects learning, remembering, and believing is called the ________ approach.

7. An approach that emphasizes people's capacity for personal growth, freedom in choosing their future, and potential for self-fulfillment is called the ________ approach.

8. The approach that studies how cultural and ethnic similarities and differences influence psychological and social functioning is called the ________ approach.

9. The approach that studies how evolutionary ideas, such as adaptation and natural selection, explain human behaviors and mental processes is called the ________ approach.

10. When psychologists use different approaches to study the same behavior, they use the ________ approach.

C. Historical Approaches

11. Considered the father of psychology, Wilhelm Wundt developed an approach called (a) ________. This approach studied the elements of the conscious mind by using a self-report technique called (b) ________. Wundt's approach was the beginning of today's cognitive approach.

12. Disagreeing with Wundt's approach, William James said that it was important to study functions rather than elements of the mind. Accordingly, James studied the functions of consciousness as well as how mental processes continuously flow and adapt to input from the environment. This approach is called ________. James's ideas contributed to the modern area of psychology and influenced educational psychology.

13. Also disagreeing with Wundt's approach was a group of psychologists, led by Wertheimer, Köhler, and Koffka, who stated that perceptions cannot be explained by breaking them down into individual elements or sensations. Instead, they believed that perceptions are more than the sum of individual sensations, an idea called the ________ approach.

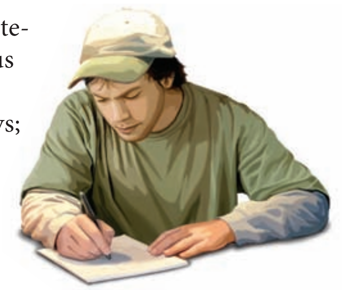
14. Another psychologist who disagreed with Wundt's approach was John B. Watson. He stated that psychology should use scientific principles to study only observable behaviors and not mental events, an approach called ________. Watson's approach gave rise to the modern behavioral approach.

D. Cultural Diversity: Early Discrimination

15. During the first 75 of its more than 100 years of existence, the field of psychology discriminated against (a) ________ and (b) ________, as indicated by the very limited number of these individuals who were granted PhDs or offered positions in major universities. During the past 25 or so years, the American Psychological Association, minority organizations, and most universities and colleges have been actively recruiting minorities and helping them enter the field of psychology.

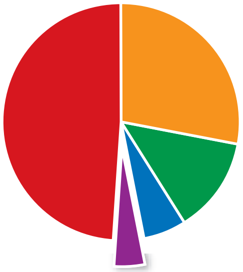
Photo Credits: top left, Courtesy of Chris Samuel, by permission of Chris Samuel; bottom right, Courtesy, Margaret Clapp Library Archives, Wellesley College, photo by Patridge

E. Research Focus: Taking Class Notes



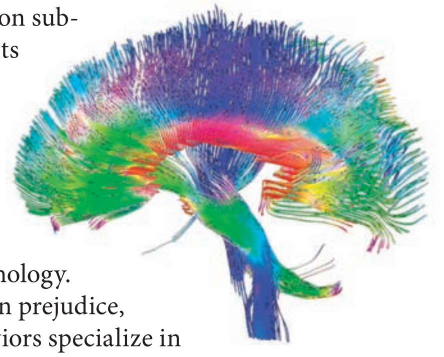
16. Three different strategies for note-taking were studied: note-taking plus review, which means writing down almost everything the instructor says; note-taking plus questions, which means asking and answering questions about the lecture material; and note-taking plus summary, which means writing a summary of the lecture in your own words. The note-taking strategy that resulted in the highest exam grades involved (a) ______________, and the note-taking strategy that resulted in the lowest exam grades involved (b) ______________.

F. Careers in Psychology



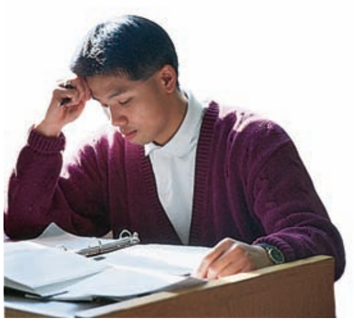
17. There are five major settings in which psychologists work and establish careers. The largest percentage of psychologists work in private practice or (a) ______________ settings, where they diagnose and help clients with psychological problems. The second largest group work in (b) ______________ settings, doing a combination of teaching and research. The third largest group work in a (c) ______________ of settings. The fourth largest group work in (d) ______________ settings, where they are involved in selecting personnel, increasing job satisfaction, and improving worker–management relations. The smallest group work in other settings, such as (e) ______________, where they do academic testing and counseling.

G. Research Areas



18. There are eight common subareas in which psychologists specialize. Psychologists interested in the assessment and treatment of people with psychological problems, such as anxiety or stress, specialize in (a) ______________ psychology. Those who are interested in prejudice, attitudes, and group behaviors specialize in (b) ______________ psychology. Those interested in social, emotional, and cognitive changes across the life span specialize in (c) ______________ psychology. Those interested in studying sensation, perceptions, and learning, often under laboratory conditions, specialize in (d) ______________ psychology. Those interested in the interaction among genes, the nervous system, and the environment choose (e) ______________ psychology. Those interested in how people process, store, and retrieve information choose (f) ______________ psychology. Those interested in the measurement and testing of skills, abilities, personality, and mental problems specialize in (g) ______________, and those interested in the relationships of people and their work specialize in (h) ______________ psychology.

H. Application: Study Skills



19. Another common mistake that students make is that they think they know the material after reading the text and reviewing their notes. A better way to judge how prepared you are for an exam is to ask yourself specific (a) ______________ rather than to trust your judgment about what you think you know. A good way to make your study time more efficient is to set specific (b) ______________ and keep track of your progress. Immediately after you reach a specific performance goal, give yourself a (c) ______________, which will both maintain and improve your motivation. To improve your lecture notes, try to associate new lecture material with what you already know, and use your notes to ask and answer (d) ______________ in your own words. One of the most effective ways to overcome a strong tendency to delay starting a task, known as (e) ______________, is to stop thinking about the final goal. Instead, break down a large assignment into a series of smaller goals and work on each goal separately. Finally, it's best to set a realistic (f) ______________ in order to accomplish each of the smaller goals.

Answers: *1. (a) behaviors, (b) mental processes; 2. (a) describe, (b) explain, (c) predict, (d) control; 3. biological; 4. (a) behavioral, (b) strict behaviorism, (c) social learning; 5. psychoanalytic; 6. cognitive; 7. humanistic; 8. cross-cultural; 9. evolutionary; 10. eclectic; 11. (a) structuralism, (b) introspection; 12. functionalism; 13. Gestalt; 14. behaviorism; 15. (a) women, (b) minorities; 16. (a) answering questions, (b) reviewing notes; 17. (a) therapy or clinical, (b) academic, (c) variety, (d) industrial, (e) schools; 18. (a) clinical and counseling, (b) social, (c) developmental, (d) experimental, (e) biological or physiological, (f) cognitive, (g) psychometrics, (h) industrial/organizational; 19. (a) questions, (b) performance goals, (c) reward, (d) questions, (e) procrastination, (f) schedule*

Critical Thinking

How Do Autistic People Think?

As a young child, Temple Grandin had a few peculiarities. She had great difficulty learning to speak and understanding language, but had an incredible eye for color and great artistic talent. Temple didn't know how to relate with other children and preferred to be alone, often rocking herself back and forth for hours. She was so sensitive to touch that she refused to allow anyone to touch her. Temple was unusually sensitive to sounds. She compared hearing the school bell to a "dentist's drill" (J. P. Shapiro, 1996) sounding in her ear. She described going through each day feeling anxious as if she were constantly "being mugged on the New York subway" (J. P. Shapiro, 1996).

Temple was diagnosed with autism at the age of 3, and doctors were certain she wouldn't ever be successful. What they didn't know is how much Temple would prove them wrong. Her childhood art projects provided a glimpse into Temple's unique way of thinking. While most of us think in words, Temple, like many others with autism, thinks in pictures. She compares her memory to a full-length movie in her head that she can replay over and over again. She can even view the movies from different points of view, which help her notice small details that otherwise would have been overlooked.

Temple has made remarkable accomplishments by applying her visual way of thinking to her love of animals (see photo). For example, she placed herself "inside a cow's head" to see the world through its eyes. By doing so she realized how frightening it is for cattle to approach the dip vat, a deep swimming pool filled with pesticide that cattle enter to rid them of ticks and other parasites. Cattle would panic while going down a steep and slippery slope and then become even more frightened as they unexpectedly dropped into water. To reduce the fear cattle had of the dip vat, Temple used her visual way of thinking to design equipment with a less steep and slippery walkway, as well as a more comfortable way for cattle to enter the water.

Using her unique way of thinking in pictures, Temple has become the most accomplished and well-known autistic adult in the world. She has taken the lead in designing and advocating for the use of more humane equipment with animals. Her unique understanding of animals led her to publish an insightful book explaining how animals feel. Temple earned a doctorate degree in animal science and is currently a university professor, a prominent author and speaker, and a consultant for the care and handling of livestock. (Adapted from Fenly, 2006; Grandin, 1992, 2002, 2009; J. P. Shapiro, 1996)

QUESTIONS

1 What three childhood symptoms of autism do Donna (introduced on p. 3) and Temple share?

2 Which of the four goals of psychology is illustrated by Donna refusing to allow anyone to touch her?

3 Which area of specialization in psychology would be best able to understand how Temple thinks in pictures?

4 Of the seven modern approaches to psychology, which should you use to study someone with autism?

5 What social skill does Temple have (unlike many with autism) that allows her to put herself "inside a cow's head"?

6 How would a humanistic psychologist understand Temple's accomplishments?

Visit this book's companion website for more resources to help you study, including learning objectives, additional quizzes, flash cards, updated links to useful websites, and a pronunciation glossary.

Study Guide and WebTutor

Work through the corresponding module in your Study Guide for tips on how to study effectively and for help learning the material covered in the book. WebTutor (an online Study Tool accessed through your eResources account) provides an interactive version of the Study Guide.

Suggested Answers to Critical Thinking

1. Three symptoms of autism Donna and Temple share are poor social relationships, sensitivity to touch and sound, and difficulty learning to speak and understand language.
2. The four goals of psychology are *describe, explain, predict,* and *control.* Donna knows that even the lightest touch can make her feel uncomfortable, and so she *controls* her discomfort by making it a rule to not allow anyone to touch her.
3. Cognitive psychology studies how we process, store, and retrieve information. One of its primary goals is to better understand how people think.
4. None of the approaches is necessarily better than the others. Rather, each approach adds a different kind of information. By using several or all seven of the approaches, we can more thoroughly understand someone with autism.
5. As we learned on page 6, empathy is a social skill allowing us to put ourselves in other people's shoes and experience how they feel. People with autism generally have difficulty expressing empathy; however, Temple conveys much empathy toward cattle.
6. Unlike the doctors who were certain Temple would not be successful, humanistic psychologists believe that all people have free will, creativity, the ability to achieve personal growth, and an enormous potential for self-fulfillment. Humanistic psychologists would say that by working hard and believing in her abilities, Temple was able to reach her potential.

Blake's Problem

What's wrong with Blake's behavior?

When Blake was 3 years old, he crawled into a *T. rex* display at a museum and set off blaring alarms. As a child, he was easily bored, couldn't focus on anything for very long, and never sat still for more than a second. Blake admits that he gets easily bored and is often so desperate to find something interesting to do that he goes "full steam ahead without thinking." One day, to keep himself entertained, he launched rockets (accidentally) into the neighbor's swimming pool! Blake's mother describes him as "exhausting" and "off the wall." "Within minutes, he'd go from concocting baking-soda volcanoes to dumping out all the Lego and K'nex sets, to emptying out the linen closet in order to build a tent city," says his mother (Taylor-Barnes, 2008) (adapted from B. E. S. Taylor, 2007).

At age 5, Blake was diagnosed with a behavioral problem that has been surrounded with controversy. Blake was diagnosed as being hyperactive and inattentive, a problem that is officially called attention-deficit/hyperactivity disorder, or ADHD (American Psychiatric Association, 2000).

Attention-deficit/hyperactivity disorder, or ADHD, is not diagnosed by any medical tests but on the basis of the occurrence of certain behavioral problems. A child must have six or more symptoms of inattention, such as making careless mistakes in schoolwork, not following instructions, and being easily distracted, and six or more symptoms of hyperactivity, such as fidgeting, leaving classroom seat, and talking excessively. These symptoms should have been present from an early age, persisted for at least six months, and contributed to maladaptive development.

One controversy surrounding ADHD involves diagnosis. Since ADHD is based not on medical tests but rather on the occurrence of certain behavioral problems, how can parents and teachers distinguish children with ADHD from those who are naturally outgoing and rambunctious (West et al., 2005)? Because of this difficulty, the American Academy of Pediatrics issued guidelines for diagnosing ADHD (AAP, 2000; M. Stein & Perrin, 2003). These guidelines stressed that, before the diagnosis of ADHD is made, a number of the symptoms described above should be present for at least six months. The guidelines focused on children aged 6 to 12 because there isn't sufficient evidence for making the diagnosis of ADHD at earlier ages. The goal of these guidelines is to prevent merely rambunctious youngsters from being overmedicated while ensuring that children with ADHD get the help they need (Leslie et al., 2004).

Another controversy is how to treat children with ADHD. To help control Blake's ADHD, he was given a popular drug that is a relatively powerful stimulant, called Adderall. With the continued aid of medication, Blake has become a successful student at the University of California at Berkeley and written his own memoir. Researchers do not completely understand why stimulant drugs, such as Adderall or Ritalin, decrease activity in children. But drugs to treat ADHD are undeniably popular as spending on these medications has reached $3 billion a year (M. Potter, 2006; Scrip, 2006).

Image not avaliable

Blake, now a college student, was diagnosed with ADHD at age 5.

Perhaps the major questions surrounding the use of Ritalin concern whether it is being overprescribed, whether it is the most effective treatment, and how long a child with ADHD should remain on the drug (Root & Resnick, 2003). In addition, Ritalin, especially in larger doses, does have side effects that may include loss of appetite and problems with sleeping. A related question is whether children with ADHD should be kept on a diet free of artificial dyes, sweeteners, and sugar, which some parents claim worsen the symptoms. We'll answer these questions in this module.

We're going to use Blake's problem with ADHD to show how researchers pursue the four goals of psychology that we discussed in Module 1. In Blake's case, the four goals are (1) to describe Blake's symptoms, (2) to explain their causes, (3) to predict their occurrence, and (4) to control Blake's behavior through some behavioral therapy or drug treatment.

Centipedes and Cough Medicine

Can beliefs cure like real medicine?

One interesting aspect of trying to control unwanted symptoms with a drug treatment is that sometimes the drug is not really a drug because it has no proven medical effects. For example, in many parts of Asia, people believe powdered tablets made from centipedes are medicine for treating a variety of physical problems. Similarly, in the United States, people spend billions of dollars a year on over-the-counter cough medicines, including cough syrups and cough drops, even though there is no reliable scientific evidence that cough medications work (J. W. Payne, 2006). The use of centipedes and cough medicine, both questionable medical treatments, raises the interesting question of how much one's mind or one's beliefs contribute to the development or treatment of physical symptoms. We'll discuss methods that researchers use to decide whether the effectiveness of a treatment is due to a drug's medical effect or the person's beliefs.

Can centipedes cure all kinds of problems?

What's Coming

Our main focus in this module is to explore the methods that researchers use to answer questions, such as how to treat ADHD and why placebos work. Specifically, we'll discuss the advantages and disadvantages of three major research methods—surveys, case studies, and experiments. We'll explain which research procedures can identify cause-and-effect relationships and which cannot. We begin with an overview of the three major research methods that psychologists use to answer questions.

A. Answering Questions

How do researchers study ADHD?

As you look at the photo of Blake on the right, you see a mature young adult. But, without medication, Blake has great difficulty focusing: "A way you can think about it is if you're taking a TV remote and somebody else is just changing it uncontrollably and your mind is floating from the History Channel to HBO to the Discovery Channel—it's like you can't really stay concentrated" (B. E. S. Taylor, 2008).

Twenty-five years ago, ADHD was a relatively small problem in the United States, while today it is the most commonly diagnosed behavioral problem in children. The diagnosis of ADHD is not straightforward, since it is based on behavioral symptoms rather than medical tests. The proposed causes of ADHD are many, including genetic, neurological, cultural, and environmental factors (Barkley, 2006). Finally, the most popular treatment of ADHD is giving children a stimulant drug.

Image not
avaliable

In the middle of these controversies are parents like Blake's mother, who, after dealing with a hyperactive and impulsive child from an early age, have little doubt ADHD exists and stimulant medication decreases hyperactivity and impulsivity. At the same time, critics warn that ADHD may be misdiagnosed or overdiagnosed and that, while stimulant medication may reduce activity, it fails to improve mental functions such as ignoring distractions and recalling information needed to reach a goal (Coghill, 2007).

Researchers use three different research methods to study ADHD.

As researchers work to resolve the controversies surrounding ADHD, they are using three research methods—survey, case study, and experiment.

Survey

Suppose you wish to know how many children have ADHD, whether it occurs more in boys or girls, which treatment is the most popular, and how many children continue to have problems when they become adults. Researchers obtain this information with surveys.

A *survey* is a way to obtain information by asking many individuals—either person to person, by telephone, or by mail—to answer a fixed set of questions about particular subjects.

The disadvantage of a survey is that such information can contain errors or be biased because people may not remember accurately or answer truthfully. The advantage of a survey is that it is an efficient way to obtain much information from a large number of people.

But if researchers wanted to know more about a particular person, they would use a case study.

Case Study

Suppose you wish to know in greater detail about how a single child, such as Blake, developed ADHD, performs in school, makes friends, plays team sports, and deals with everyday problems. Or suppose you wish to know about how a family copes with a child who has ADHD. For example, one mother said, "Ritalin doesn't take away the problems at all. It just helps him focus on what he's doing. You can talk to him; he can get his school work done. It still takes him a long time to get things done. He's still behind, emotionally and socially" (*San Diego Tribune,* November 27, 1989). When another mother was told that sugar doesn't increase activity, she replied, "I say, they're nuts! Where were they last Christmas when my sons ate candy canes and green frosting for days and never slept!" (*Los Angeles Times,* February 9, 1994). Researchers gather in-depth data about a particular individual with a case study.

A *case study* is an in-depth analysis of the thoughts, feelings, beliefs, experiences, behaviors, or problems of a single individual.

One disadvantage of a case study is that its detailed information about a particular person, such as Blake, may not apply to other children with ADHD.

One advantage of a case study is that its detailed information allows greater understanding of a particular person's life.

But if researchers wanted to establish whether sugar really increases activity in children with ADHD, they would use an experiment.

Experiment

Suppose you thought that sugar or artificial dyes caused hyperactivity in your child and you wondered if this were true. For example, based on case studies and parents' reports, one researcher thought that certain artificial dyes, chemicals, and sweeteners increased the activity and impulsive behavior of children diagnosed with ADHD (Feingold, 1975). When researchers want to identify a cause-and-effect relationship, such as whether sugar increases activity, they use an experiment.

An *experiment* is a method for identifying cause-and-effect relationships by following a set of rules and guidelines that minimize the possibility of error, bias, and chance occurrences.

A disadvantage of an experiment is that information obtained in one experimental situation or laboratory setting may not apply to other situations. An experiment's primary advantage is that it has the greatest potential for identifying cause-and-effect relationships with less error and bias than either surveys or case studies.

Which method is best?

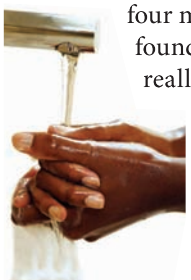
Very often, researchers use all three research methods—survey, case study, and experiment—because each provides a different kind of information. Surveys provide information about fixed questions from a large number of people. Case studies give in-depth information about a single person. Experiments point to cause-and-effect relationships. We'll discuss the advantages and disadvantages of each of the three methods, beginning with surveys.

Kind of Information

What do surveys tell us?

Almost every day the media report some new survey. Although surveys tell us what others believe or how they behave, survey questions can be written to bias the answers; moreover, people may not always answer truthfully (N. Schwartz, 1999). For example, how many people do you think always wash their hands after going to the bathroom? We'll sample some surveys and then discuss their problems.

Do you wash your hands?



Although 92% of the people surveyed by telephone said they always washed their hands after using a public bathroom, direct observation of 6,076 people in four major cities found that only 77% really do and that more women (88%) washed their hands than men (66%) (ASM, 2007).

Do you multitask while driving?

A survey of 1,503 drivers found that 72% say they do other things while driving (use cell phone, drink, eat). The percentages of people in each age group who multitask are 60% for 16–17-year-olds, 78% for 18–30-year-olds, 80% for 31–44-year-olds, and 65% for 45–61-year-olds (NMI, 2008).

How many children are diagnosed with ADHD?

Recent telephone surveys of parents report that 5% of U.S. children between 6 and 17 years old are diagnosed with ADHD. Boys are reported to be diagnosed with ADHD twice as often as girls. ADHD is reported to be more common among adolescents than younger children, and more common among White and African American children than Hispanic children (CDC, 2008c).

These examples show that surveys provide a great deal of useful information. However, surveys have potential problems with accuracy (as in the hand-washing survey) and, as you'll see next, with how questions are worded and who asks the questions.

Disadvantages

How questions are worded

You may be surprised to learn that surveys may get very different results depending on how questions are worded. Here are two examples:

QUESTION: "Would you say that **industry** contributes more or less to air pollution than **traffic**?"

Traffic contributes more: **24%**
Industry contributes more: 57%

QUESTION: "Would you say that **traffic** contributes more or less to air pollution than **industry**?"

Traffic contributes more: **45%**
Industry contributes more: 32%

These two examples indicate that the way questions are phrased and the way the possible answers are ordered can greatly influence people's responses and, in this case, produce opposite results (reported in *U.S. News & World Report,* Dec. 4, 1995, p. 55).

Who asks the questions

You may also be surprised to learn that the sex or race of the questioner can also affect how people answer the questions.

QUESTION: "The problems faced by Blacks were brought on by Blacks themselves."

When the interviewer was **White, 62%** of Whites who were interviewed agreed.
When the interviewer was **Black, 46%** of Whites who were interviewed agreed.

These two examples indicate that when asked about sensitive or emotional issues, people take into account the race of the interviewer and tend to give socially acceptable rather than honest answers (*U.S. News & World Report,* Dec. 4, 1995, p. 55).

We can conclude that surveys can be biased because people may not answer questions truthfully, may give socially acceptable answers, or may feel pressured to answer in certain ways. Also, surveys can be biased by how questions are worded and by interviewing a group of people who do not represent the general population (Gravetter & Forzano, 2009; S. J. Jackson, 2009). Despite these potential problems, surveys have advantages.

Advantages

While guarding against error and bias, surveys can be a useful research tool to quickly and efficiently collect information on behaviors, beliefs, experiences, and attitudes from a large sample of people and can compare answers from various ethnic, age, socioeconomic, and cultural groups.

For example, surveys suggest that ADHD interferes with performance in school settings, decreases the chances of graduating from high school, and may lead to conduct disorder problems in adolescence as well as continued problems in adulthood (Root & Resnick, 2003).

Because surveys indicate that children with ADHD have major problems in school settings, psychologists are developing methods for improving performance. These methods include: teaching ADHD children how to organize their work, giving them constant feedback on reaching their goals, and starting programs that train teachers and families to work together to help ADHD children control their disruptive behaviors (Hechtman et al., 2004). Thus, another advantage of surveys is their ability to identify problems and evaluate treatment programs.

However, if researchers wish to focus on a particular individual rather than a group, they use a case study.

C. Case Study

Kind of Information

What's a case study?

Sometimes researchers answer questions by studying a single individual in great detail, which is called a case study.

A ***case study*** **is an in-depth analysis of the thoughts, feelings, beliefs, or behaviors of a single person.**

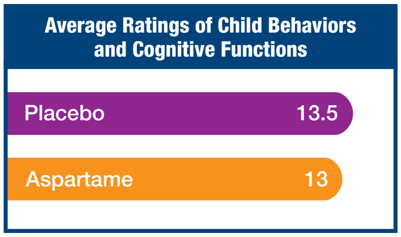
We've been discussing the case of Blake Taylor throughout the module. From the age of 3, Blake has had problems paying attention and completing tasks. Throughout his childhood, he felt no one understood the challenges he endured. To help others understand what it's like to live with ADHD, he wrote his autobiography called *ADHD & Me* (left image). In it, he discusses the challenges he faced from early childhood through the present. He talks about how he must take his ADHD medication, keep a daily routine, and make sure to get 9 hours of sleep at night to keep his ADHD symptoms from getting out of control. As a result of his motivation and self-discipline, Blake enjoys a balanced college life spent studying, working out, playing music, socializing, volunteering, and, of course, getting enough sleep (Anwar, 2008; B. E. S. Taylor, 2007). Sometimes case studies help answer questions, but case studies can also result in wrong or biased answers.

Image not avaliable

Personal Case Study: Testimonial

Why did parents make a mistake?

Observations from case studies may be misinterpreted if the observer has preconceived notions of what to look for. For example, beginning in the mid-1970s, parents were told that food with artificial additives, dyes, and preservatives could cause hyperactivity in children (Feingold, 1975). Shortly after, parents reported that, yes indeed, artificial additives caused a sudden increase in restlessness and irritability in their hyperactive children (Feingold, 1975). The parents' reports and beliefs that additives cause hyperactivity are examples of another kind of case study, called a testimonial.



A ***testimonial*** **is a statement in support of a particular viewpoint based on detailed observations of a person's own personal experience.**

However, contrary to the parents' testimonials, researchers have generally found that amounts of artificial additives within a normal range did not affect hyperactivity (Kinsbourne, 1994). More recently, there are testimonials from parents that children with attention-deficit disorder who ate foods with an artificial sweetener, aspartame (Nutrasweet), showed noticeable increases in symptoms.

To test the accuracy of these recent testimonials, researchers asked teachers and parents to evaluate the behaviors and cognitive functions of children who were given a capsule containing either ten times their normal daily intake of aspartame or a placebo. Neither parent, child, nor teacher knew if the capsule contained aspartame or the placebo. As the graph on the left shows, there was little or no difference between the effect of aspartame (Nutrasweet) and that of the placebo on the behaviors or cognitive functions of children with attention-deficit disorder (B. A. Shaywitz et al., 1994). Although testimonials from parents, friends, or peers can be very convincing, we'll point out two problems that make testimonials especially susceptible to error.

Error and Bias

What's the problem with testimonials?

One of the major problems with testimonials is that they are based on our personal observations, which have great potential for error and bias. For example, if parents reported that sweeteners increased their son's activity, we would have to rule out personal beliefs and self-fulfilling prophecies.

Personal beliefs. If parents hear that artificial sweeteners may cause physical or psychological problems, they may interpret their child's problems as caused by artificial sweeteners. Because of biased perceptions, parents may overlook other potential causes, such as frustration, anger, or changes in the child's environment, and make the error of focusing only on artificial sweeteners. If we believe strongly in something, it may bias our perception and cause us to credit an unrelated treatment or event as the reason for some change.

Parents mistakenly believed that artificial sweeteners caused ADHD.

Self-fulfilling prophecy. If parents believe that artificial sweeteners cause problems, they may behave in ways—being more strict or less sympathetic—that cause the problems to occur. This phenomenon is called a self-fulfilling prophecy.

A ***self-fulfilling prophecy*** **involves having a strong belief or making a statement (prophecy) about a future behavior and then acting, usually unknowingly, to fulfill or carry out the behavior.**

If we strongly believe that something is going to happen, we may unknowingly behave in such a way as to make it happen (R. Rosenthal, 2003). Self-fulfilling prophecies reinforce testimonials and thus keep our biased beliefs alive.

The main disadvantage of testimonials is their high potential for error and bias. But they have the advantage of providing detailed information that may point to potential answers or lead to future studies. We'll discuss how case studies are used in developmental research in Module 18 and clinical research in Module 21.

Next, we'll discuss how testimonials are a popular source of information, especially when we are talking about placebos.

D. Cultural Diversity: Use of Placebos

Examples of Mind over Body

Have you taken a placebo?

Psychologists are interested in how the mind influences the body, such as happens when someone takes a pill that happens to be a placebo.

A ***placebo*** is some intervention, such as taking a pill, receiving an injection, or undergoing an operation, that resembles medical therapy but that, in fact, has no medical effects.

A ***placebo effect*** is a change in the patient's illness that is attributable to an imagined treatment rather than to a medical treatment.

For example, the results of a study involving children who were depressed showed that an antidepressant medication decreased depression in 69% of children. However, 59% of the children reported equally good results from taking a placebo (a sugar pill) (Saxbe, 2004). In fact, many similar studies have reported a placebo to be just as effective as antidepressant medication (R. Rubin, 2008).

Researchers estimate that between 35% and 75% of patients benefit from placebos for various problems (pain, depression, asthma, gastric reflux, high blood pressure, headaches) (Begley, 2008b; Christensen, 2001). Because placebos can be effective in treating different problems, almost 50% of U.S. doctors prescribe placebos to their patients (Steenhuysen, 2008a).

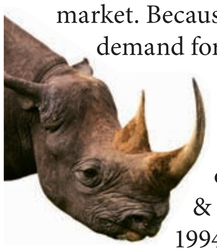
The power of placebos is in the mind.

You may be wondering how it is that placebos can be so effective. Placebos may work because beliefs and thoughts are powerful enough to produce the same relief provided by real drugs (Ariely, 2008; Kluger, 2009). For instance, researchers in one study injected subjects with a pain-inducing solution and then falsely told subjects they had been injected with pain-relieving medication (placebo). Pictures of subjects' brains were then taken (PET, p. 71), and results showed that for those people who said they felt less pain, their brain released natural painkillers after the placebo was injected (Haslinger, 2005). Our beliefs can actually change what is happening in our brain!

As you'll see, testimonials from around the world claim that different kinds of placebos can cure a wide variety of symptoms.

Rhino Horn

Millions of people in China, Taiwan, Thailand, and South Korea claim rhino horn will increase their sexual desire and stamina and will cure everything from headaches and nosebleeds to fevers and typhoid. A single rhino horn weighing 4 to 5 pounds will bring as much as $50,000 on the black market. Because of the high demand for rhino horns, the number of rhinos in Asia has sharply declined (Berger & Cunningham, 1994). Despite the healing claims of rhino horn, its basic ingredient is compacted hair (keratin), which has no proven medicinal powers (*Sierra,* 1989).



Centipedes

In parts of Asia, a popular "medicine" to treat many kinds of physical problems is a tablet made from the Korean centipede. It is believed to cure arthritis, kidney stones, malaria, skin diseases, and severe scars. Folk logic seems to guide the use of centipedes as "medicine." For instance, centipedes have many legs and are used to treat leg problems (Pemberton, 2005; SACU, 2001). In fact, centipede poison may cause pain, nausea, and fatal cases of organ failure (Norris, 2008; Yuen et al., 2006).

Tiger Bones

There has been a massive decline of tigers in Asia because tiger bones are used to treat ulcers, typhoid, malaria, joint pain, and burns; to increase longevity; to improve sexual desire; and to cure devil possession (Friend, 1997; T. Sylvester, 2009). In addition, wealthy Taiwanese pay $320 for a bowl of tiger penis soup that is thought to increase flagging libidos (Nagarahole, 1994). Tiger bones and tiger penises function as powerful placebos in traditional Asian medicine.

Cough Medication

When we have a cold with a relentless cough, many of us purchase cough syrup. In the United States, billions of dollars are spent every year on cough medications (cough syrups and lozenges), yet there is no scientific evidence that these over-the-counter medications work (Ignelzi, 2006a; J. W. Payne, 2006).

COUGH SYRUP

Conclusion: Testimonials and Placebos

Why are placebos so popular?

The main reason placebos are used worldwide, even to the point of destroying certain wild animals, is that the placebos' beneficial "medical" effects are supported by countless testimonials. For example, compared to the results of surveys, testimonials are much more convincing because they are based on real-life experiences of friends, peers, and parents, who are honest and believable. However, it is common for people, honest and trustworthy, to unknowingly make a mistake and conclude a rhino horn, centipede, tiger bone, or cough medication is producing a beneficial "medical" effect when the beneficial effect is actually being caused by the individual's mental thoughts influencing the brain or body's functioning (Ariely, 2008).

As you'll see next, people often make mistakes about the effect of placebos because there is often no way to figure out what causes what.

E. Correlation

Definition

Research suggests that ADHD has a genetic basis.

What's a correlation?

The photo on the left shows a boy running wild in a supermarket. Researchers would like to know if this boy's hyperactivity has a genetic basis. One way to identify genetic factors is to study identical twins because they share almost 100% of their genes. Suppose you were studying the occurrence of ADHD in identical male twins and found that about 75% of the time, if one identical twin had ADHD so did the second twin (Faraone et al., 2005). This strong relationship between behaviors in identical twins suggests a genetic basis for ADHD. Such a relationship is called a correlation.

A ***correlation*** is an association or relationship in the occurrence of two or more events.

For example, if one twin has hyperactivity, a correlation will tell us the likelihood that the other twin also has hyperactivity. The likelihood or strength of a relationship between two events is called a correlation coefficient.

A ***correlation coefficient*** is a number that indicates the strength of a relationship between two or more events: the closer the number is to –1.00 or +1.00, the greater is the strength of the relationship.

We'll explain correlation coefficients in more detail because they can be confusing.

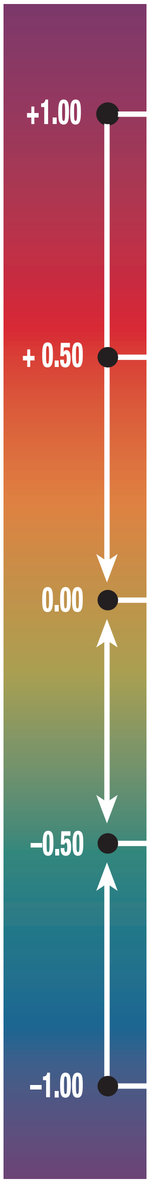
Correlation Coefficients

What are these numbers?

There are two major points to understand about correlations:

First, a correlation means there is an association between two or more events. For example, there is an association, or correlation, between the sex of a child and the occurrence of ADHD; four to five times more boys are diagnosed with ADHD than girls.

A second point to understand about correlations is that the strength of the relationship or association is measured by a number called a correlation coefficient. Because the correlation coefficient ranges from +1.00 to –1.00, its meaning can be confusing. In the boxes on the right, we'll describe what correlation coefficients mean, beginning at the top of the scale with a +1.00.



If each of 20 identical pairs showed equal levels of hyperactivity, the correlation coefficient would be positive and perfect and would be indicated by a +1.00 correlation coefficient.

A **perfect positive correlation coefficient** of +1.00 means that an increase in one event is always matched by an equal increase in a second event. For example, if one identical twin has hyperactivity, then the other twin always has hyperactivity. A correlation of +1.00 is virtually never found in applied psychological research (Hemphill, 2003).

If some identical pairs but not all 20 pairs were similar in hyperactivity, the result would be a positive correlation coefficient, which can range from +0.01 to +0.99.

A **positive correlation coefficient** indicates that as one event tends to increase, the second event tends to, but does not always, increase.

As the coefficient increases from +0.01 to +0.99, it indicates a strengthening of the relationship between the occurrence of two events.

If one twin of 20 pairs showed hyperactivity while the other twin sometimes did and sometimes did not show hyperactivity, the result would be no association, or zero correlation (0.00).

A **zero correlation** indicates that there is no relationship between the occurrence of one event and the occurrence of a second event.

If, in some identical pairs, one twin showed an increase while the other showed an equivalent decrease in activity, the result would be a negative correlation coefficient, which can range from –0.01 to –0.99.

A **negative correlation coefficient** indicates that as one event tends to increase, the second event tends to, but does not always, decrease.

As the coefficient increases in absolute magnitude from –0.01 to –0.99, it indicates a strengthening in the relationship of one event increasing and the other decreasing.

If one twin of 20 identical pairs showed hyperactivity and the second twin always showed decreased activity, the correlation coefficient would be negative and perfect and would be indicated by a –1.00 correlation coefficient.

A **perfect negative correlation coefficient** of –1.00 means that an increase in one event is always matched by an equal decrease in a second event. For example, if one identical twin has hyperactivity, then the other twin always has decreased activity. A correlation of –1.00 is virtually never found in applied psychological research (Hemphill, 2003).

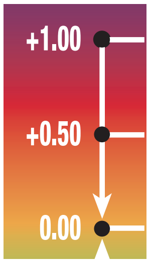
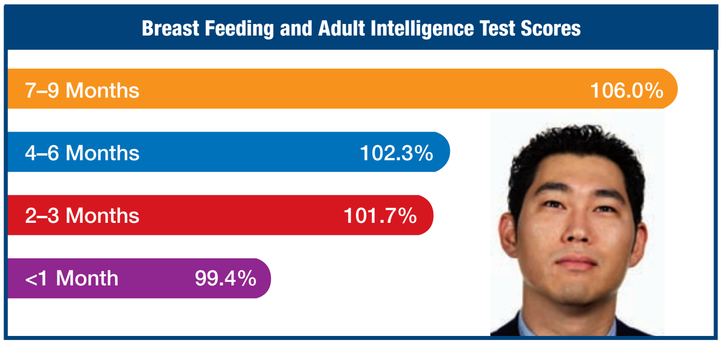
Can you recognize a correlation?

The media often headline interesting findings: Thin people live longer than heavier ones; overweight people earn less money than their peers; wearing school uniforms decreases violence. Before you assume that one event causes the other, such as thinness causing one to live longer, you must check to see what researchers did. If researchers measured only the relationship between two events, such as thinness and length of life, then it's a correlation. In fact, all three findings reported here are correlations. The reason you should check whether some finding is a correlation is that correlations have one very important limitation: They do not identify what causes what. For example, let's look closely at findings about breast feeding and intelligence test scores.



Correlation Versus Causation

The biggest mistake people make in discussing correlations is assuming that they show cause and effect. For instance, many parents have been told that breast feeding their infant leads to greater intelligence. The graph on the right shows that duration of breast feeding was correlated with higher intelligence test scores during adulthood. Since an increase in the duration of breast feeding was associated with higher intelligence test scores, this is a positive correlation (Mortensen et al., 2002).



Does breast feeding increase intelligence?

Although the correlation between breast feeding duration and intelligence test scores is impressive, you must keep in mind that even though breast feeding may have caused the higher test scores, correlations themselves cannot demonstrate cause and effect between variables.

Let's think carefully what is actually causing the higher intelligence test scores. Is it something in the breast milk (a hormone or protein) that isn't found in formula or cow's milk? Is it the physical contact or special interactions between baby and mother during breast feeding? Or, do infants who benefit most from their mother's breast milk have specific genes that process the breast milk (Caspi et al., 2007; Kramer et al., 2008)? The correlation findings leave many questions unanswered.

Although correlations cannot indicate cause-and-effect relationships, they do serve two very useful purposes: Correlations help predict behavior and also point to where to look for possible causes, as has happened in the case of lung cancer.

Correlation as Clues

Although cigarette smoking was positively correlated with lung cancer deaths (right graph), it was unknown whether smoking was the *cause* of cancer. Acting on the clue that some ingredient of cigarette smoke might trigger the development of lung cancer, researchers rubbed tar, an ingredient of cigarette smoke, on the skin of animals. After repeated applications over a period of time, the animals developed cancerous growths. This research proved that tar could cause cancer. Later, researchers discovered that one particular ingredient of cigarette smoke (benzo[a]pyrene) turns off a gene that normally suppresses tumors. When that particular gene is turned off by cigarette smoke, lung cancer develops (Liu et al., 2005). In this case, correlations told researchers where to look for causes of lung cancer. In other cases, correlations help predict behavior.

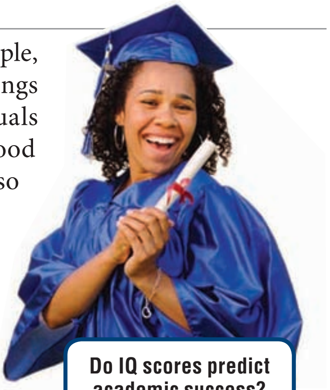
Correlation and Predictions

One way to predict how well students will do in academic settings is by looking at their IQ scores. For example, there is a positive correlation, from +0.24 to +0.38, between IQ scores and performance in academic settings (Chamorro-Premuzic & Furnham, 2008; D. M. Higgins et al., 2007). Thus, we would predict that individuals who score high on IQ tests have the skills to do well in college. However, IQ scores are only relatively good predictors for any single individual because doing well in college involves not only academic skills but also other motivational, emotional, and personality factors that we'll discuss in Module 13.

So far, we have discussed the advantages and disadvantages of two major research methods—surveys and case studies—that psychologists use to answer questions. We have also explained a statistical procedure—correlation—that shows the strength of relationships and points to possible causes of behaviors. Next, we'll describe the other kinds of research decisions that psychologists make as they try to understand and explain behavior.



Do IQ scores predict academic success?

F. Decisions about Doing Research

Choosing Research Techniques

What's the best technique for answering a question?

You are constantly asking questions about human behavior, such as "Why did she say that?" or "Why did he behave that way?" Similarly, psychologists are continually asking questions, such as "What percentage of the population is gay?" or "Of what use are SAT scores?" or "How do we diagnose ADHD?" or "Can human stem cell transplants cure paralysis?" After asking one of these questions, psychologists must decide which research technique or procedure best answers it. We'll describe four different techniques for finding answers.

Questionnaires and Interviews

What percentage of the population is gay? This question is often answered by doing a survey using interviews or questionnaires.

An ***interview*** is a technique for obtaining information by asking questions, ranging from open-ended to highly structured, about a subject's behaviors and attitudes, usually in a one-on-one situation.

A ***questionnaire*** is a technique for obtaining information by asking subjects to read a list of written questions and check off specific answers.

You might think this question about what percentage of the population is gay would be relatively easy to answer. But three different surveys have reported three different answers: 2.3%, 10%, and 22% (Billy et al., 1993; Janus & Janus, 1993; Kinsey et al., 1948). These different answers resulted from surveys using differently worded questions, different groups of people, and different kinds of interview techniques. As we discussed earlier, when it comes to surveys on personal issues—such as Did you vote? Do you wear seat belts? Do you go to church? or What is your sexual preference?—people may give a desirable rather than a honest answer.

Laboratory Experiments

How do we diagnose ADHD? As of this writing, the diagnosis of ADHD is based primarily on behavioral symptoms, which are less reliable than medical tests. For this reason, researchers are currently searching for more reliable tests to diagnose ADHD. To identify such tests, researchers are using laboratory experiments.

A ***laboratory experiment*** is a technique to gather information about the brain, genes, or behavior with the least error and bias by using a controlled environment that allows careful observation and measurement.

For example, in the photo on the right, a boy is taking a laboratory test that is believed to be an accurate way of diagnosing ADHD. In this test, children wear special goggles to monitor their eye movements and are asked to follow spots of light moving across the screen. Children with ADHD are expected to be able to follow the light for only 3 to 5 seconds, whereas children without ADHD may be able to follow the light for as long as 5 minutes (Vince, 2005).

Can a laboratory or psychological test be used to diagnose ADHD?

Standardized Tests

Of what use are SAT scores? The standardized test that you may be most familiar with is the SAT, which is given to many high school seniors to help predict how they will perform in college. Each year only 0.017% of students who take the SAT score a perfect 2400, a feat accomplished by 16-year-old high-school junior Austin Weiss (photo on left) (Associated Press, 2005b; Lewin, 2006).

Image not available due to copyright restrictions

A ***standardized test*** is a technique to obtain information by administering a psychological test that has been standardized, which means that the test has been given to hundreds of people and shown to reliably measure thought patterns, personality traits, emotions, or behaviors.

One disadvantage of standardized tests, such as the SAT, is that they may be biased toward a certain group of people. One advantage of standardized tests is that they allow comparisons to be made across schools, states, and groups of people. Another well-known standardized test is the IQ test, which we'll discuss in Module 13.

Animal Models

Can mice help identify causes of schizophrenia? About 2.2 million adults in the United States are living with schizophrenia (see p. 538), a severe mental illness. Scientists have been trying to find the causes of schizophrenia for many years, and recently they have made some exciting advances with the use of animal models.

An ***animal model*** involves examining or manipulating some behavioral, genetic, or physiological factor that closely approximates some human problem, disease, or condition.

For example, researchers genetically altered mice to have extra receptors for brain chemicals involved in schizophrenia. As a direct result of these receptors, the mice had attention and memory deficits similar to those of people with schizophrenia. This finding could help researchers develop new drugs to prevent such brain damage from occurring in people susceptible to schizophrenia (C. Brownlee, 2006a). One advantage of the animal model is it answers questions about physiological factors that cannot be investigated in humans.

Mice are used to study schizophrenia, a severe mental illness.

Deciding which of these four research techniques to use depends on the kind of question being asked. As you'll see next, the kind of question also influences which research setting to use.

PowerStudy 4.5™

Module 4
B. Studying the Living Brain

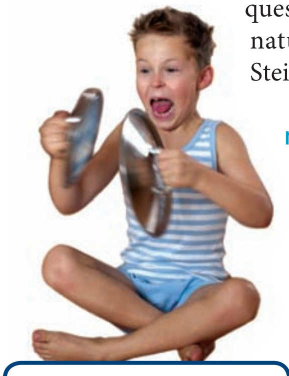
Choosing Research Settings

Which problems do children with ADHD have?

In trying to understand the kinds of problems faced by children with ADHD, psychologists study these children in different research settings, which may include observing them in the home, in the classroom, on the playground, or at their individual work. In addition, researchers may try to find the causes of ADHD by using different research settings, which may include studying children in the laboratory, hospital, or clinic. All these research settings can be grouped under either laboratory or naturalistic environments. We'll explain each setting and compare their advantages and disadvantages, beginning with more naturalistic environments.

Naturalistic Setting

Parents and teachers want to know if ADHD children have different problems at home (photo below) than in school. Researchers answer this question by studying ADHD children in different naturalistic settings (home versus school) (M. T. Stein, 2004).



Does this ADHD child have different problems in school than at home?

A ***naturalistic setting*** is a relatively normal environment in which researchers gather information by observing individuals' behaviors without attempting to change or control the situation.

For example, observations of children with ADHD in school settings indicate that they have difficulty remaining in their seats, don't pay attention to the teacher, can't sit still, rudely interrupt the teacher or students, and get angry when they don't get their way (Junod et al., 2006). Parents report that, at home, ADHD children do not respond when called, throw tantrums when frustrated, and have periods of great activity (Hancock, 1996). Based on these naturalistic observations, researchers and pediatricians developed a list of primary symptoms of ADHD (AAP, 2000; M. Stein & Perrin, 2003). Similarly, psychologists study how normal people behave in different naturalistic settings, including schools, workplaces, college dormitories, bars, and sports arenas. One problem with naturalistic observations is that the psychologists' own beliefs or values may bias their observations and cause them to misinterpret behaviors. One advantage of naturalistic observations is the opportunity to study behaviors in real-life situations and environments, which cannot or would not be duplicated in the laboratory.

Case studies. As we discussed earlier, a single individual may be studied in his or her natural environment, and this is called a case study. The case study approach is often used in clinical psychology to understand the development of a personality or psychological problem or in developmental psychology to examine a person's behavior across his or her life span.

One ***disadvantage*** of a case study is that the information obtained is unique to an individual and may not apply to, or help us understand, the behaviors of others. One ***advantage*** of a case study is that psychologists can obtain detailed descriptions and insights into aspects of an individual's complex life and behaviors that cannot be obtained in other ways.

As you can see, naturalistic settings are very useful for observing how individuals behave in relatively normal environments. However, since naturalistic settings are uncontrolled and many things happen, researchers find it difficult to identify what causes what. For this reason, researchers may have to answer some questions in a more controlled setting, such as a laboratory or clinic.

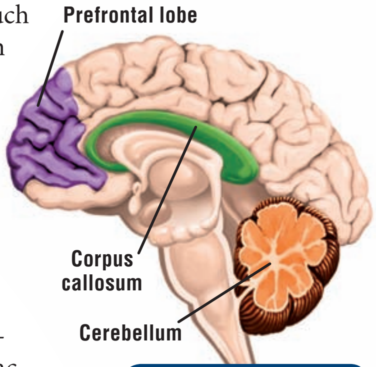
Photo Credit: © Ole Graf/zefa/Corbis

Laboratory Setting

Is there something different about the brains of children with ADHD? Questions about the brain are usually answered under very controlled conditions, such as in a laboratory setting.

A ***laboratory setting*** involves studying individuals under systematic and controlled conditions, with many of the real-world influences eliminated.

For example, researchers used special techniques (MRI brain scans, p. 70) that actually took pictures of the living brains of children with and without ADHD. Researchers focused on specific areas of the brain involved in paying attention and controlling impulses, which are difficult for ADHD children. Findings showed that ADHD children have smaller total brain size and smaller sizes of specific brain areas involved in paying attention and controlling impulses (prefrontal lobes, corpus callosum, cerebellum) (D. E. Hill et al., 2003). Other research showed that these same brain areas of children with ADHD develop much slower than in children without ADHD, which explains their smaller brain size compared to same-age peers (Shaw et al., 2007).



Brain parts involved in ADHD

Researchers use laboratory settings to study and identify a wide range of psychological and biological factors involved in motivation, emotion, learning, memory, drug use, sleep, and mental disorders.

One disadvantage of laboratory settings is that they may be so controlled or artificial that their results are not always transferable to, or meaningful for, real-life situations. However, one advantage of the laboratory setting is psychologists can carefully control and manipulate one or more treatments while reducing error or bias from other situational or environmental factors.

Researchers may combine the advantages of naturalistic and laboratory settings to identify cause-and-effect relationships. That's what happened when psychologists answered the difficult question: Does Ritalin help children with ADHD?

G. Scientific Method: Experiment

Advantages of the Scientific Method

How do researchers reduce error and bias?

There have been many different treatments, including diets, vitamins, drugs, and behavior therapy, that claimed to help children with ADHD. To discover which of these claims were valid, researchers followed a general approach called the scientific method.

The ***scientific method*** is an approach of gathering information and answering questions so that errors and biases are minimized.

Remember that information from surveys, case studies, and testimonials has considerable potential for error and bias. Remember too that information from correlations can suggest, but not pinpoint, cause-and-effect relationships. One way to reduce error and bias and identify cause-and-effect relationships is to do an experiment.

An ***experiment*** is a method of identifying cause-and-effect relationships by following a set of rules and guidelines that minimize the possibility of error, bias, and chance occurrences.

An experiment, which is an example of using the scientific method, is the most powerful method for finding what causes what. If we wanted to find out if medication improves the behavior of children with ADHD, we would want to do an experiment. We will divide an experiment into seven rules that are intended to reduce error and bias and identify the cause of an effect.

Conducting an Experiment: Seven Rules

Why seven rules?

Some researchers and parents claimed that diets without sugar, artificial colors, and additives reduced ADHD symptoms, but most of these claims proved false because the rules to reduce error had not been followed (Kinsbourne, 1994). Here are seven rules that reduce error and bias and that researchers follow when conducting an experiment.

Rule 1: Ask

Every experiment begins with one or more specific questions that are changed into specific hypotheses.

A ***hypothesis*** is an educated guess about some phenomenon and is stated in precise, concrete language to rule out confusion or error in the meaning of its terms.

Researchers develop different hypotheses based on their own observations or previous research findings. Following this first rule, researchers change the general question—Does Ritalin help children with ADHD?—into a very concrete hypothesis (see below).

Hypothesis:
Ritalin will increase positive classroom behaviors of children diagnosed with ADHD.

Rule 2: Identify

After researchers make their hypothesis, they identify a treatment that will be administered to the subjects. This treatment is called the independent variable.

The ***independent variable*** is a treatment or something that the researcher controls or manipulates.

The independent variable may be a single treatment, such as a single drug dose, or various levels of the same treatment, such as different doses of the same drug.

In our experiment, the independent variable is administering three different doses of Ritalin and a placebo.

Independent Variable:
Drug treatment

After researchers choose the treatment, they next identify the behavior(s) of the subjects, called the dependent variable, that will be used to measure the effects of the treatment.

The ***dependent variable*** is one or more of the subjects' behaviors that are used to measure the potential effects of the treatment or independent variable.

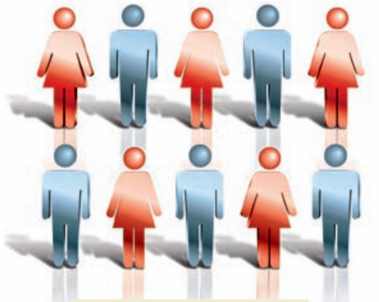
The dependent variable, so called because it is dependent on the treatment, can include a wide range of behaviors, such as observable responses, self-reports of cognitive processes, or recordings of physiological responses from the body or brain. In the present experiment, the dependent variable is the teacher's rating of the child's positive classroom behaviors.

Dependent Variable:
Child's positive classroom behaviors

Rule 3: Choose

After researchers identify the independent and dependent variables, they next choose the subjects for the experiment. Researchers want to choose participants who are representative of the entire group or population, and they do this through a process called random selection.

Random selection means that each participant in a sample population has an equal chance of being selected for the experiment.



Random Selection

Examples of random selection include the way lottery numbers are drawn and selecting people using a random number table.

The reason researchers randomly select participants is to avoid any potential error or bias that may come from their knowingly or unknowingly wanting to choose the "best" subjects for their experiment.

Rule 4: Assign

After randomly choosing the subjects, researchers then randomly assign participants to different groups, either an experimental group or a control group.

Experimental Group

The ***experimental group*** is composed of those who receive the treatment.

The ***control group*** is composed of participants who undergo all the same procedures as the experimental participants except that the control participants do not receive the treatment.

Control Group

In this study, some of the children are assigned to the experimental group and receive Ritalin; the other children are assigned to the control group and receive a similar-looking pill that is a placebo.

The reason participants are randomly assigned to either the experimental or control group is to take into account or control for other factors or traits, such as intelligence, social class, age, sex, and genetic differences. Randomly assigning participants reduces the chances that these factors will bias the results.

Rule 5: Manipulate

After assigning participants to experimental and control groups, researchers manipulate the independent variable by administering the treatment (or one level of the treatment) to the experimental group. Researchers give the same conditions to the control group but give them a different level of the treatment, no treatment, or a placebo.

In this study, researchers give the experimental group a pill containing Ritalin, while the control group receives a placebo. Drugs and placebos are given in a double-blind procedure.

A ***double-blind procedure*** means neither participants nor researchers know which group is receiving which treatment.

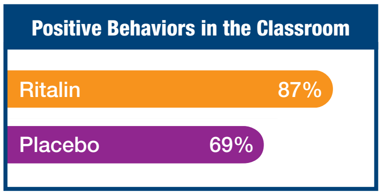
A double-blind procedure is essential in drug research to control for self-fulfilling prophecies (see p. 30), placebo effects (see p. 31), and possible influences or biases of the experimenters.

Double-blind procedure is an important research tool.

Rule 6: Measure

By manipulating the treatment so that the experimental group receives a different treatment than the control group, researchers are able to measure how the independent variable (treatment) affects those behaviors that have been selected as the dependent variables.

For example, the hypothesis in this study is: Ritalin will increase the positive classroom behaviors of children with ADHD. Researchers observe whether treatment (Ritalin or placebo) changes positive behaviors of ADHD children in the classroom. Positive behaviors include following a variety of classroom rules, such as remaining in seat, not disturbing others, not swearing or teasing, and following instructions. As the graph at the right indicates, ADHD children given placebos follow classroom rules 69% of the time, compared with 87% for the children given Ritalin (Pelham et al., 2005). Thus, compared to placebos, Ritalin increases positive behaviors in the classroom. However, to be absolutely sure, researchers must analyze the results more carefully by using statistical procedures.



Rule 7: Analyze

Although there appears to be a large increase in positive behaviors, from 69% for the placebo control group to 87% for the Ritalin experimental group, researchers must analyze the size of these differences with statistical procedures.

Statistical procedures are used to determine whether differences observed in dependent variables (behaviors) are due to independent variables (treatment) or to error or chance occurrence.

Statistical analysis shows if the result occurred by chance.

Using statistical procedures, which are described in Appendix A, researchers compared the effect of the placebo with that of Ritalin on positive behaviors. They concluded that, compared with the placebo, Ritalin significantly increased positive behaviors. In this case, significantly means there was a 95% likelihood that it was Ritalin and not some error or chance occurrence that increased positive behaviors (Pelham et al., 2005).

These significant findings support the hypothesis that Ritalin increases positive classroom behaviors of children with ADHD.

Conclusion

What does an experiment tell you?

By following these seven rules for conducting an experiment, researchers reduced the chances that error or bias would distort the major finding, which was that Ritalin increased the positive behaviors of children in the classroom. This example shows that when an experiment is run according to these seven rules, it is a much more powerful method for identifying cause-and-effect relationships than are surveys, testimonials, correlations, or case studies. Even so, researchers usually repeat experiments many times before being confident that the answers they found were correct. That's why a newly reported finding, no matter how significant, is usually regarded as questionable until other researchers have been able to repeat the experiment and replicate the finding.

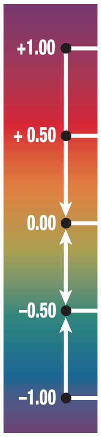
After the Concept Review, we'll discuss why, after more than 20 years of research, there are still controversies surrounding ADHD.

Concept Review

Image not avaliable

1. If psychologists obtain information through an in-depth analysis of the thoughts, beliefs, or behaviors of a single person, this method is called a (a) ________________. If a method is used that minimizes error and identifies cause-and-effect relationships, it is called an (b) ________________. If individuals are asked a fixed set of questions, it is called a (c) ________________. If individuals make statements in support of a particular viewpoint on the basis of personal experience, it is called a (d) ________________.

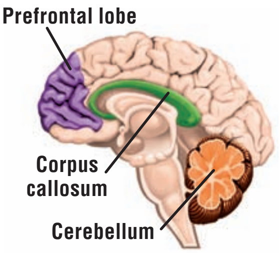
2. Some intervention that is designed to look like a medical treatment but that has no actual medical effect is called a (a) ________________. A change in a patient's illness that is due to a supposed treatment and not to any medical therapy is called a (b) ________________.



3. Psychologists describe the association, relationship, or linkage among two or more events as a (a) ________________. They describe the strength of such a relationship by a number called the (b) ________________, which may vary from –1.00 to +1.00. If an increase in one event is associated with an increase in a second event, this relationship is called a (c) ________________ correlation. If an increase in one event is associated with a decrease in a second event, this relationship is called a (d) ________________ correlation. Finding that two or more events are linked together does not prove that one event (e) ________________ the other.

4. Psychologists use at least five common research techniques. They can ask subjects oral or written questions by using (a) ________________ and (b) ________________. They might ask subjects to answer questions on established tests, which are called (c) ________________ tests. They might observe and measure behaviors, brains, or genes with the least error and bias by using a controlled environment, called a (d) ________________. They could study some question or problem in animals by developing an (e) ________________ that closely approximates the human condition.

5. If psychologists study individuals in their real-life environments, without trying to control the situation, they are using a (a) ________________ setting. A variation of this approach is to study a single individual in great depth in his or her own environment, which is called a (b) ________________. If psychologists study individuals under carefully controlled conditions, they are using a (c) ________________ setting.



6. One example of searching for cause-and-effect relationships by following the rules and guidelines of the scientific method is to answer questions by conducting an ________________, which has seven rules.

7. If you are conducting an experiment, you should follow 7 rules.

Rule 1 is to *ask* specific questions in very concrete terms: these statements are called (a) ________________.

Rule 2 is to *identify* the treatment, which is called the (b) ________________, and to choose the behaviors or responses that will be observed to judge the effectiveness of the treatment. These behaviors or responses are called the (c) ________________.

Rule 3 is to *choose* subjects through a process called (d) ________________, which gives everyone in a sample population an equal chance of being selected.

Rule 4 is to *assign* subjects to different groups by random selection. The group that will receive the treatment is called the (e) ________________, and the group that undergoes everything but the treatment is called the (f) ________________.

Rule 5 is to *manipulate* the (g) ________________ by administering it to the experimental group but not the control group.

Rule 6 is to *measure* the effects of the independent variable on behaviors that have been selected as the (h) ________________.

Rule 7 is to *analyze* the difference between the experimental and control groups by using (i) ________________.

8. Researchers usually repeat experiments many times to make sure that their ________________ are correct.

***Answers:** 1. (a) case study, (b) experiment, (c) survey, (d) testimonial; 2. (a) placebo, (b) placebo effect; 3. (a) correlation, (b) correlation coefficient, (c) positive, (d) negative, (e) causes; 4. (a) questionnaires, (b) interviews, (c) standardized, (d) laboratory experiment, (e) animal model; 5. (a) naturalistic, (b) case study, (c) laboratory; 6. experiment; 7. (a) hypotheses, (b) independent variable, (c) dependent variable, (d) random selection, (e) experimental group, (f) control group, (g) independent variable, (h) dependent variables, (i) statistical procedures; 8. answers or results*

H. Research Focus: ADHD Controversies

Why do controversies still remain?

You might ask why, after so many years of research, there are still controversies over how to diagnose and treat ADHD. Although researchers have reached the first goal of psychology, which is to describe ADHD, they have not reached the second goal, which is to explain the causes of ADHD, which will lead to better treatment. Explaining the causes of ADHD means combining biological, psychological, behavioral, and cultural factors, which is a slow process. We'll review the current controversies involving ADHD to show how far researchers have come and how far they have to go.

Controversy: Diagnosis

The first controversy involves the accuracy and reliability of how ADHD is diagnosed. In the United States, as many as 7 million school-age children are diagnosed with ADHD, with three times as many boys having ADHD as girls (B. Bower, 2006b).

The controversy arises from the fact that the current diagnosis of ADHD is based solely on reported and observed behavioral symptoms rather than on medical or laboratory tests. Because the behavioral symptoms vary in severity (more or less), setting (home versus school), and culture (fewer Asian American children than African American), there is the potential for misdiagnosis (Root & Resnick, 2003). For example, parents or teachers may label a child as having ADHD if the child is overwhelmed by the demands of school and acts outgoing, rambunctious, or difficult to discipline (Sinha, 2001). Sometimes children with problems in learning, vision, or hearing are misdiagnosed with ADHD (Hillier, 2004; Lyle, 2003).

There are three big controversies surrounding ADHD.

Because of diagnostic difficulties, pediatricians and family doctors were recently given the following guidelines for diagnosing ADHD: Children should be 6–12 years old, show six or more symptoms of inattention and hyperactivity, have symptoms for at least six months, and exhibit symptoms in both home and school (J. E. Allen, 2000). The purpose of the guidelines is to prevent the merely rambunctious child from being diagnosed with ADHD and given unnecessary drugs.

Controversy: Treatment

The second controversy involves how best to treat ADHD. As we discussed earlier (p. 30), researchers found that using diets that avoid artificial flavors and colors, preservatives, artificial sweeteners, and sugars did little to reduce hyperactive behaviors (Kinsbourne, 1994). More recently, researchers have compared nondrug and drug treatments for ADHD and made the following recommendations.

Nondrug, Behavioral Treatment

There is a nondrug, behavioral treatment program that involves changing or modifying undesirable behaviors by using learning principles (p. 232). Such a behavioral treatment program, which requires considerable efforts by the parents and teachers, has been effective in reducing ADHD symptoms (Barkley, 2006; DuPaul, 2008).

Experts in the treatment of ADHD recommend a behavioral treatment program be used for preschool-age children with ADHD, for milder forms of ADHD, for children who also have deficits in social skills, and when the family prefers the nondrug, behavioral treatment.

Use of Ritalin: 600% increase since 1993

Combined Drug and Behavioral Treatment

A combination of Ritalin (methylphenidate) and behavioral treatment is recommended when children have severe ADHD, such as when ADHD symptoms cause a major disruption in home and/or school (Barkley, 2006). The use of Ritalin has risen 600% since 1993, and total ADHD medication sales more than quadrupled between 2000 and 2004 (Alonso-Zaldivar, 2006; Haislip, 2003). Currently, there are more than 2.5 million Americans aged 19 or younger who are using ADHD medications (Boyles, 2008).

ADHD medications help decrease children's hyperactivity and increase their concentration; however, they may cause side effects, including sleeping and eating problems, irritability, and slowed growth rate (B. Bower, 2006c). ADHD medications don't improve some of the skill deficits of these children, such as difficult interactions with peers and parents (Fabiano, 2008). Because of the risk for serious side effects and the increase in Ritalin use, the Food and Drug Administration recommended Ritalin and other similar drugs include a warning (*New York Times,* Feb. 12, 2006). The use of drug and/or behavioral treatment for ADHD depends on an accurate diagnosis, the severity of symptoms, and concerns of teachers and parents.

Controversy: Long-Term Effects

The third controversy involves the long-term effects of ADHD. It used to be thought that children outgrew ADHD, but researchers have found that even when ADHD children are treated with Ritalin, 50% continue to have problems as adults. In fact, 1.5 million adults in the United States take ADHD medication (Alonso-Zaldivar, 2006). Adults with ADHD are more likely to have school, work, and relationship problems (Barkley et al., 2008; *Medical News Today,* 2005). Because ADHD is a continuing problem, the use of medication and/or behavioral programs that focus on setting goals, establishing rules, and rewarding performance should be encouraged to help those with ADHD deal with adolescence and adulthood (Barkley, 2006; Barkley et al., 2008).

The controversies surrounding ADHD point out the difficulties in understanding, explaining, and treating complex human problems, such as ADHD. Using Ritalin to treat children also raises questions about the rights of subjects, both humans and animals, in research.

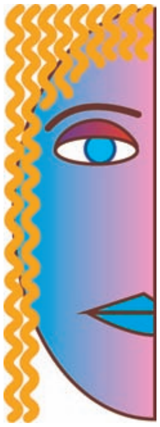
I. Application: Research Concerns

Concerns about Being a Subject



What's it like to be a subject?

When you hear about a new research finding—such as a drug to control weight or treat depression, or the discovery of a gene related to happiness, or ways to improve memory—you rarely think about the treatment of subjects, humans and animals, used in these experiments.

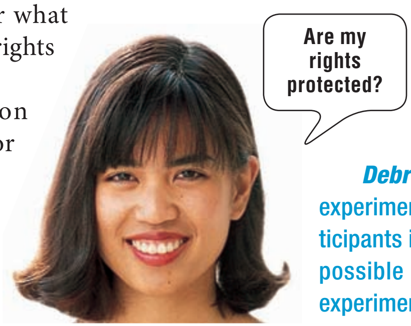
For example, if you were asked to volunteer to be a participant, you would certainly be concerned about whether someone has checked to ensure that the experiment is safe, that there are safeguards to protect you from potential psychological or physical harm, and that you won't be unfairly deceived or made to feel foolish. These are all real concerns, and we'll discuss each one in turn.

Additionally, a separate and controversial question concerns the use of animals in research. We'll answer this question in some detail, since there are many misconceptions about the use and misuse of animals in research.

We'll begin by considering the concerns of human subjects.

Code of Ethics

If you are a college student, there is a good possibility that you will be asked to participate in a psychology experiment. If you are considering becoming a subject, you may wonder what kinds of safeguards are used to protect subjects' rights and privacy.



Are my rights protected?

The American Psychological Association has published a code of ethics and conduct for psychologists to follow when doing research, counseling, teaching, and related activities (American Psychological Association, 2002). This code of ethics spells out the responsibilities of psychologists and the rights of participants.

Besides having to follow a code of ethics, psychologists must submit the details of their research programs, especially those with the potential for causing psychological or physical harm, to university and/or federal research committees (institutional review boards). The job of these research committees is to protect the participants (human or animal) by carefully checking the proposed experiments for any harmful procedures (Breckler, 2006).

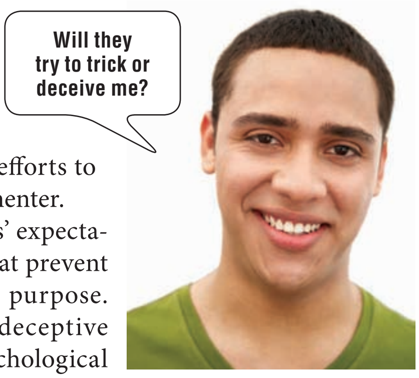
Experiments are not approved unless any potentially damaging effects can be eliminated or counteracted. Counteracting potentially harmful effects is usually done by thoroughly describing the experiment, a process called debriefing.

Debriefing **includes explaining the purpose and method of the experiment, asking the participants their feelings about being participants in the experiment, and helping the participants deal with possible doubts or guilt that arise from their behaviors in the experiment.**

During the debriefing sessions, researchers will answer any questions or discuss any problems that participants may have. The purpose of debriefing is to make sure that participants have been treated fairly and have no lingering psychological or physical concerns or worries that come from participating in an experiment (Aronson et al., 2004).

Role of Deception

When recruiting participants for their experiments, psychologists usually give the experiments titles, such as "Study of eyewitness testimony" or "Effects of alcohol on memory." The reason for using such general titles is that researchers do not want to create specific expectations that may bias how potential participants will behave. It is well known that an experiment's results may be biased by a number of factors: by participants' expectations of how they should behave, by their unknowingly behaving according to self-fulfilling prophecies, or by their efforts to make themselves look good or to please the experimenter.



Will they try to trick or deceive me?

One way that researchers control for participants' expectations is to use bogus procedures or instructions that prevent participants from learning the experiment's true purpose. However, before researchers can use bogus or deceptive methodology, they must satisfy the American Psychological Association's (2002) code of ethics. For example, researchers must justify the deceptive techniques by the scientific, educational, or applied value of the study and can use deception only if no other reasonable way to test the hypothesis is available (APA, 2002).

Another way to avoid bias from participants' expectations is to keep both the researcher and participants in the dark about the experiment's true purpose by using a double-blind procedure. As discussed earlier (p. 37), a double-blind procedure means that neither participants nor researchers are aware of the experiment's treatment or purpose.

Thus, researchers must be careful not to reveal too many details about their experiments lest they bias how potential subjects may behave.

Ethics of Animal Research

How many animals are used in research?

It is estimated that over 25 million animals are used each year in biomedical research, which includes the fields of psychology, biology, medicine, and pharmaceuticals (Humane Society, 2008). Although these numbers seem large, they are small in comparison to the 5 billion chickens eaten annually by people in the United States. However, it is the use of animals in research that has generated the most concern and debate (Rowan, 1997).

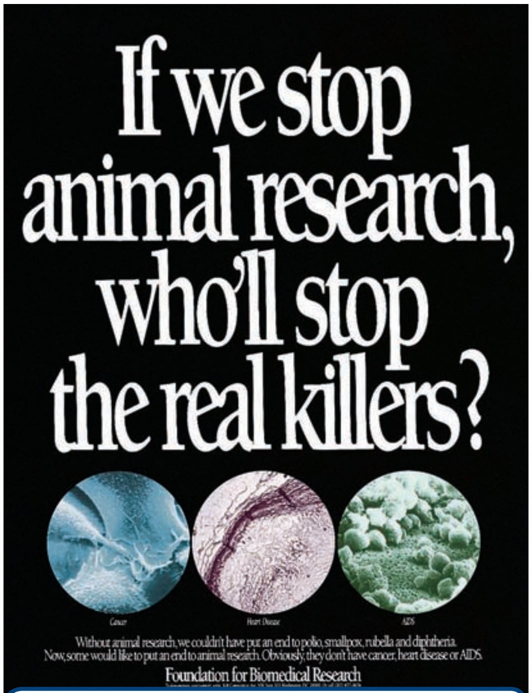
In the field of psychology, about 7 to 8% of research involves the use of animals. About 90% of the nonhuman animals used by researchers are rats, mice, and birds, while the remaining 10% are other animals such as cats, dogs, and monkeys (C.A.R.E., 2008). We'll examine the justification for using animals in research and how their rights are protected.

Are research animals mistreated?

You may have seen a disturbing photo or heard about a laboratory animal being mistreated (C.A.R.E., 2008). The fact is that, of the millions of animals used in research, only a few cases of animal mistreatment have been confirmed. That is because scientists know that proper care and treatment of their laboratory animals are vital to the success of their research. To abolish the use of all laboratory animals because of one or two isolated cases of mistreatment would be like abolishing all medical practice because of isolated cases of malpractice. Instead, researchers support the Animal Research Act, which balances the rights of animals to be treated with care with the needs for advancing the medical, physiological, and psychological health of humans (Albright et al., 2005).

Is the use of animals justified?

Adrian Morrison, director of the National Institute of Mental Health's Program for Animal Research Issues, offers this view: "Because I do experimental surgery, I go through a soul-searching every couple of months, asking myself whether I really want to continue working on cats. The answer is always yes because I know that there is no other way for medicine to progress but through animal experimentation and that basic research ultimately leads to unforeseen benefits" (Morrison, 1993).



If we stop animal research, who'll stop the real killers?
Cancer
Heart Disease
AIDS
Without animal research, we couldn't have put an end to polio, smallpox, rubella and diphtheria.
Now, some would like to put an end to animal research. Obviously, they don't have cancer, heart disease or AIDS.
Foundation for Biomedical Research

The small print in the poster reads, "Without animal research, we couldn't have put an end to polio, smallpox, rubella and diphtheria. Now, some would like to put an end to animal research. Obviously, they don't have cancer, heart disease or AIDS."

It's the animals you don't see that really helped her recover.
Recently, a surgical technique perfected on animals was used to remove a malignant tumor from a little girl's brain. We lost some lab animals. But look what we saved.
Foundation for Biomedical Research

The small print in the poster reads, "Recently, a surgical technique perfected on animals was used to remove a malignant tumor from a little girl's brain. We lost some lab animals. But look what we saved."

According to Frederick King, the former chair of the American Psychological Association's Committee on Animal Research and Experimentation, animal research has resulted in major medical advances, new treatments for human diseases, and a better understanding of human disorders (F. A. King et al., 1988).

In the field of psychology, animal research has led to a better understanding of how stress affects one's psychological and physical health, mechanisms underlying learning, the development and treatment of depression, anxiety, and schizophrenia, and critical information about sensory processes of taste, vision, hearing, and pain perception, to mention but a few (C.A.R.E., 2008).

Who checks on the use of animals in research?

Numerous government and university regulations ensure the proper care and humane treatment of laboratory animals. For example, the U.S. Department of Agriculture conducts inspections of all animal research facilities to ensure proper housing and to oversee experimental procedures that might cause pain or distress. Also, universities have committees with authority to decide whether sufficient justification exists for using animals in specific research projects (Kalat, 2004).

How do we strike a balance?

One of the basic issues in animal research is how to strike a balance between animal rights and research needs (Albright et al., 2005). Based on past, present, and potential future benefits of animal research, many experts in the scientific, medical, and mental health communities believe the responsible use of animals in research is justified. This is especially true in light of recent rules that regulate the safe and humane treatment of animals kept in laboratories or used in research (C.A.R.E., 2008; OACU, 2008).

Summary Test

A. Answering Questions

1. Psychologists use at least three methods to answer questions or obtain information. An in-depth analysis of a single person's thoughts and behaviors is called a (a) _______________. One advantage of this method is that researchers obtain detailed information about a person, but one disadvantage is that such information may not apply to others. Asking a large number of individuals a fixed set of questions is called a (b) _______________. Gathering information in a controlled laboratory setting is called an (c) _______________.

Image not
avaliable

B. Surveys

2. Measuring the attitudes, beliefs, and behaviors of a large sample of individuals by asking a set of questions is called a _______________. One advantage of this method is that psychologists can quickly and efficiently collect information about a large number of people. One disadvantage is that people may answer in a way that they think is more socially acceptable.

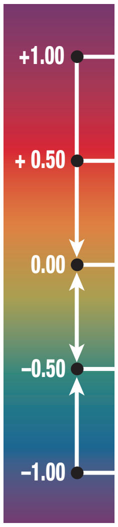
C. Case Study

3. A statement that supports a particular viewpoint and is based on a person's own experience is called a (a) _______________, which has two potential sources of error and bias. First, strongly held personal beliefs may bias an individual's (b) _______________ of events. Second, believing strongly that something will happen and then unknowingly acting in such a way as to make that something occur can cause an error called (c) _______________. This source of error is one of the major reasons that people believe that their (d) _______________ are true.

D. Cultural Diversity: Use of Placebos

4. Some intervention that resembles a medical therapy but that, in fact, has no medical effects is called a (a) _______________. If a person reports an improvement in some medical condition that is due to a supposed treatment rather than some medical therapy, that is called a (b) _______________. One reason people around the world believe in placebos is that people give (c) _______________ to their effectiveness.

E. Correlation



5. If two or more events are associated or linked together, they are said to be (a) _______________. The strength of this association is indicated by a number called the (b) _______________, which has a range from –1.00 to +1.00.

6. If there were a perfect association between two events—for example, when one increased, the other did also—this would be called a (a) _______________. If an increase in one event is usually, but not always, accompanied by an increase in a second event, this is called a (b) _______________. If an increase in one event were always accompanied by a decrease in a second event, this would be called a (c) _______________. If an increase in one event is usually, but not always, accompanied by a decrease in a second event, this is called a (d) _______________.

7. Although a correlation indicates that two or more events are occurring in some pattern, a correlation does not identify which event may (a) _______________ the other(s). Although correlations do not identify cause-and-effect relationships, they do provide (b) _______________ as to where to look for causes and they help to (c) _______________ behavior.

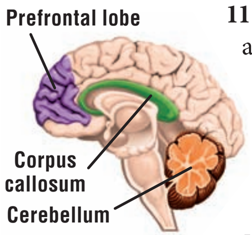
F. Decisions about Doing Research

8. Psychologists may answer some question by using one or more of five commonly used research techniques. Asking questions about people's attitudes and behaviors, usually in a one-on-one situation, is using an (a) _______________. Asking subjects to read a list of questions and indicate a specific answer is using a (b) _______________. Asking subjects to complete established tests that measure personality, intelligence, or other behaviors is using (c) _______________. If psychologists study subjects' behaviors under carefully controlled conditions that allow manipulation of the treatment, they are conducting a (d) _______________. Psychologists can study a problem using animals by developing an (e) _______________, which closely approximates the human disease or condition.

9. Psychologists conduct research in two common settings. If psychologists obtain information by observing an individual's behaviors in his or her environment, without attempts to control or manipulate the situation, they would be using a _______________. The advantage of this method is that it gives information that would be difficult to obtain or duplicate in a laboratory. The disadvantage of this method is that the psychologists' own beliefs or values may bias their observations and cause them to misinterpret the behaviors under observation.

Photo Credits: center left, © Blend Images/SuperStock; bottom left, © DLILLC/Corbis

10. If psychologists study a single individual in considerable depth in his or her own environment, they are using a __________. The advantage of this method is that it results in detailed descriptions and insights into many aspects of an individual's life. The disadvantage is that the information obtained may be unique and not applicable to others.



11. If psychologists want to study individuals under controlled and systematic conditions, with many of the real-life factors removed, they do the study in a __________. The advantage of this setting is that it permits greater control and manipulation of many conditions while ruling out possible contaminating factors. The disadvantage of this setting is that it may be too artificial or controlled, so that the results may not necessarily apply to real-life situations.

G. Scientific Method: Experiment

12. The scientific method offers a set of rules or guidelines on how to conduct research with a minimum of error or bias. We have divided these guidelines into seven rules.

Rule 1 is to make a statement in precise, concrete terms. Such a statement is called a (a) __________, which researchers often develop based on previous observations or studies.

Rule 2 is to identify the treatment or something the experimenter manipulates, which is called the (b) __________. In addition, the experimenter selects behaviors that are to be used to measure the potential effects of the treatment. These selected behaviors are called the (c) __________, and they may include a wide range of behaviors, such as cognitive processes, observable behaviors, or measurable physiological responses.

Rule 3 is to choose subjects so that each one in a sample has an equal chance of being selected. One procedure for doing so is called (d) __________.

Rule 4 is to assign subjects randomly to one of two groups. The group that will receive the treatment is called the (e) __________, and the group that will undergo everything but the treatment is called the (f) __________.

Rule 5 is to manipulate the (g) __________ by administering it (or one level of it) to the experimental group but not to the control group. The procedure for preventing researchers or subjects from knowing who is getting the treatment is called the (h) __________.

Rule 6 is to measure the effects of the independent variable on behaviors that have been selected as the (i) __________.

Rule 7 is to analyze differences between behaviors of subjects in the experimental group and those in the control group by using various (j) __________, which determine whether differences were due to the treatment or to chance occurrences. By following these seven rules, researchers reduce the chances that (k) __________ caused their results.

H. Research Focus: ADHD Controversies

13. One controversy over ADHD is that, as of this writing, the diagnosis of ADHD is based on (a) __________ observations, which are not always clear-cut, rather than on more reliable (b) __________ tests. Another controversy involves how best to treat ADHD. For more severe ADHD, researchers recommend a combination of (c) __________ and (d) __________ treatment. However, even though Ritalin can decrease hyperactivity in children and increase their ability to pay (e) __________, Ritalin does not necessarily improve reading or social skills and does not necessarily reduce problems occurring during adolescence and adulthood.

I. Application: Research Concerns

14. One method of counteracting potential harmful effects on experimental subjects is by thoroughly __________ them. This includes explaining the purpose and method of the experiment, asking subjects about their feelings, and helping subjects deal with possible doubts or problems arising from the experiment.

15. The justification for using __________ in research is that it has resulted in major medical advances, treatments for diseases, and understanding of human disorders.

Answers: *1. (a) case study, (b) survey, (c) experiment; 2. survey; 3. (a) testimonial, (b) perceptions, (c) self-fulfilling prophecy, (d) testimonials; 4. (a) placebo, (b) placebo effect, (c) testimonials; 5. (a) correlated, (b) correlation coefficient; 6. (a) perfect positive correlation, (b) positive correlation, (c) perfect negative correlation, (d) negative correlation; 7. (a) cause, (b) clues, (c) predict; 8. (a) interview, (b) questionnaire, (c) standardized tests, (d) laboratory study or experiment, (e) animal model; 9. naturalistic setting; 10. case study; 11. laboratory setting; 12. (a) hypothesis, (b) independent variable, (c) dependent variables, (d) random selection, (e) experimental group, (f) control group, (g) independent variable, (h) double-blind procedure, (i) dependent variables, (j) statistical procedures, (k) error or bias; 13. (a) behavioral, (b) medical or laboratory, (c) Ritalin, (d) behavioral, (e) attention; 14. debriefing; 15. animals*

Does Binge Drinking Cause Later Health Problems?

It is well known that adolescent drinking causes plenty of immediate health problems such as sleeplessness, fatigue, headaches, and lower cognitive functioning. But does adolescent binge drinking (having at least 5 alcoholic drinks on one occasion) have any long-term effects on health? According to a recent study, the answer is yes. Binge drinking during adolescence was found to have a variety of long-term, negative health consequences, and the risks remained even for people who stopped drinking during their teenage years.

Researchers at the University of Washington followed 808 people (about equal numbers of males and females) from ages 10 to 24, interviewing them numerous times asking about their drinking and other drug use, exercise habits, and health. They identified four types of teenage drinkers: nonbinge drinkers (including nondrinkers), who never or rarely engaged in binge drinking; chronic heavy drinkers, who drank throughout adolescence; escalators, who started drinking in mid-adolescence and quickly increased their alcohol use; and late onsetters, who began drinking late in their teenage years.

Findings showed that nonbinge drinkers were in the best health at age 24, based on weight, physical activity, blood pressure, and number of times they got sick. Chronic heavy drinkers were in the worst physical health. For example, compared to nonbinge drinkers, they were almost 4 times as likely to be overweight and to have high blood pressure. Also, late onsetters were more likely to get sick than nonbinge drinkers, but surprisingly escalators were not found to have poorer health than teens who did not binge drink.

The researchers adjusted the study's statistical analyses to account for factors that might explain the findings, such as income level, gender, ethnicity, and level of drinking at age 24. Even so, they still found teenage binge drinking to be associated with later health problems. These results support the role of alcohol in long-term health risk.

Although these findings are impressive, the researchers cannot conclude that adolescent binge drinking causes later health problems. Instead, they state that those who binge drink may choose certain lifestyles and engage in certain behaviors that more directly contribute to poorer health. When these factors are better understood, interventions can be more effective in reducing the occurrence of teenage binge drinking. (Adapted from Oesterle et al., 2004; Querna, 2004)

QUESTIONS

1 What are the three major methods for answering questions in psychology, and which method was used in this study?

2 Do the results of this study show a cause-and-effect relationship between teenage binge drinking and poorer health for young adults? Why or why not?

3 Why were "escalators" found not to have poorer health than "nonbinge drinkers"?

4 What should alcohol prevention programs emphasize to help reduce teenage binge drinking?

5 What are the advantage and disadvantage of this study?

6 What bias or error may explain why an adult blames his recent headaches and sleeping problems on the binge drinking he did during adolescence?

Suggested Answers to Critical Thinking

1. The three major methods for answering questions are survey, case study, and experiment. In this study, researchers asked people questions about their drinking and physical health, so this study used the survey method.
2. Surveys cannot show cause-and-effect relationships but only correlations between events: teenagers who engaged in binge drinking more often had poorer physical health as young adults than those who engaged in binge drinking less often. To show a cause-and-effect relationship, this study would have to be designed as an experiment in which an experimental group got one treatment (alcohol) while a control group got no or different treatment (no alcohol/placebo).
3. This is difficult to know for certain. It may be helpful to examine additional aspects of physical health (cholesterol level, family history) and health behaviors (diet, routine medical care).
4. Alcohol prevention programs should emphasize the immediate and long-term negative health consequences resulting from adolescent binge drinking.
5. The advantage of this survey study is that it suggests an unexpected cause or explanation for why some young adults have poorer health (adolescent binge drinking). One disadvantage of this survey study is that it cannot identify cause-and-effect relationships.
6. If he believes that binge drinking during adolescence causes later health problems, he may behave in ways (worrying more, eating poorly) that cause the problems to occur. This error or bias is called a self-fulfilling prophecy.

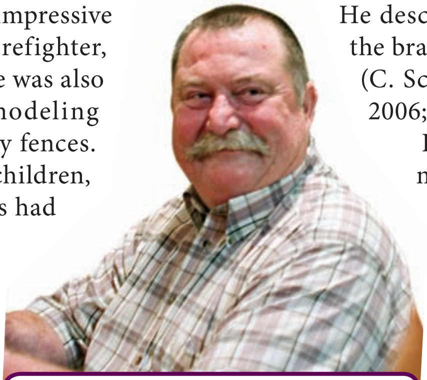
Introduction

Losing One's Mind

Why does Charles have Post-it® Notes everywhere?



He had everything in life he could want until he developed Alzheimer's.

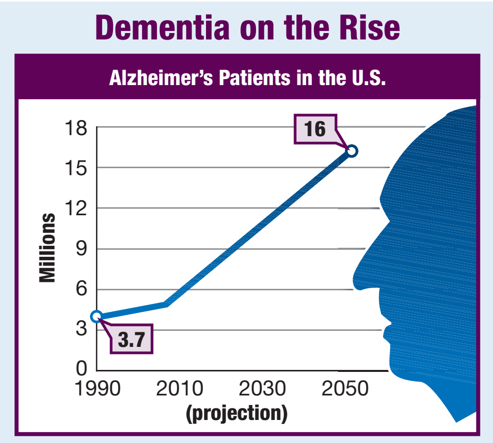
Photo Credit: © Jeffrey MacMillan/*U.S. News & World Report*

Charles Schneider had an impressive career—a police officer, firefighter, and private investigator. He was also quite the craftsman, remodeling houses and building sturdy fences. He had a loving wife, two children, and five grandchildren. In his early fifties, Charles had everything he could ever want in life.

But that was before he started to forget things. What could explain why he could no longer remember his lock combination at the firehouse or why he had to open every compartment in the firetruck to find the tools he needed? Why did the names of his coworkers and other people he knew well escape him? Why couldn't he remember his home phone number?

Because Charles had been healthy and his family believed he was too young to have any serious medical problem, he didn't go to the doctor right away. But, when he could no longer remember his wife's name, he went for help. When Charles saw a neurologist, he was diagnosed with Alzheimer's (*ALTS-hi-mers*) disease.

In 10% of the cases, ***Alzheimer's disease*** begins after age 50, but in 90% of the cases, it begins after age 65. Its initial symptoms are problems with memory, such as forgetting and repeating things, getting lost, and being mildly confused. There are also cognitive deficits, such as problems with language, difficulties in recognizing objects, and inability to plan and organize tasks. Over a period of five to ten years, these symptoms worsen and result in profound memory loss, lack of recognition of family and friends, deterioration in personality, and emotional outbursts. There is widespread damage to the brain, especially the hippocampus, which is involved in memory. At present, there is no cure for Alzheimer's, which is always fatal (NIH, 2005, 2008).



In the United States, Alzheimer's is one of the leading causes of death among adults. Currently, there are more than 5 million people in the United States and 25 million people worldwide who have Alzheimer's disease (Alzheimer's Association, 2008; Cheng, 2008). The number of patients is projected to rise dramatically in the coming decades (right graph) as people are expected to live longer. It is estimated that nearly half of those over age 85 have Alzheimer's (Alzheimer's Association, 2007).

Charles is an example of how someone in his fifties can develop Alzheimer's disease, which is often incorrectly associated only with elderly people. As expected with this devastating disease, his condition is worsening over time. Charles is never without a pen and pad to write down things to not forget, and he has Post-it Notes with written reminders in his pockets and placed throughout his house. These notes are a tremendous help in getting Charles through his day. He now has trouble completing even very simple tasks. He describes Alzheimer's disease as a "cloud over the brain. The simplest things take extreme effort" (C. Schneider, 2006b) (adapted from Fischman, 2006; C. Schneider, 2006a).

For Charles, the worst is yet to come. His memory will fail, he will be bedridden, and he will not know who he is or be able to recognize his family. When he dies—for Alzheimer's has, at present, no cure—Charles will have lost his memory, his wonderful personality, and all signs of humanity.

Diagnosis and Causes

In Charles's case, as well as all cases of individuals with memory and cognitive difficulties, Alzheimer's is diagnosed by identifying a combination of behavioral, neurological, physical, and psychological symptoms. Recently, there has been great success in diagnosing Alzheimer's by identifying brain damage from pictures of living brains (MRI and PET scans, pp. 70–71) (Larson, 2008; Skerrett & Leopold, 2008).

Researchers believe they are close to identifying the causes of Alzheimer's disease, which involve genetic, neurological, and possible environmental factors (Aamodt & Wang, 2008). For example, individuals who inherit a specific gene from their parents are at an increased risk of developing Alzheimer's (Alzheimer's Association, 2008). Also, certain chemicals (proteins and peptides) that occur naturally in all brains for some reason multiply and are believed to cause Alzheimer's. These chemicals act like glue that destroys brain cells (Wolfe, 2006). With these new leads, researchers are optimistic about finding the causes of and developing treatments for Alzheimer's. New treatments are needed because current drugs cannot reverse the brain damage and cognitive impairments caused by Alzheimer's, but only treat its symptoms (Seppa, 2007). Drugs that attack the suspected causes of Alzheimer's are now in clinical trials (Mandavilli, 2009; Skerrett & Leopold, 2008).

What's Coming

The reason Alzheimer's disease will eventually destroy Charles's memory, personality, and humanity is that it gradually destroys the building blocks that form the brain's informational network. We'll explain the two groups of brain cells—glial cells and neurons—that make up this network. We'll discuss how the cells in one group—neurons—have a remarkable ability to receive and send information. You'll discover how brain cells communicate with chemicals that have the ability to start or stop the flow of information. Finally, we'll explain an experimental treatment of implanting neurons to treat brain diseases. We'll use the story of Charles and Alzheimer's disease to illustrate the brain's building blocks.

A. Overview: Human Brain

As Alzheimer's disease slowly destroys Charles's brain, he is also slowly losing his mind. In Charles's case, Alzheimer's disease has progressed to the point that he can no longer get through his day without Post-it Note reminders placed throughout his house.

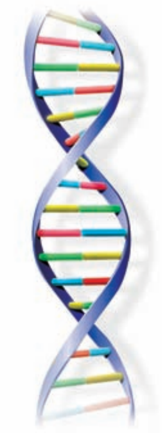
We'll use Charles's brain and his current problems with Alzheimer's disease to answer four related questions: Why isn't the brain a nose? What's in the brain? Can a brain grow new neurons? Can you take a picture of the mind?

Development of the Brain

Why isn't the brain a nose?

The fact that your brain does not develop into a nose is because of instructions contained in your genes.

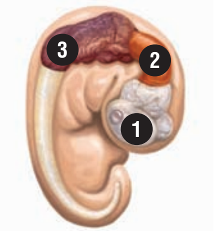
Genes **are chains of chemicals arranged like rungs on a twisting ladder (right figure). There are about 20,000–25,000 genes that contain chemical instructions equal to about 300,000 pages of typed instructions (IHGSC, 2004). The chemical instructions in the genes program the development of millions of individual parts into a complex body and brain.**



Chemical instructions

An amazing feature of the 20,000–25,000 genes is they are contained in a fertilized egg, which is a single cell about the size of a grain of sand. We'll explain more about the genes and their chemical instructions in the next module (see p. 68).

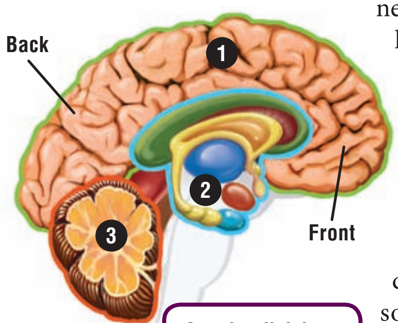
In the brain's early stages of development, it looks nothing like the final product. For example, the figure below looks more like some strange animal than what it really is, a six-week-old human embryo with a developing brain.



3 major divisions of 6-week-old brain

Six-Week-Old Brain. This drawing represents a greatly enlarged six-week-old human embryo. The 3 labeled areas (in 3 colors) will eventually develop into the 3 major divisions of the mature human brain that is shown below.

Mature Brain. The 3 labeled areas represent the 3 major divisions of the mature brain that we'll discuss in the next module. The mature human brain (side view) weighs almost 3 pounds and contains about 1 trillion cells (Ropper & Samuels, 2009).



3 major divisions of adult brain

In the case of Charles, who developed Alzheimer's disease, researchers think some of his genetic instructions were faulty. The faulty instructions resulted in an abnormal buildup in the brain of gluelike substances that gradually destroy brain cells (Cheng, 2008; Sergo, 2008). Next, we'll explain the two different kinds of brain cells and which ones are destroyed by Alzheimer's disease.

Structure of the Brain

What's in your brain?

On the right is a top view of a human brain. It is shaped like a small wrinkled melon, weighs about 1,350 grams (less than 3 pounds), has a pinkish-white color, and has the consistency of firm JELL-O®. Your brain is fueled by sugar (glucose) and has about 1 trillion cells that can be divided into two groups—glial cells and neurons.

Top view of human brain

Glial Cells. The most numerous brain cells, about 900 billion, are called glial (*GLEE-all*) cells.

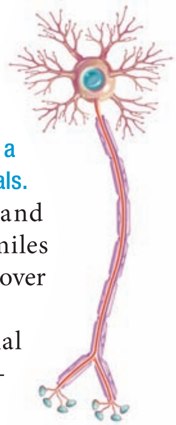
Glial cell

Glial cells **(astrocytes) have at least three functions: providing scaffolding to guide the growth of developing neurons and support mature neurons; wrapping around neurons to form insulation to prevent interference from other electrical signals; and releasing chemicals that influence a neuron's growth and function (Verkhratsky & Butt, 2007).**

Glial cells grow throughout one's lifetime. If something causes the uncontrolled growth of glial cells, the result is brain cancer. Until recently, glial cells were believed to have only supportive functions (as described above), but research now shows some glial cells may transmit electrical signals, which is the major function of neurons, which we'll discuss next (Leitzell, 2008; Saey, 2008b).

Neurons. The second group of brain cells, which number about 100 billion, are called neurons (*NER-ons*); one is shown on the right.

A ***neuron*** **is a brain cell with two specialized extensions. One extension is for receiving electrical signals, and a second, longer extension is for transmitting electrical signals.**



Neuron

Depending upon their size, neurons receive and transmit electrical signals at speeds of up to 200 miles per hour over distances from a fraction of an inch to over 3 feet, such as from your toe to your spinal cord.

Neurons form a vast, miniaturized informational network that allows us to receive sensory information, control muscle movement, regulate digestion, secrete hormones, and engage in complex mental processes such as thinking, imagining, dreaming, and remembering.

Charles's brain was constructed from two kinds of building blocks—glial cells and neurons. However, it is the neurons that Alzheimer's disease gradually destroys; the result is that Charles's brain is losing its ability to transmit information, causing memory and cognitive difficulties. Why neurons do not usually repair or replace themselves is our next topic.

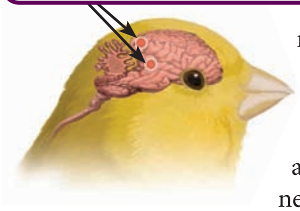
Growth of New Neurons

Can a brain grow new neurons?

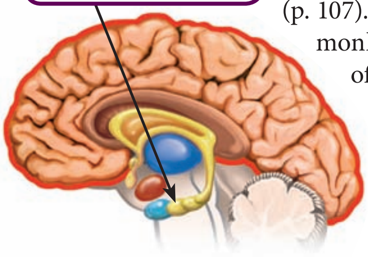
If you had a bird's brain, you could grow new neurons every spring. A male canary learns to sing a breeding song in the spring, but when breeding season is over, the ability to sing the song disappears. However, come next spring, an adult canary's brain begins growing about 20,000 new neurons a day, and, during this short period, the bird relearns the breeding song. These new neurons result in a 50% or more increase in neurons in two areas of the canary's brain (left figure) that control singing (G. Miller, 2003). Without a doubt, an adult canary's brain can regularly grow new neurons (Kim et al., 2008).



The two red dots show two areas of the mature canary's brain that increase by 50% with the growth of new neurons.

Primate Brains. Does the fact that adult canaries as well as adult mice, rats, and other animals can grow new neurons also hold true for adult human brains (Barinaga, 2003)? Researchers believe that, with few exceptions, the brains of adult primates, such as humans and chimpanzees, develop almost all their neurons at birth and adult brains do not grow new neurons (Kornack & Rakic, 2001).

The few exceptions to the finding that new neurons do not grow in adult brains were found in two areas of the brain—hippocampus (p. 80) and olfactory bulb (p. 107). Researchers concluded that adult monkey and human brains are capable of growing a relatively limited number of new neurons throughout adulthood and that some of these new neurons play an important role in our continuing ability to learn and remember new things (S. Halpern, 2008; Saey, 2008c).



Growth of new neurons is found in this area of the mature human brain (hippocampus).

Repairing the Brain. Besides having a limited capacity to grow new neurons throughout adulthood, mature human brains also have a limited capacity to replace, rewire, or repair damaged neurons, such as after a stroke, gunshot wound, or blow to the head (SFN, 2007; J. Silver & Miller, 2004). One reason neurons have only a limited capacity to be repaired or rewired after damage is that there is a genetic program that turns off regrowth when neurons become fully grown (Aamodt & Wong, 2008; McKerracher & Ellezam, 2002). This limited capacity of the adult brain to rewire itself by forming new connections helps explain why people may recover some, but rarely all, of the functions initially lost after brain damage. Recent advances in stem cell research suggest the human brain may be able to grow more neurons. If this were possible, the brain could repair damage caused by an accident or disease, such as Alzheimer's (Wieloch & Nikolich, 2006).

The reason Alzheimer's disease is so destructive and eventually leads to death is that this disease destroys neurons many times faster than the brain's limited capacity for regrowth, repair, or rewiring. As Alzheimer's destroys Charles's brain, what is happening to his mind?

Brain Versus Mind

Can you take a picture of the mind?

As Alzheimer's disease destroys Charles's brain, he is also losing his mind, which brings us to the mind-body question.

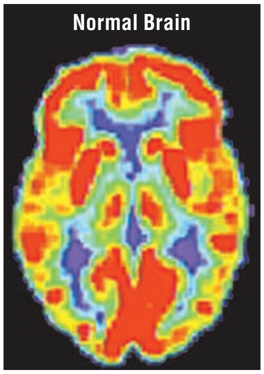
The *mind-body question* asks how complex mental activities, such as feeling, thinking, and learning, can be explained by the physical, chemical, and electrical activities of the brain.

Through the centuries, philosophers and scientists have given different answers to the mind-body question, some believing the mind and brain are separate things and others saying the mind and brain are one and the same (Hergenhahn, 2009).

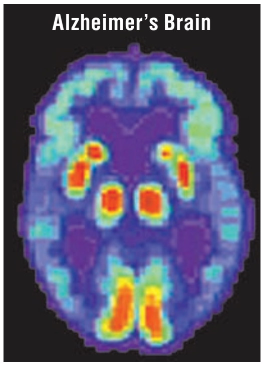
For example, Nobel Prize winner and geneticist Francis Crick (2002) believes the mind ***is*** the brain: "You, your joys and your sorrows, your memories and your ambition, your sense of personal identity and free will, are in fact no more than the behavior of a vast assembly of nerve cells and their associated molecules." Although some agree with Crick's answer—that the mind and brain are the same—others reply that mental activities cannot be reduced to the physical activities of the brain (Mahoney, 2005).

Another answer comes from Nobel Prize winner and neurophysiologist Roger Sperry (1993), who said that the brain is like a coin with two sides. One side consists of physical reactions, such as making chemicals that neurons use for communicating. The other side consists of all of our mental functions, such as thinking, imagining, and deciding. According to Sperry, the brain's chemicals (physical side) influence consciousness and mental activities, which, in turn, influence the production of more or different brain chemicals. There is considerable support for Sperry's idea of continuous interaction between the physical and mental sides (Dolan, 2007).

Alzheimer's. In Charles's case, as Alzheimer's disease destroys his brain, he also loses more and more of his mental activities, such as knowing, thinking, and deciding. Researchers can study a person's mental activities by taking brain scans of the neural activities going on inside the living brain (brain scans are discussed on pp. 70–71). For example, the top right brain scan shows a great amount of neural activity occurring inside a normal brain (red/yellow indicate most neural activity, blue/green indicate least activity). In comparison, the bottom right brain scan shows relatively little neural activity and thus relatively little mental activity occurring inside an Alzheimer's brain. These kinds of brain scans show that neural activities and mental activities are closely linked, and researchers are studying how these links occur (E. L. Diamond et al., 2007; Mosconi et al., 2005).



Normal Brain



Alzheimer's Brain

Knowing now how important neurons are to your mental and physical functions, we next examine them in more detail.

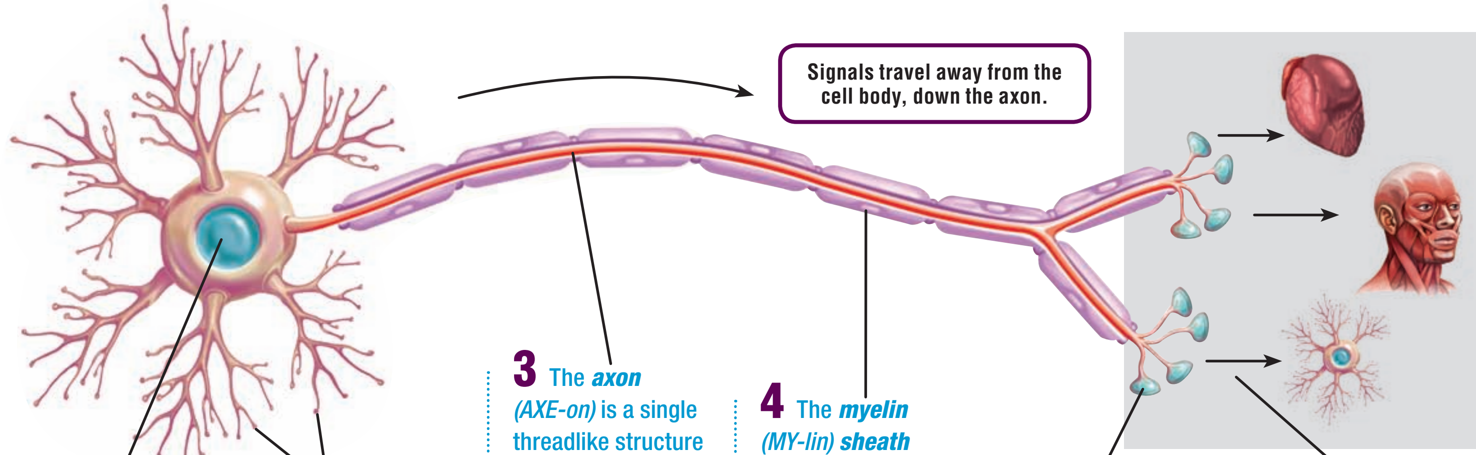
B. Neurons: Structure & Function

Parts of the Neuron

Why could Charles think, move, and talk?

Before Charles developed Alzheimer's disease, he was able to engage in an incredible variety of cognitive and physical behaviors. He was able to think, remember, walk, smile, and speak—all because of the activity of millions of microscopic brain cells called neurons. We'll examine the neuron, which comes in many wondrous shapes and sizes and has only three basic structures—cell body, dendrites, and axon.



1 The ***cell body*** (or soma) is a relatively large, egg-shaped structure that provides fuel, manufactures chemicals, and maintains the entire neuron in working order.

In the center of the cell body is a small oval shape representing the nucleus, which contains genetic instructions (in the form of DNA) for both the manufacture of chemicals and the regulation of the neuron.

2 ***Dendrites*** *(DEN-drites)* are branchlike extensions that arise from the cell body; they receive signals from other neurons, muscles, or sense organs and pass these signals to the cell body.

At the time of birth, a neuron has few dendrites. After birth, dendrites undergo dramatic growth that accounts for much of the increase in brain size. As dendrites grow, they make connections and form communication networks between neurons and other cells or organs.

3 The ***axon*** *(AXE-on)* is a single threadlike structure that extends from, and carries signals away from, the cell body to neighboring neurons, organs, or muscles.

Here the axon is indicated by an orange line inside the tube composed of separate gray segments. Axons vary in length from less than a hair's breadth to as long as 3 feet (from your spinal cord to your toes). An axon conducts electrical signals to a neighboring organ (heart), a muscle, or another neuron.

4 The ***myelin*** *(MY-lin)* ***sheath*** looks like separate tubelike segments composed of fatty material that wraps around and insulates an axon. The myelin sheath prevents interference from electrical signals generated in adjacent axons.

The axons of most large neurons, including motor neurons, have myelin sheaths. You may have heard the brain described as consisting of gray and white matter. Gray is the color of cell bodies, while white is the color of myelin sheaths.

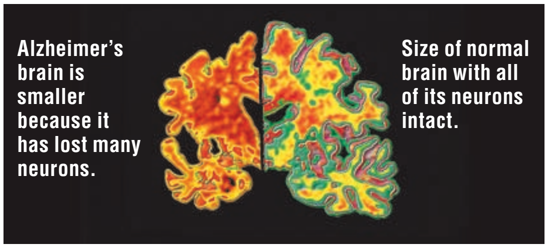
5 ***End bulbs*** or ***terminal bulbs*** look like tiny bubbles that are located at the extreme ends of the axon's branches. Each end bulb is like a miniature container that stores chemicals called neurotransmitters, which are used to communicate with neighboring cells.

End bulbs reach right up to, but do not physically touch, the surface of a neighboring organ (heart), muscle (head), or another cell body.

6 The ***synapse*** *(SIN-apse)* is an infinitely small space (20–30 billionths of a meter) that exists between an end bulb and its adjacent body organ (heart), muscles (head), or cell body.

When stimulated by electrical signals from the axon, the end bulbs eject neurotransmitters into the synapse. The neurotransmitters cross the synapse and act like switches to turn adjacent cells on or off. We'll explain this switching process a little later.

Alzheimer's Disease and Neurons



Alzheimer's brain is smaller because it has lost many neurons.
Size of normal brain with all of its neurons intact.

In Alzheimer's disease there is an excessive buildup of gluelike substances, which gradually destroy neurons (Larson, 2008). In Charles's case, these gluelike substances will destroy many of his neurons, causing his brain to actually shrink, as shown by the very deep creases in the Alzheimer's brain (left photo). Researchers have been testing experimental vaccines that may help stop and prevent the buildup of these killer substances, and they continue to search for other interventions (Reinberg, 2008).

We have discussed the structure and function of neurons, but it is important not to confuse neurons (in your brain and spinal cord) with nerves (in your body).

C. Neurons Versus Nerves

Reattaching Limbs

What's unusual about John's arms?

John Thompson was 18 when a farm machine ripped off both of his arms just below his shoulders. Since he was home alone, he had to walk to the farmhouse, open the front door with his mouth, and with a pencil clenched in his teeth, dial the phone for help. When paramedics arrived, he reminded them to get his two arms, which were still stuck in the farm equipment. John was taken to the hospital, where doctors reattached both arms (indicated by red arrows in left photo).

Both his arms were torn off and then reattached.

Three months later, John could raise his arms up but could not move them below his elbows. After several years of physical therapy and 20 operations, John can raise his reattached arms over his head, make fists, and grip with his hands. John must constantly work at maintaining mobility and strength in his arms (Thompson & Grosinger, 2001). In another case, a donor hand was attached to the arm of a person whose own hand was severed (B. Bower, 2008d).

Transplanting a Face

Can parts of your face be transplanted onto someone else's?

In 2005, French doctors performed the world's first-ever face transplant, a very risky and complex procedure. Doctors removed facial tissue from a dead woman's face and transplanted it onto Isabelle, a 38-year-old woman whose face had been severely disfigured by a dog. She received a new nose, lips, and chin during the surgery (Gorman, 2005b). A few months after the surgery, Isabelle said, "I can open my mouth and eat. I feel my lips, my nose and my mouth" (Doland, 2006). Her ability to experience facial sensations and control facial muscles continues to improve now years later. There is still the risk her body will reject the donor's facial tissue (it has already done so twice), but so far the surgery has been a great success (R. Weiss, 2007).

The fact that severed nerves in arms, hands, or face can be reattached but neurons in a severed spinal cord are difficult to reattach illustrates a major difference between the peripheral and central nervous systems.

Isabelle with makeup one year after face transplant.

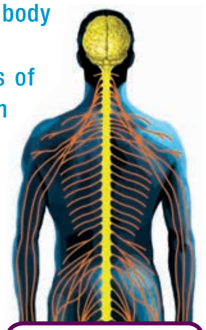
Peripheral Nervous System

Why can limbs be reattached?

Severed limbs can be reattached and regain movement and sensation because their nerves are part of the peripheral nervous system.

The ***peripheral nervous system*** is made up of nerves, which are located throughout the body except in the brain and spinal cord.

Nerves are stringlike bundles of axons and dendrites that come from the spinal cord and are held together by connective tissue (shown in orange in right figure). Nerves carry information from the senses, skin, muscles, and the body's organs to and from the spinal cord. Nerves in the peripheral nervous system have the ability to regrow or reattach if severed or damaged.



Peripheral nerves can be reattached.

The fact that nerves can regrow means that severed limbs can be reattached and limb transplants are possible. However, limb transplants are risky because a person must take drugs long-term to suppress his or her own immune system, whose normal job is to destroy "foreign" things, such as a donor's transplanted limb. When his or her own immune system is suppressed, a person is at risk for getting serious infectious diseases (Lake et al., 2007).

The remarkable ability of nerves to regrow and be reattached distinguishes them from neurons.

Central Nervous System

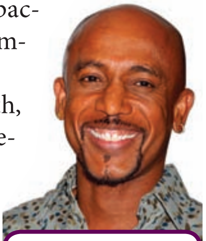
Why do Montel's feet hurt?

People may have numbness or paralysis after damage to their brain or spinal cord because of what neurons cannot easily do.

The ***central nervous system*** is made up of neurons located in the brain and spinal cord (shown in blue in left figure).

The adult human brain has a limited capacity to grow new neurons and to make new connections. Once damaged, neurons usually die and are not replaced.

Because neurons have a limited capacity for repair and regrowth, people who have an injured or damaged brain or spinal cord experience some loss of sensation and motor movement, depending upon the severity of the damage. For example, Montel Williams (right photo), a former television talk-show host, has suffered from pain in his feet and legs for many years as a result of ***multiple sclerosis,*** a disease that attacks the myelin sheaths that wrap around and insulate cells in the central nervous system.



Montel was diagnosed with multiple sclerosis.

As a result of this damage, messages between the brain and other parts of the body are disrupted, often causing problems in motor coordination, strength, and sensation (Pirko & Noseworthy, 2007).

Currently, one of the most exciting areas of research involves techniques that stimulate the regrowth or repair of damaged neurons. For example, axons, which carry information up and down the spinal cord, normally wither and die after injury. Two methods to promote the regrowth of axons are providing tubes that guide their growth and injecting growth-producing chemicals (M. E. Schwab, 2002). The newest approach for treating brain damage is to replace damaged neurons by transplanting fetal tissue or stem cells (taken from embyros) into the damaged area. This method has great potential for treating brain and spinal cord diseases, such as Alzheimer's and multiple sclerosis (Karussis & Kassis, 2007; A. M. Wong et al., 2005). We'll discuss stem cell transplants in the Application section.

Now that you know the structure of the neuron, we'll explain one of its amazing functions: sending information at speeds approaching 200 miles per hour.

D. Sending Information

Sequence: Action Potential

1 Feeling a Sharp Object

When you step on a sharp object, you seem to feel the pain almost immediately because neurons send signals at speeds approaching 200 mph. To feel the pain involves the following series of electrochemical events:

A. Some stimulus, such as a tack, causes a change in physical energy. The tack produces mechanical pressure on the bottom of your foot.

B. Your skin has sensors that pick up the mechanical pressure and transform it into electrical signals. (We'll discuss various kinds of sensors in Module 5.)

C. The sensors' electrical signals are sent by the neuron's axon to various areas in the spinal cord and brain.

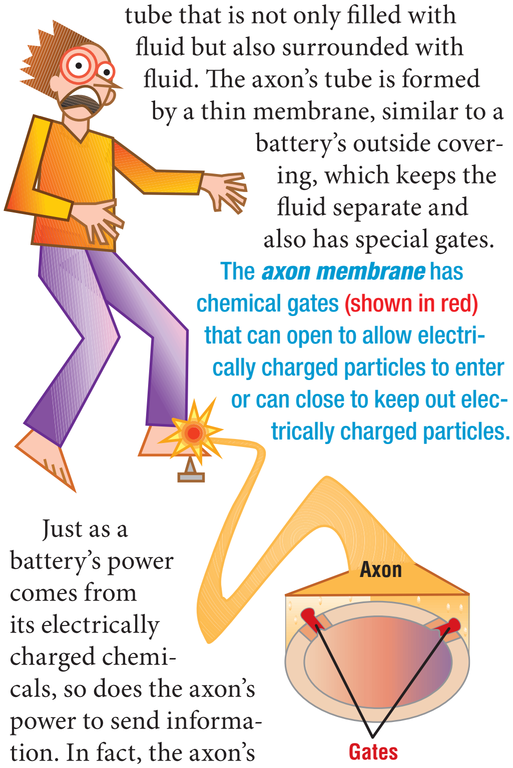
D. Finally, your brain interprets these electrical signals as "pain."

We're going to focus on step C and explain how axons send electrical signals by using the analogy of a battery. We'll begin by enlarging the inside of an axon.

2 Axon Membrane: Chemical Gates

Just as a battery has a protective covering, so too does the axon. Think of an axon as a long tube that is not only filled with fluid but also surrounded with fluid. The axon's tube is formed by a thin membrane, similar to a battery's outside covering, which keeps the fluid separate and also has special gates.

The ***axon membrane*** has chemical gates (shown in red) that can open to allow electrically charged particles to enter or can close to keep out electrically charged particles.

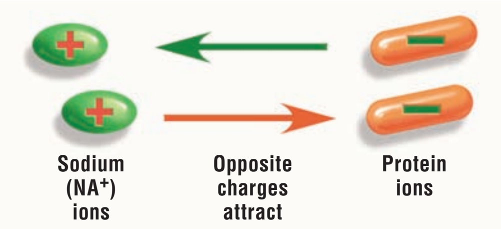


Just as a battery's power comes from its electrically charged chemicals, so does the axon's power to send information. In fact, the axon's electrically charged particles are the key to making it a living battery.

3 Ions: Charged Particles

The fluid inside and outside the axon contains ions.

Ions are chemical particles that have electrical charges. Ions follow two rules: Opposite charges attract (figure below), and like charges repel.



The fluid contains several different ions, such as sodium, potassium, chloride, and protein. The axon's function is often explained by discussing sodium and potassium ions. However, it is simpler and easier to focus on just sodium ions, which have positive charges and are abbreviated Na^+, and large protein ions, which have negative charges and are labeled protein$^-$. Because they have opposite charges, Na^+ ions will be attracted to protein$^-$ ions (figure above).

Because the axon's membrane separates the positive sodium ions from the negative protein ions, we have the makings of a living battery, as shown in section 4 on the next page.

Sequence: Nerve Impulse

6 Sending Information

One mistake students make is to think that the axon has ONE action potential, similar to the bang of a gunshot. However, unlike a gunshot, the axon has numerous individual action potentials that move down the axon, segment by segment; this movement is called the nerve impulse.

The ***nerve impulse*** refers to the series of separate action potentials that take place segment by segment as they move down the length of an axon.

Thus, instead of a single bang, a nerve impulse goes down the length of the axon very much like a lit fuse. Once lit, a fuse doesn't go off in a single bang but rather burns continuously until it reaches the end. This movement of a nerve impulse all the way down to the end of an axon is actually a natural law.

7 All-or-None Law

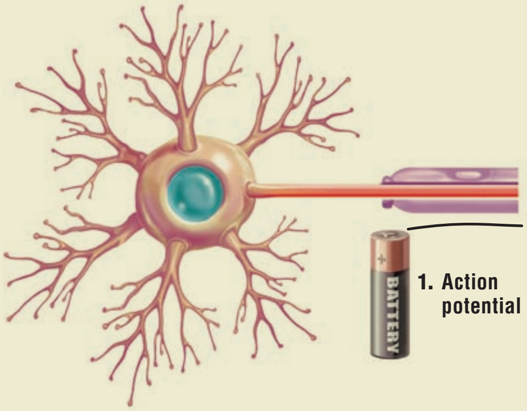
Why does a nerve impulse travel down the axon's entire length? The answer is the all-or-none law.

The ***all-or-none law*** says that, if an action potential starts at the beginning of an axon, the action potential will continue at the same speed, segment by segment, to the very end of the axon.

You'll see how the all-or-none law works in the next figure.

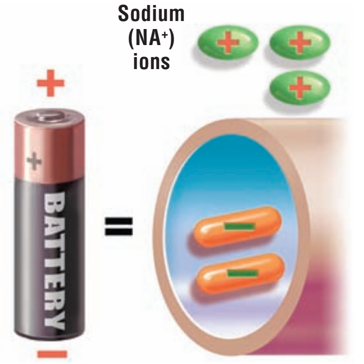
8 Nerve Impulse

Notice in this drawing, which continues on the next page, that the nerve impulse is made up of a sequence of six action potentials, with the first action potential occurring at the beginning of the axon.



4 Resting State: Charged Battery

The axon membrane separates positively charged sodium ions on the outside from negatively charged protein ions on the inside. This separation produces a miniature chemical battery that is not yet discharging and, thus, is said to be in its resting state.



The ***resting state*** means that the axon has a charge, or potential; it resembles a battery. The charge, or potential, results from the axon membrane separating positive ions on the outside from negative ions on the inside (left figure).

The axon membrane has a charge across it during the resting state because of several factors, the primary one being the sodium pump. (To simplify our explanation of the resting state, we won't discuss other pump or transport systems.)

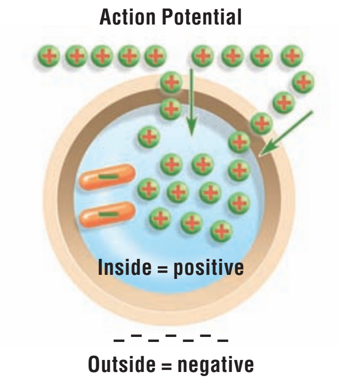
The ***sodium pump*** is a transport process that picks up any sodium ions that enter the axon's chemical gates and returns them back outside. Thus, the sodium pump is responsible for keeping the axon charged by returning and keeping sodium ions outside the axon membrane.

In the resting state, the axon is similar to a fully charged battery. Let's see what happens when the resting state is disrupted and the battery discharges.

5 Action Potential: Sending Information

If a stimulus, such as stepping on a tack, is large enough to excite a neuron, two things will happen to its axon. First, the stimulus will eventually open the axon's chemical gates by stopping the sodium pump. Second, when the stoppage of the sodium pump causes the gates to open, thousands of positive sodium ions will rush inside because of their attraction to the negative protein ions. The rush of sodium ions inside the axon is called the action potential.

The ***action potential*** is a tiny electric current that is generated when the positive sodium ions rush inside the axon. The enormous increase of sodium ions inside the axon causes the inside of the axon to reverse its charge. The inside becomes positive, while the outside becomes negative.



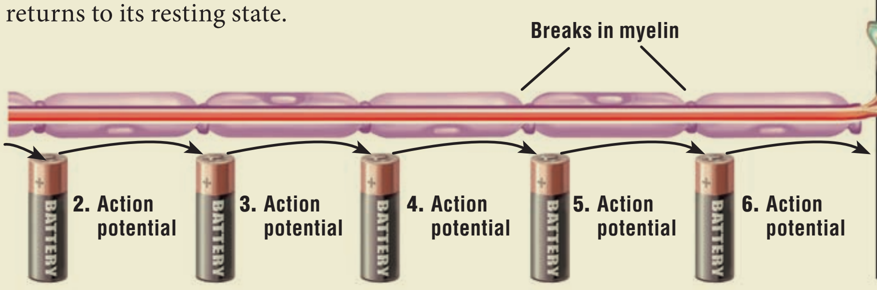
5a Just as a current flows when you connect the poles of a battery, current also flows when sodium ions rush through the opened gates of the axon membrane.

5b During an action potential, the inside of the axon changes to positive and the outside changes to negative. Immediately after the action potential, the sodium pump starts up and returns the axon to the resting state.

At this point, imagine that an action potential has started at the beginning of an axon. How action potentials whiz at race-car speeds down the entire length of an axon is what we'll examine next in the section below, Sequence: Nerve Impulse.

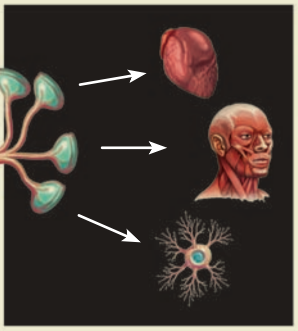
8a According to the all-or-none law, once a nerve impulse begins, it goes to the end of the axon. This means that when action potential 1 occurs, it will be followed in order by potentials 2, 3, 4, 5, and 6. After the occurrence of each action potential, the axon membrane at that point quickly returns to its resting state.

8b Notice that the ***myelin sheath*** has regular breaks where the axon is bare and uninsulated. It is at these bare points that the axon's gates open and the action potential takes place.



9 End Bulbs and Neurotransmitters

Once the nerve impulse reaches the end of the axon, the very last action potential, 6, affects the end bulbs, which are located at the very end of the axon. This last action potential triggers the end bulbs to release their neurotransmitters. Once released, neurotransmitters cross the synapse and, depending upon the kind, they will either excite or inhibit the function of neighboring organs (heart), muscles (head), or cell bodies.



As you can now see, neurotransmitters are critical for communicating with neighboring organs, muscles, and other neurons. We'll examine transmitters in more detail and show you how they excite or inhibit.

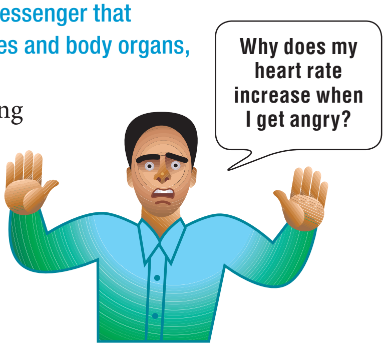
E. Transmitters

Excitatory and Inhibitory

What makes your heart pound?

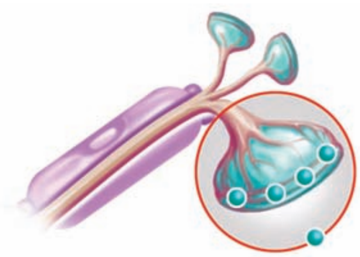
There's no doubt that you have felt your heart pounding when you are afraid, stressed, or angry. One reason for your pounding heart has to do with transmitters.

A ***transmitter*** is a chemical messenger that carries information between nerves and body organs, such as muscles and heart.



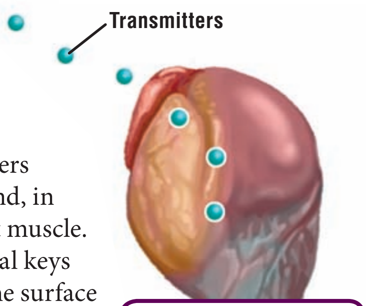
Why does my heart rate increase when I get angry?

Everything you do, including thinking, deciding, talking, and getting angry, involves transmitters. For example, imagine seeing someone back into your brand new car and then just drive away. You would certainly become angry and your heart would pound. Let's see why getting angry can increase your heart rate from a normal 60 to 70 beats per minute to over 180.



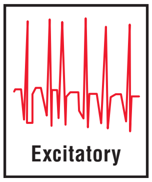
1 In the figure on the left, you see the end of an axon with 3 branches. At the end of the bottom branch is a greatly enlarged ***end bulb.*** Inside the bulb are 4 colored circles that represent transmitters.

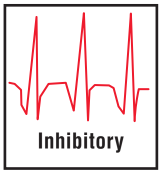
2 When the action potential hits the ***end bulb,*** it causes a miniature explosion, and the transmitters are ejected outside. Once ejected, transmitters cross a tiny space, or synapse, and, in this case, reach the nearby heart muscle. Think of transmitters as chemical keys that fit into chemical locks on the surface of the heart muscle. End bulbs usually hold either excitatory or inhibitory transmitters, which have opposite effects.



Transmitters can increase or decrease heart rate.

3 Strong emotions cause the release of ***excitatory transmitters,*** which open chemical locks in the heart muscle and cause it to beat faster (left figure). When you get very angry, excitatory transmitters may cause your heart rate to double or even triple its rate. When you start to calm down, there is a release of ***inhibitory transmitters,*** which block chemical locks in the heart muscle and decrease its rate (right figure). Think of transmitters acting like chemical messengers that either excite or inhibit nearby body organs (heart), neurons, or muscle fibers. One special class of transmitters that are made in the brain are called neurotransmitters.





Neurotransmitters

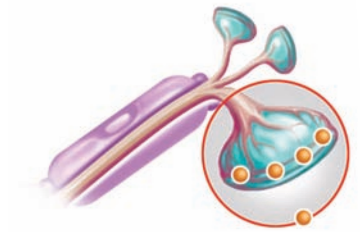
What makes your brain work?

Writing a paper on a computer requires your brain to use millions of neurons that communicate with one another by using chemicals called neurotransmitters.

Neurotransmitters are about a dozen different chemicals that are made by neurons and then used for communication between neurons during the performance of mental or physical activities.

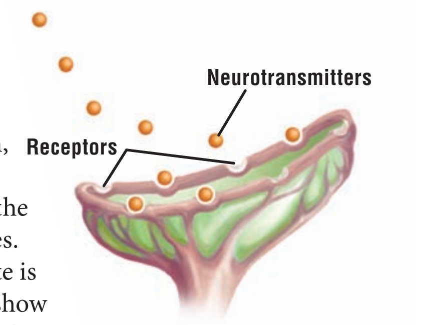
What happens in my brain when I use my computer?

Since billions of neurons that are packed tightly together use different neurotransmitters for eating, sleeping, talking, thinking, and dreaming, why don't neurotransmitters get all mixed up? The answer is that neurotransmitters are similar to chemical keys that fit into only specific chemical locks.



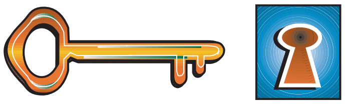
1 The figure on the left again shows the end of an axon with 3 branches. We have again enlarged one ***end bulb*** to show that it contains neurotransmitters (4 colored circles).

2 The action potential causes the end bulbs to eject their neurotransmitters (yellow circles), which, in turn, cross the synapse and, in this case, land on the surface of nearby dendrites. The surface of one dendrite is enlarged (right figure) to show its ***receptors*** (white notches), which are special areas that function like chemical locks.



Receptors on dendrites are like chemical locks.

3 Although there are many different neurotransmitters, each one has a unique chemical key that fits and opens only certain chemical locks, or receptors. Thus, billions of neurons use this system of chemical keys that open or close matching locks to communicate and to participate in so many different activities. Also, remember that some neurotransmitters are ***excitatory***—they open receptor locks and turn on neurons—while others are ***inhibitory***—they close locks and turn off neurons.



Since neurons use neurotransmitters to communicate, any drug that acts like or interferes with neurotransmitters has the potential to change how the brain functions and how we feel, think, and behave. For example, here's what alcohol does.

Alcohol

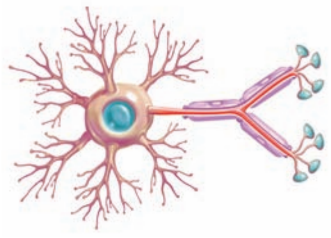
What does alcohol do?

Drinking alcoholic beverages usually raises the level of alcohol in the blood, which is measured in terms of blood alcohol content (BAC). For example, at low to medium doses (0.01–0.06 BAC), alcohol causes friendliness, loss of inhibitions, decreased self-control, and impaired social judgment; after 3 or 4 drinks, the average person's BAC will range from 0.08 to 0.1, which meets the legal definition of drunkenness in most states. (Alcohol is discussed more fully in Module 8.)

Why do I feel different after drinking?
B

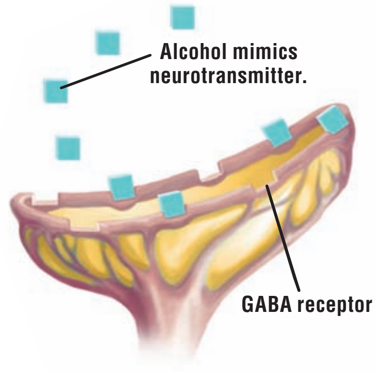
***Alcohol* (ethyl alcohol) is a psychoactive drug that is classified as a depressant, which means that it depresses the activity of the central nervous system.**

Alcohol has been around for 3,000 years, but researchers have only recently determined its many effects on the brain. We'll discuss one of its major effects on the brain.



GABA neurons. Alcohol affects the nervous system in a number of ways, blocking some neural receptors and stimulating others. For example, some neurons are excited by a neurotransmitter called GABA *(GAH-bah),* which the brain normally manufactures. This means that GABA neurons (figure above) have chemical locks that can be opened by chemical keys in the form of the neurotransmitter GABA (Purves et al., 2008).

GABA keys. Now here's the interesting part. Alcohol molecules so closely resemble those of the GABA neurotransmitter that alcohol can function like GABA keys and open GABA receptors (figure right). Opening GABA receptors excites GABA neurons. Although it seems backward, when GABA neurons are *excited,* they *decrease* neural activity and produce inhibitory effects, such as a loss of inhibitions and self-control, as well as reduced anxiety. In fact, one reason alcohol has become so popular is that many people drink alcohol to feel less anxious and more relaxed. It is interesting that there appears to be a biological link between alcohol and anxiety. Researchers found that a deficiency in a specific brain protein is associated with high anxiety and excessive alcohol use (Wand, 2005).



We learned that alcohol affects the brain by imitating a naturally occurring neurotransmitter, GABA. Let's now look at the effects other drugs have on the brain's neurotransmitters.

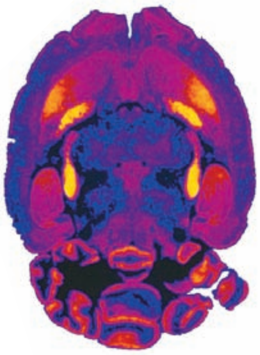
New Transmitters

What are the latest discoveries?

There are a number of well-known neurotransmitters, such as norepinephrine, GABA, dopamine, and serotonin. And researchers continue to discover new ones to add to the list of neurotransmitters.

Endorphins. In the 1970s, researchers discovered the brain makes its own painkiller, very similar to morphine. They called this neurotransmitter endorphin, which is secreted to decrease pain during great bodily stress, such as an accident (Drolet et al., 2001). We'll discuss the effects of endorphins on page 113.

Anandamide. In the early 1990s, researchers discovered a somewhat surprising neurotransmitter, called anandamide, which is similar in chemical makeup to THC, the active ingredient in marijuana (discussed on p. 186) (Fackelmann, 1993). The figure on the right shows a horizontal section of a rat brain treated with a radioactive version of anandamide. The yellow areas, which were most affected by anandamide, are involved in memory, motor coordination, and emotions (Herkenham, 1996). Anandamide may help people regulate emotions, which would help them better cope with anxiety and stress (Moreira & Lutz, 2008).



Yellow areas show where marijuana-like anandamide acts.

Nitric oxide. In the mid-1990s, researchers discovered that a gas, nitric oxide, functions like a neurotransmitter and may regulate emotions. For example, mice genetically altered to lack nitric oxide were six times more likely to pick a fight compared to normal mice (R. J. Nelson et al., 1995). Researchers believe nitric oxide may regulate aggressive and impulsive behaviors not only in mice but also in humans (Chiavegatto et al., 2006).

Changing neurotransmitter levels in rats causes increased aggression.

Orexin (hypocretin). In the late 1990s, researchers discovered orexin (hypocretin), a neurotransmitter involved in the brain's pleasure and reward system. In animal studies, researchers could initiate or reduce cravings for drugs and food by activating or blocking orexin (G. C. Harris et al., 2005). Orexin is also involved in regulating sleep and wakefulness. For instance, low levels of this neurotransmitter have been linked to a serious sleep disorder called narcolepsy (discussed on p. 163) (Sakurai, 2007).

The important point to remember about neurotransmitters is their system of chemical keys and locks permits very effective communication among billions of neurons, which allow us to move, sense, think, feel, and perform hundreds of other functions.

Now that you are familiar with neurons and neurotransmitters, we'll explain a response that many of you have experienced—what happened when you touched a hot object.

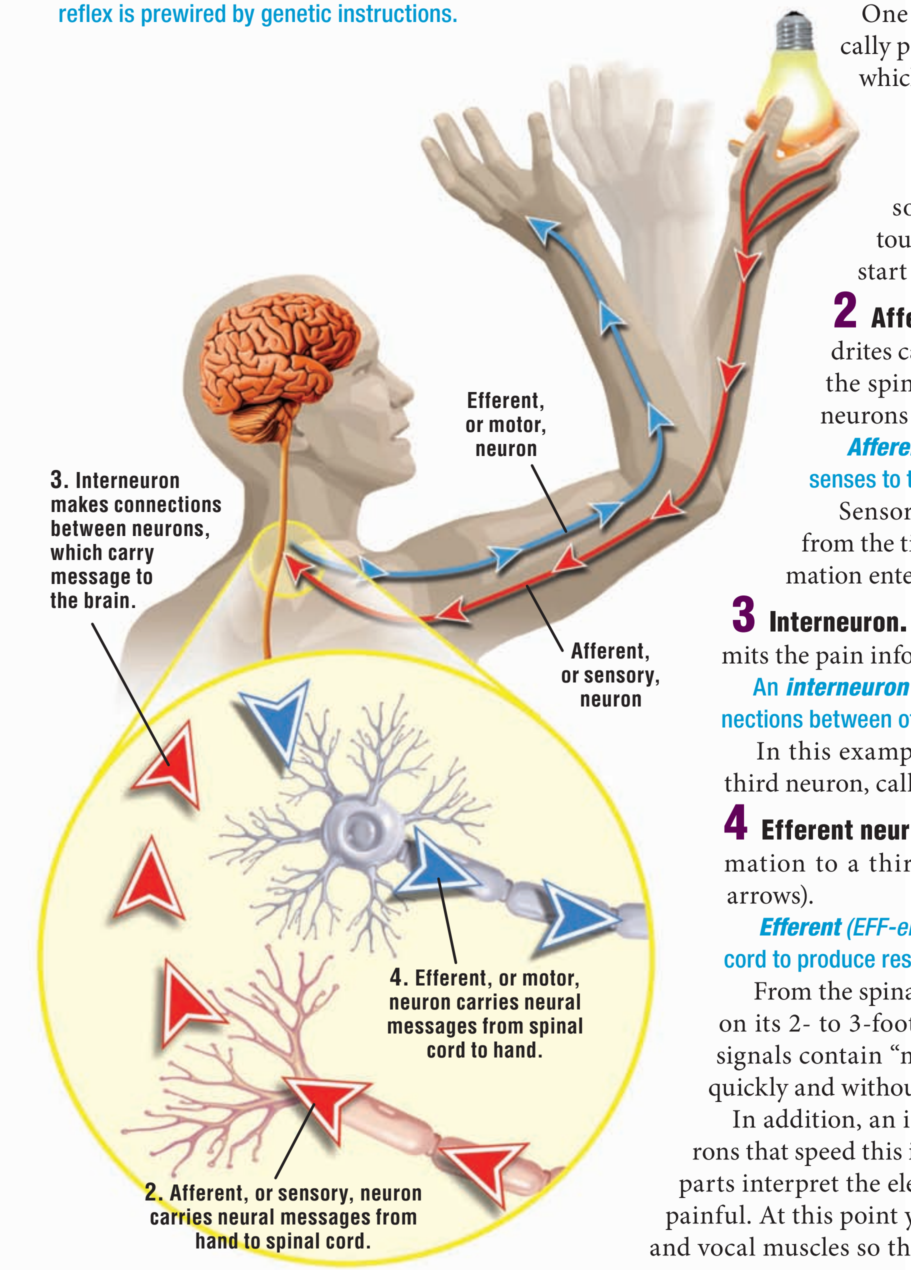
F. Reflex Responses

Definition and Sequence

Can you move without thinking?

If you accidentally touched a hot light bulb, your hand would instantly jerk away, without any conscious thought or effort on your part. This is an example of a reflex.

A *reflex* is an unlearned, involuntary reaction to some stimulus. The neural connections or network underlying a reflex is prewired by genetic instructions.



Efferent, or motor, neuron
3. Interneuron makes connections between neurons, which carry message to the brain.
Afferent, or sensory, neuron
4. Efferent, or motor, neuron carries neural messages from spinal cord to hand.
2. Afferent, or sensory, neuron carries neural messages from hand to spinal cord.

In some cases, such as when a doctor taps your knee, the knee-jerk reflex is controlled by the spinal cord. In other cases, such as when someone shines a bright light into your eye, the pupillary reflex causes the pupil to constrict. We are all born with a number of programmed reflexes, and all reflexes share the same two or three steps, depending upon how they are wired in the nervous system.

One reason reflexes occur so quickly is that they are genetically programmed and involve relatively few neural connections, which saves time. Here's the sequence for how a reflex occurs:

1 Sensors. The skin of your fingers has specialized sensors, or receptors, that are sensitive to heat. When you touch a hot light bulb, these skin sensors trigger neurons that start the withdrawal reflex.

2 Afferent neuron. From the receptors in your skin, long dendrites carry "pain information" in the form of electrical signals to the spinal cord. These dendrites are part of sensory, or afferent, neurons (red arrows).

Afferent **(AFF-er-ent), or *sensory, neurons* carry information from the senses to the spinal cord.**

Sensory neurons may have dendrites 2 to 3 feet long, to reach from the tips of your fingers to the spinal cord. When the pain information enters the spinal cord, it is transmitted to a second neuron.

3 Interneuron. Once the afferent neuron reaches the spinal cord, it transmits the pain information to a second neuron, called an interneuron.

An *interneuron* is a relatively short neuron whose primary task is making connections between other neurons.

In this example, an interneuron transmits the pain information to a third neuron, called the efferent, or motor, neuron.

4 Efferent neuron. Inside the spinal cord, an interneuron transfers information to a third neuron, called an efferent, or motor, neuron (blue arrows).

Efferent **(EFF-er-ent), or *motor, neurons* carry information away from the spinal cord to produce responses in various muscles and organs throughout the body.**

From the spinal cord, an efferent (motor) neuron sends electrical signals on its 2- to 3-foot-long axon to the muscles in the hand. These electrical signals contain "movement information" and cause the hand to withdraw quickly and without any thought on your part.

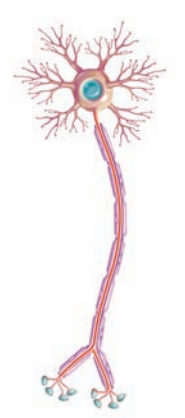
In addition, an interneuron will send the pain information to other neurons that speed this information to different parts of the brain. These different parts interpret the electrical signals coming from your hand as being hot and painful. At this point your brain may direct motor neurons to move your facial and vocal muscles so that you look pained and yell "Ouch!" or something much more intense.

Functions of a Reflex

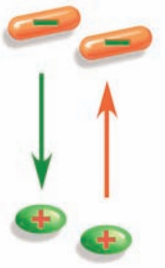
The primary reason you automatically withdraw your hand when touching a hot object, turn your head in the direction of a loud noise, or vomit after eating tainted food has to do with survival. Reflexes, which have evolved through millions of years, protect body parts from injury and harm and automatically regulate physiological responses, such as heart rate, respiration, and blood pressure. One primitive reflex that is no longer useful in our modern times is called piloerection, which causes the hair to stand up on your arms when you are cold. Piloerection helped keep heat in by fluffing hair for better insulation, but clothes now do a better job.

After the Concept Review, we'll discuss a very strange neural phenomenon that you may have heard of—phantom limb.

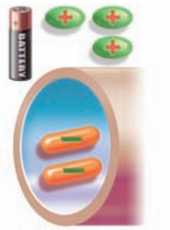
Concept Review



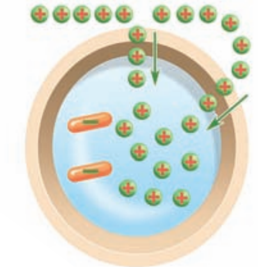
1. The structure that nourishes and maintains the entire neuron is the (a) ____________. Branchlike extensions that receive signals from senses and the environment are called (b) ____________. A single threadlike extension that speeds signals away from the cell body toward a neighboring cell is the (c) ____________. A tubelike structure that insulates the axon from interference by neighboring signals is the (d) ____________. Tiny swellings at the very end of the axon are called (e) ____________, which store neurotransmitters.



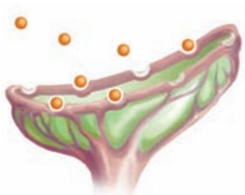
2. Chemicals that have electrical charges are called (a) ____________. They obey the rule that opposite charges attract and like charges repel. Although the fluid of the axon contains a number of ions, we have focused on only two, a positively charged (b) ____________ ion, whose symbol is Na+, and a negatively charged (c) ____________ ion.



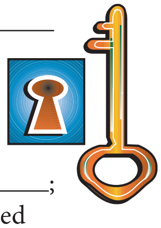
3. If an axon membrane has a potential similar to a charged battery, the axon is in the (a) ____________. During this state, the ions outside the membrane are positively charged (b) ____________ ions; the ions inside the membrane are negatively charged (c) ____________ ions.



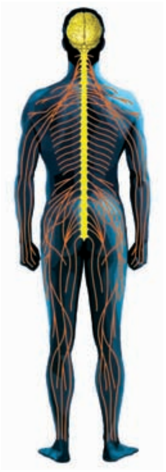
4. If an axon membrane is in a state similar to a discharging battery, the axon is generating an (a) ____________. During this potential, the chemical gates open and positively charged (b) ____________ rush inside, changing the inside of the membrane to a (c) ____________ charge, while the outside of the membrane has a (d) ____________ charge. As the action potential moves down the axon, it is called an (e) ____________. Once it is generated, the impulse travels from the beginning to the end of the axon; this phenomenon is referred to as the (f) ____________.



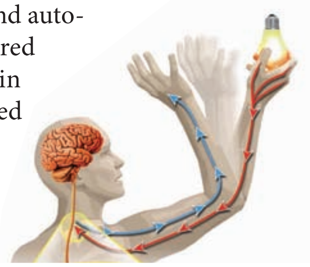
5. The end bulbs of one neuron are separated from the dendrites of a neighboring neuron by an extremely small space called the (a) ____________. Into this space, end bulbs release chemicals, called (b) ____________, which open/excite or block/inhibit neighboring receptors.



6. From end bulbs, chemical keys or (a) ____________ are secreted into the synapse. These chemical keys open matching locks called (b) ____________, which are located on the surface of neighboring dendrites, muscles, or organs. Neurotransmitters that open a receptor's lock are called (c) ____________; neurotransmitters that block a receptor's lock are called (d) ____________.



7. Neurons in the brain and spinal cord make up the (a) ____________. If neurons are damaged, they have little ability to (b) ____________ and usually die. The mature human brain has a limited ability to regrow (c) ____________ throughout adulthood. Information from the body's senses, skin, organs, and muscles is carried to and from the spinal cord by nerves that make up the (d) ____________. If this nervous system is damaged, (e) ____________ in this system have a remarkable ability to regrow and make new connections. If your finger were accidentally cut off, it could be (f) ____________ and there is a good chance that your finger would regain most of its sensory and motor functions.



8. If you touch a sharp object, your hand automatically withdraws because of a prewired reflex response. Neurons that carry "pain information" to the spinal cord are called (a) ____________ neurons. Inside the spinal cord, there are short neurons, called (b) ____________, that make connections between other neurons that carry information to the brain. Neurons that carry information away from the spinal cord to muscles or organs are called (c) ____________ neurons.

Answers: *1. (a) cell body or soma, (b) dendrites, (c) axon, (d) myelin sheath, (e) end bulbs; 2. (a) ions, (b) sodium, (c) protein; 3. (a) resting state, (b) sodium, (c) protein; 4. (a) action potential, (b) sodium ions, (c) positive, (d) negative, (e) impulse, or nerve impulse, (f) all-or-none law; 5. (a) synapse, (b) neurotransmitters; 6. (a) neurotransmitters, (b) receptors, (c) excitatory, (d) inhibitory; 7. (a) central nervous system, (b) regrow, repair, or reconnect, (c) neurons, (d) peripheral nervous system, (e) nerves, (f) reattached; 8. (a) sensory, or afferent, (b) interneurons, (c) motor, or efferent*

G. Research Focus: What Is a Phantom Limb?

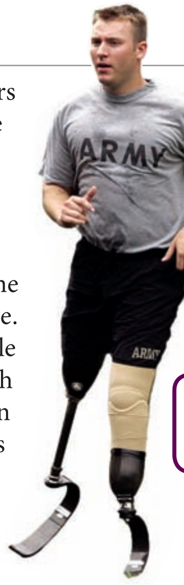
Case Study

Why does Christian feel pain in his missing toes?

A puzzling question for researchers to answer is: How can someone feel a phantom limb?

This question applies to Sgt. Christian Bagge, who was hit by two roadside bombs in Iraq. The next thing he remembers is waking up in a hospital with one leg amputated above the knee and the other below the knee. He didn't realize the worst of his condition until a short while later when he suddenly felt a crushing pain in his toes (which were no longer there!) (Bierma & Woolston, 2006). Christian describes the intense pain by saying it "feels like someone is smashing my toes with a hammer." He goes on to say, "On the pain scale of one to 10, I'd say it was a six or a seven. But then again, my '10' is getting both of my legs blown off" (Bagge, 2006).

Despite frequent episodes of excruciating pain, Christian wants to do everything he did before the injury. With the use of his artificial legs (left photo), he is doing just that. For instance, one year after his injury, Christian ran side by side with former President George W. Bush (Gehlert, 2006). Donald's case introduces you to the strange phenomenon of phantom limb.



Christian feels "real" pain coming from his amputated legs.

Definition and Data

What is phantom limb?

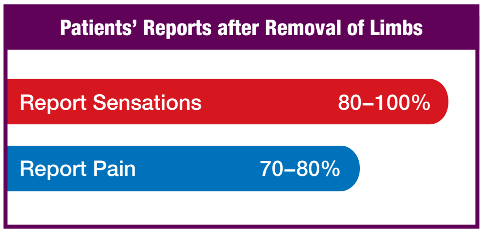
Very few symptoms have so surprised doctors as when patients reported feeling strange sensations or movements in arms or legs that had been amputated, a phenomenon called phantom limb.

Phantom limb refers to feeling sensations or movements coming from a limb that has been amputated. The sensations and movements are extremely vivid, as if the limb were still present.

As the graph on the right shows, the vast majority of individuals feel sensations ("pins and needles") or intense pain coming from their removed limbs (A. Hill et al., 1996). In other cases, amputees felt their removed limbs were not only still present but stuck in certain positions, such as permanently twisted in a spiral, painfully pinned to their backs, or sticking straight out from their bodies, so they felt they had to be careful not to hit their phantom limbs when going through doorways (Katz & Melzack, 2003; Nicolelis, 2007).

Scientists have been struggling for many years to better understand what causes the feelings of sensations and movements coming from phantom limbs.

Patients' Reports after Removal of Limbs



Answers and Treatment

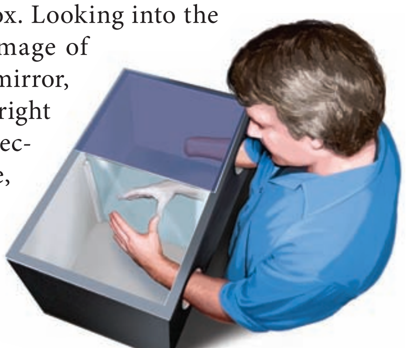
Answers. Early researchers thought the phantom limb sensations came from cut nerves remaining in the stump or from the spinal cord. Researchers now believe the origin of phantom limb sensations must be the brain itself (Purves et al., 2008). But, researchers are puzzled about how the brain generates these sensations.

The newest and most supported answer about the origin of phantom limb sensations comes from researcher Ronald Melzack, who has been studying this problem for over 40 years (Melzack, 1989, 1997). He states that each of us has a genetically programmed system of sensations that results in our knowing where our body parts are and in our developing an image of our body. Based on sensations from body parts, Melzack believes the brain pieces together a complete body image. Thus, having a body image, the brain can generate sensations as coming from any body part, even if that part is a phantom limb. With time, the brain can correct its representation of the body to acknowledge the loss of a limb, which could explain why phantom sensation is most severe at first and then decreases in intensity over time (Purves et al., 2008).

Because traditional medical treatment has had limited success in treating phantom limb pain, researchers are looking for more creative and effective treatments (Nicolelis, 2007).

Treatment. One interesting treatment method has been to create an illusion that the phantom limb exists. This has been done by having people with amputations of the arm and phantom limb pain place their arm inside a mirror box. Looking into the box, they see the reverse image of their remaining arm on the mirror, rather than a missing limb (right photo). By helping patients recreate a complete body image, the use of mirrors has had some success in reducing phantom pain in lower and upper limb amputations (Brodie et al., 2007; Chan et al., 2007; Maclachlan et al., 2003). Researchers are also investigating the effectiveness of virtual reality in reducing phantom limb pain (C. D. Murray et al., 2006, 2007).

The phantom limb phenomenon points out that the brain sometimes functions in mysterious ways. Less mysterious is how certain drugs affect the functioning of the brain and the body.



This mirror box can help to reduce phantom limb pain.

H. Cultural Diversity: Plants & Drugs

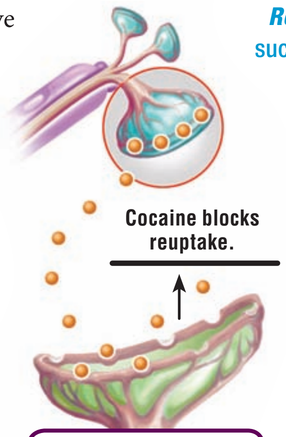
Where did the first drugs come from?

The very first drugs that affected neurotransmitters came from various plants, which people used long before researchers knew what those plants contained. We'll discuss three such drugs—cocaine, curare, and mescaline—which come from plants found in different parts of the world. We'll explain what these plants contain and their actions on the nervous systems.

Cocaine: Blocking Reuptake

For almost 3,500 years, South American Indians have chewed leaves of the coca plant. Following this ancient custom, adult Indians habitually carry bags of toasted coca leaves, which contain cocaine. Throughout the day, they chew small amounts of coca leaves to relieve fatigue and feelings of hunger. Here's how cocaine affects neurotransmitters.

The drawing on the right shows a neuron's end bulb containing the neurotransmitter dopamine (*DOPE-ah-mean*). Once released, dopamine (orange circles) reaches the dendrite's receptors, opens their chemical locks, and activates the neuron. However, after a short period of time, the neurotransmitter is normally removed by being transported back into the end bulb through a process called reuptake.



Cocaine works by blocking reuptake.

Reuptake **is a process through which some neurotransmitters, such as dopamine, are removed from the synapse by being transported back into the end bulbs.**

If reuptake does not occur, the released neurotransmitter would continually affect the neuron by remaining longer in the synapse. What cocaine does is block reuptake so that dopamine remains longer in the synapse (Huang et al., 2007). Because cocaine blocks reuptake, neurons are stimulated longer, resulting in the physiological arousal and feelings of euphoria that are associated with cocaine usage. Researchers now understand why South American Indians chewed coca leaves. The cocaine released from chewing coca leaves blocked the reuptake of dopamine, which in turn caused physiological arousal that relieved fatigue and feelings of hunger.

Curare: Blocking Receptors

When hunting animals, the Indians of Peru and Ecuador coat the ends of blowdarts with the juice of a tropical vine that contains the paralyzing drug curare.

Curare **(*cure-RAH-ree*) is a drug that enters the bloodstream, reaches the muscles, and blocks receptors on muscles. As a result, the neurotransmitter that normally activates muscles, which is called acetylcholine, is blocked, and muscles are paralyzed (M. R. Lee, 2005).**

Once hit by a curare-tipped blowdart, an animal's limb muscles become paralyzed, followed by paralysis of chest muscles used to breathe.

Why did Indians coat blowdarts with curare?

Curare is an example of a drug that stops neural transmission by blocking the muscles' receptors. Today, the purified active ingredient in curare (tubocurarine chloride) is used to induce muscle paralysis in humans, such as when doctors insert a breathing tube down a patient's throat. Curare doesn't easily enter the brain because the body's blood must go through a filtering system before it can enter the brain. This filtering system, called the ***blood-brain barrier,*** prevents some, but not all, potentially harmful substances in the body's blood supply from reaching the brain.

Mescaline: Mimicking a Neurotransmitter

A golf-ball-sized, gray-green plant (right photo) called peyote cactus grows in Mexico and the southwestern United States. Peyote contains mescaline (J. H. Halpern et al., 2005).

Mescaline **(*MESS-ka-lin*) is a drug that causes physiological arousal as well as visual hallucinations. Mescaline's chemical keys are similar to those of the neurotransmitter norepinephrine (*nor-epee-NEFF-rin*).**

Because mescaline's chemical keys open the same chemical locks (receptors) as norepinephrine, mescaline produces its effects by mimicking the actions of norepinephrine.

In 1965, an estimated 250,000 members of the Native American Church in the United States and Canada won a Supreme Court case that permits them to be the only group legally authorized to use peyote in their religious services. To enhance meditation, members may eat from 4 to 12 peyote buttons, which results in visual sensations, euphoria, and sometimes nausea and vomiting.

Mescaline comes from peyote cactus.

Conclusion. These three plants—cocaine, curare, and mescaline —contain potent drugs that illustrate three different ways of affecting the nervous system. Researchers have discovered numerous plants, including the opium poppy, marijuana, and "magic" mushrooms, that contain drugs that in turn affect neurotransmitters (discussed in Module 8).

Neurotransmitters are the keys that turn the brain's functions on or off. For example, Alzheimer's disease interferes with neurons and neurotransmitters and turns off the brain's functions. Such is the case with another terrible disease, called Parkinson's, which we'll discuss next.

I. Application: Experimental Treatments

Parkinson's Disease

Why do Michael's arms and legs shake?

Michael J. Fox is a talented actor who has starred in popular TV series, such as *Family Ties* and *Spin City,* and numerous movies, including the *Back to the Future* trilogy. He was really good at his job until he noticed a twitch in his left pinkie (Fox, 2002). Within only 6 months, this twitch spread to his whole hand. Michael tried to conceal his symptoms from the public by using medication to calm his tremors, and he was successful doing so for the first seven years (Dudley, 2006). However, it became increasingly difficult to hide his symptoms as he began having tremors that would shake his entire arm. Also, his legs would shake or become really stiff, making it difficult for him to walk. Eventually, these symptoms led Michael to quit his starring role in *Spin City* (Weinraub, 2000). Michael had all the symptoms of Parkinson's disease.

Parkinson's disease **includes symptoms of tremors and shakes in the limbs, a slowing of voluntary movements, muscle stiffness, problems with balance and coordination, and feelings of depression. As the disease progresses, patients develop a peculiar walk and may suddenly freeze in space for minutes or hours at a time.**

Michael's Parkinson's symptoms worsened because neurons in his ***basal ganglia,*** **a group of structures located in the center of the brain that are involved in regulating movements,** were running out of the neurotransmitter dopamine. Without a sufficient supply of dopamine in the basal ganglia, the brain loses its ability to control movement.

Like most Parkinson's patients, Michael was placed on a medication called L-dopa, which boosts the levels of dopamine in the brain, enabling him to have better control over his movements. Unfortunately, patients must take increasing amounts of L-dopa, and after prolonged use (5 to 10 years), L-dopa's beneficial effects may be replaced by unwanted jerky movements that may be as bad as those produced by Parkinson's disease (Mercuri & Bernardi, 2005). Even though Michael still takes medication, at times he has so little movement control he cannot speak clearly, raise his arms from his side, or even smile (Dagostino, 2008). Yet, he continues to have an optimistic outlook on life (Fox, 2009).

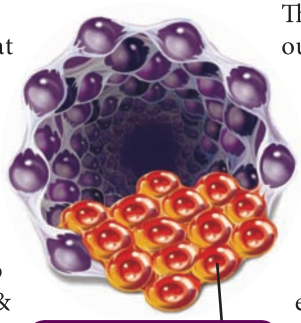
In the United States, about 1.5 million adults, usually over the age of 50, have Parkinson's disease. In rare cases, such as Michael's, people are diagnosed with young-onset Parkinson's disease (Michael was only 30). The causes of Parkinson's disease include genetic and possible environmental factors (Jankovic, 2007). To date, Parkinson's has no cure, but, as you'll see, several experimental treatments are under study.

Issues Involving Transplants

Why not just use drugs?

Human cells. As we learned above, the prolonged use of L-dopa to treat Parkinson's disease produces unwanted side effects. Because of these disappointing long-term results, researchers are investigating alternative treatments, such as fetal brain tissue transplants.

Previously, researchers had shown that when fetal rat brain tissue was transplanted into older rats, the fetal neurons lived, grew, functioned, and allowed brain-damaged older rats to relearn the solutions to mazes (Shetty & Turner, 1996). Following successes in animal research, human fetal brain tissue has been transplanted into patients with Parkinson's disease (Roitberg & Kordower, 2004).



Embryonic stem cells have the ability to form new brain cells.

The primary reason for using 6- to 8-week-old fetal tissue for transplants is that they have a unique ability to survive and make connections in a patient's brain or body. Because fetal brain tissue is primed for growth, it has a far greater chance of survival after transplantation than does tissue from mature brains (Holden, 2002). More recently, researchers are exploring the use of stem cells to treat Parkinson's disease and spinal cord injuries.

Stem cells. About four days after a sperm has fertilized an egg, the resulting embryo, which is about the size of the period in this sentence (see p. 379), has divided and formed embryonic stem cells (shown on left).

Stem cells, **not discovered until 1998, have the amazing capacity to change into and become any one of the 220 types of cells that make up a human body, including skin, heart, liver, bones, and neurons.**

The discovery of stem cells creates possibilities for treating various diseases. For example, when embryonic animal stem cells were transplanted into rats and mice with spinal cord injuries, the stem cells imitated the neighboring neurons and developed into new neurons that, in turn, helped the animals regain their lost functions (Wade, 2002). Some exciting news is that the first embryonic human stem cell study is now taking place in patients with spinal cord injuries (DeNoon, 2009a).

The use of human embryonic stem cells is controversial for ethical and political reasons. That's because these embryos, which are fertilized in laboratories and have the potential to develop into humans, are destroyed when the stem cells are removed. Because stem cell research has such potential, however, it has received wide support and funding from private and state sources. Michael J. Fox advocates for embryonic stem cell research in hopes it may lead to finding a cure for Parkinson's disease (Fox, 2007). Some researchers believe embryonic stem cells will soon be used to treat Parkinson's disease (Freed, 2008).

Next, we'll take a closer look at how fetal and stem cells are used in treating Parkinson's. We'll also learn about other experimental treatment options.

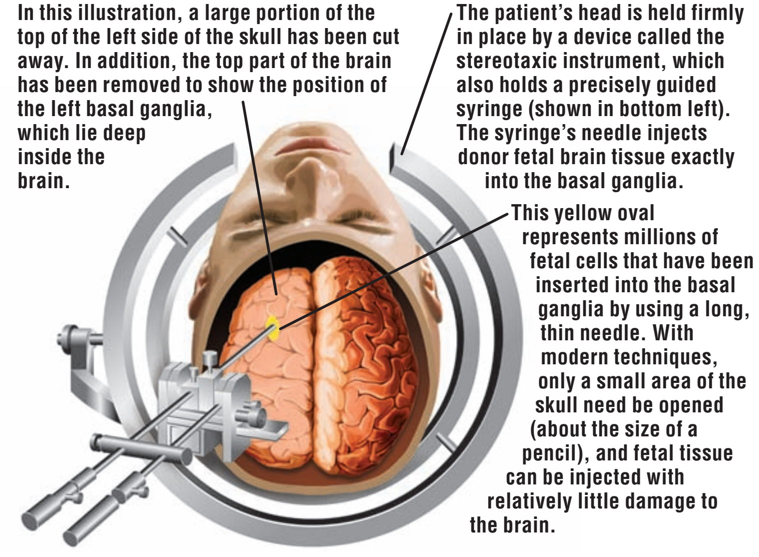
Experimental Treatments

Placing tissue in the brain. A neurosurgeon can transplant fetal cells or stem cells into a precise location in either animal or human brains by using the stereotaxic procedure.

The ***stereotaxic procedure*** (right figure) involves fixing a patient's head in a holder and drilling a small hole through the skull. The holder has a syringe that can be precisely guided to inject cells into a predetermined location in the brain.



In this illustration, a large portion of the top of the left side of the skull has been cut away. In addition, the top part of the brain has been removed to show the position of the left basal ganglia, which lie deep inside the brain.

The patient's head is held firmly in place by a device called the stereotaxic instrument, which also holds a precisely guided syringe (shown in bottom left). The syringe's needle injects donor fetal brain tissue exactly into the basal ganglia.

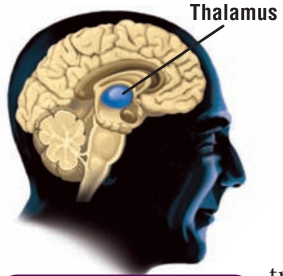
This yellow oval represents millions of fetal cells that have been inserted into the basal ganglia by using a long, thin needle. With modern techniques, only a small area of the skull need be opened (about the size of a pencil), and fetal tissue can be injected with relatively little damage to the brain.

In the figure, a large part of the skull has been removed to show the brain, but in actual surgery, only a small, pencil-sized hole is drilled in the skull. A long needle from the syringe is inserted into the patient's brain area that is involved with regulating movement, the basal ganglia. The surgeon injects fetal or stem cells into the designated brain area.

The advantages of the stereotaxic procedure are that a thin syringe can be placed in precise locations in the brain and that it causes relatively little damage to the brain. The stereotaxic procedure can be used to either inject solutions or, as we'll later learn, destroy diseased brain tissue.

Based on a number of experimental treatments, researchers learned that when injected into a human adult brain, fetal tissue does survive and function. Fetal tissue transplants have benefited some people, but others have reported serious side effects. Therefore, critics suggest that researchers identify the best location for injecting the tissue into the brain and aim to prevent the unwanted motor side effects by determining the optimum number of fetal cells to inject (Sanberg, 2007).

Stem cell research is still in its infancy, but already some success has been reported in using stem cells to treat people with Parkinson's disease. Recently, a case study found that adult stem cell transplantation improved motor functioning in a patient with Parkinson's disease by 80% over a three-year period (Levesque et al., 2009). Researchers are hopeful that the use of stem cells will help replace cells damaged during the progression of Parkinson's disease, and consequently restore lost function (such as motor control) (Sonntag et al., 2005).



Michael J. Fox chose to have part of his thalamus removed.

Removing part of the brain. People with Parkinson's disease have regained control over their limbs after having part of their thalamus (p. 80) removed. The thalamus is an oval-shaped structure (see left) of the brain that closely interacts with the basal ganglia. One of its functions is to help make voluntary motor movements, such as when a person wants to move a leg to walk (Brazis et al., 2007; Murat et al., 2005).

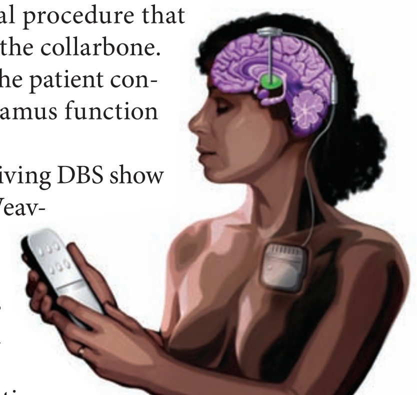
Michael J. Fox chose to have a thalamotomy, a surgery that removed part of his thalamus. During the surgery, the stereotaxic procedure was used to drill a hole in his skull and apply heat to destroy very precise sections of his thalamus. Michael's surgeon warned him that the procedure would not cure his Parkinson's, but if successful, it would stop the severe tremors in his arm. The surgery was a success in Michael's case, as most of his severe tremors went away. He now takes medication to control his milder tremors (Fox, 2002).

Thalamotomy has proven to have a high success rate, but there are serious risks, including paralysis, coma, and death. Therefore, this procedure is used only in severe cases of Parkinson's, such as Michael's. Doctors treated Michael with medication for several years before suggesting he undergo a dangerous surgery (Fox, 2002).

Brain stimulation. About 35,000 people have received deep brain stimulation (DBS), a surgical procedure that involves implanting electrodes into the thalamus and placing a battery-powered stimulator under the collarbone. The electrodes are wired to the stimulator, which provides electrical stimulation to the thalamus. The patient controls the stimulation by using a remote control to turn it on and off. This procedure helps the thalamus function better and, as a result, reduces or eliminates tremors (Kluger, 2007b; Kringelbach & Aziz, 2008).

An advantage of DBS is being able to modify the level of stimulation as needed. Also, patients receiving DBS show greater long-term improvement than patients receiving only medication (Deuschl et al., 2006; F. M. Weaver et al., 2009). The limitation of this procedure is that the batteries must be surgically replaced every few years (Pahwa & Lyons, 2003). There is also a risk of dangerous bleeding and getting an infection (Kringelbach & Aziz, 2008; F. M. Weaver et al., 2009). In addition, because Parkinson's disease is degenerative, DBS controls the tremors for only 10 years or so; after that, the electrical stimulation is no longer effective. But, DBS can offer a patient about 10 symptom-free years (Kluger, 2007b).

Given its effectiveness and relatively minimal risk, researchers believe DBS will be effective in treating a variety of health problems. DBS is currently being investigated in the treatment of depression, anxiety, phantom limb pain, comas, and Alzheimer's disease, such as that of Charles, described in the beginning of the module (Kluger, 2007b; Kringelbach & Aziz, 2008; G. Miller, 2009; Mullins, 2008; N. D. Schiff et al., 2007).



Electrodes implanted in the thalamus provide stimulation to reduce tremors.

Summary Test

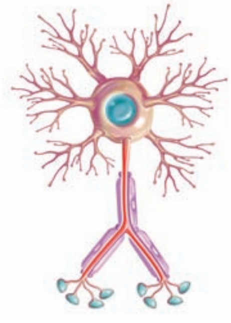
A. Overview: Human Brain

1. The brain is composed of a trillion cells that can be divided into two groups. One group of cells has specialized extensions for receiving and transmitting information. These cells, which are called (a) ________________, are involved in communicating with other neurons, receiving sensory information, and regulating muscles, glands, and organs. The other group of cells provide the scaffolding to guide and support neurons, insulate neurons, and release chemicals that influence neuron functions. These cells are much more numerous than neurons and are called (b) ________________.

2. There is a major difference between the growth of neurons in the brains of humans and in the brains of birds. A mature human brain is normally not capable of developing new (a) ________________, which are almost all developed at the time of birth. In contrast, a mature (b) ________________ brain has the capacity to develop new neurons.

3. The age-old question of how the brain's membranes, fluids, and chemicals are involved in generating complex mental activities, such as thoughts, images, and feelings, is called the ________________ question.

B. Neurons: Structure & Function



4. Although neurons come in wondrous shapes and sizes, they all share three structures. The structure that maintains the entire neuron in working order, manufactures chemicals, and provides fuel is called the (a) ________________. The structure with many branchlike extensions that receive signals from other neurons, muscles, or organs and conduct these signals to the cell body is called a (b) ________________. The single threadlike extension that leaves the cell body and carries signals to other neurons, muscles, or organs is called the (c) ________________. At the very end of this structure are individual swellings called (d) ________________, which contain tiny vesicles filled with (e) ________________.

5. Surrounding most axons is a fatty material called the (a) ________________. This material acts like (b) ________________ and diminishes interference from electrical signals traveling in neighboring axons.

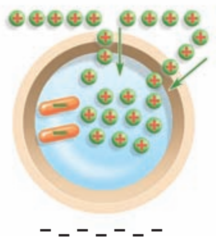
6. Neurons do not make physical contact with one another or with other organs. Instead, there is an infinitely small space between a neuron's end bulbs and neighboring dendrites, cell bodies, or other organs. This space is called the (a) ________________. When an axon's end bulbs secrete a neurotransmitter, it flows across this space and affects the (b) ________________ on the neighboring membrane.

C. Neurons Versus Nerves

7. There are major differences between neurons and nerves. Cells with specialized extensions for conducting electrical signals are called (a) ________________. These cells, which are located in the brain and spinal cord, make up the (b) ________________ nervous system. Stringlike bundles of neurons' axons and dendrites, which are held together by connective tissue, are called (c) ________________. These string-like bundles, which are located throughout the body, make up the (d) ________________ nervous system. Nerves carry information back and forth between the body and the spinal cord. If a neuron in the central nervous system is damaged, it normally does not have the capacity to (e) ________________. In comparison, a nerve in the (f) ________________ nervous system has the capacity to regrow or reattach if cut or damaged. The mature human brain has a limited ability to regrow (g) ________________ throughout adulthood.

D. Sending Information

Action Potential



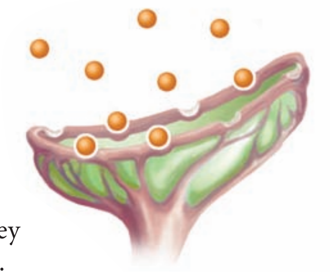
8. The axon membrane has (a) ________________ that can be opened or closed. These gates keep some ions inside the membrane and other ions outside. If the axon is ready to conduct but not actually conducting an impulse, the axon is said to be in the (b) ________________ state. In this state, most of the positively charged (c) ________________ ions are on the outside of the membrane and all the negatively charged (d) ________________ ions are trapped inside. In the resting state, the outside of the membrane has a (e) ________________ charge compared to the (f) ________________ charge on the inside. The process responsible for picking up and transporting sodium ions from the inside to the outside of the axon membrane is called the (g) ________________.

9. If a stimulus is strong enough to excite a neuron, two things happen to its axon. First, the stimulus will eventually open the axon's (a) ________________. Second, after the gates are opened, the (b) ________________ pump is stopped, and all the positive (c) ________________ ions rush inside because they are attracted to the negatively charged protein ions. The rush of sodium ions inside generates a tiny electric current that is called the (d) ________________. When this current is generated, the inside of the axon membrane changes to a (e) ________________ charge and the outside changes to a (f) ________________ charge.

Photo Credit: top right, © Taro Yamasaki

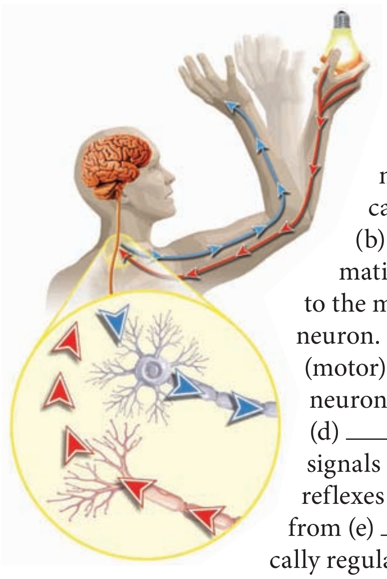
10. Once an action potential starts in the axon, it continues, segment by segment, down the entire length of the axon, creating the (a) ______________. Once an action potential is triggered in the segment at the beginning of the axon, other action potentials will be triggered in sequence down the entire length of the axon; this phenomenon is called the (b) ______________.

E. Transmitters



11. Once started, the action potential will reach the end bulbs at the end of the axon. The action potential excites the end bulbs and causes them to secrete (a) ______________ that were stored in the end bulbs. Neurotransmitters function like chemical keys that unlock chemical locks or (b) ______________, which are located on neighboring neurons, muscles, or other organs. If neurotransmitters open the receptors' locks on neighboring cells, they are said to be (c) ______________. If neurotransmitters block the receptors' locks, they are said to be (d) ______________. Because of these different actions, neurotransmitters can cause different and even opposite responses in neurons, muscles, or organs. There are about a dozen well-known neurotransmitters. One of the newly discovered neurotransmitters that has a chemical makeup similar to THC in marijuana is called (e) ______________ and is involved in emotions and motor coordination.

F. Reflex Responses



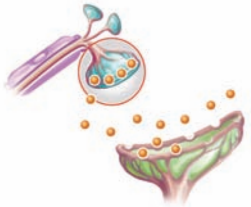
12. The movement of automatically withdrawing your hand after touching a hot object is called a (a) ______________, which involves several or more neurons. Information is carried to the spinal cord by the (b) ______________ neuron. Information is carried from the spinal cord to the muscle by the (c) ______________ neuron. Connections between efferent (motor) and afferent (sensory) neurons are made by relatively short (d) ______________, which also send signals to the brain. The functions of reflexes include protecting body parts from (e) ______________ and automatically regulating the (f) ______________ responses of the body.

Photo Credit: top right, © Getty Images

G. Research Focus: What Is a Phantom Limb?

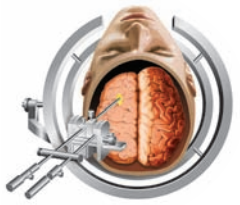
13. The experience of sensations from a limb that has been amputated is called the (a) ______________ phenomenon. About 70–80% of patients report sensations of intense pain coming from limbs that have been amputated. A recent explanation of phantom limb sensations is that they arise from the brain's genetically programmed system of sensations that allows the brain to know the locations of all the body's (b) ______________.

H. Cultural Diversity: Plants & Drugs



14. One of cocaine's effects on the nervous system is to block the process of (a) ______________ so that the neurotransmitter remains longer in the synapse, which causes physiological arousal. A drug that blocks receptors on muscles and causes muscle paralysis is (b) ______________. A drug that mimics the naturally occurring neurotransmitter norepinephrine and can produce visual hallucinations is (c) ______________.

I. Application: Experimental Treatments



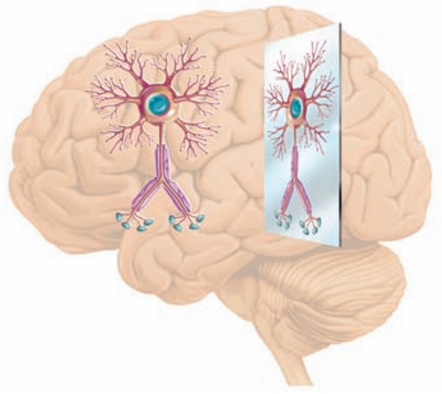
15. The tremors and rigidity of Parkinson's disease result when a group of structures that regulate movement, called the (a) ______________, lose their supply of dopamine. In experimental treatment, fetal brain cells or stem cells can be transplanted into a precise location of a patient's brain by a technique called the (b) ______________ procedure. Cells that have the amazing capacity to develop into any of the 220 types of cells that make up the human body are called (c) ______________. These cells can be used to treat spinal cord injuries and diseases like Alzheimer's and Parkinson's because stem cells can develop into (d) ______________.

Answers: *1. (a) neurons, (b) glial cells; 2. (a) neurons, (b) bird; 3. mind-body; 4. (a) cell body, or soma, (b) dendrite, (c) axon, (d) end bulbs, (e) neurotransmitters; 5. (a) myelin sheath, (b) insulation; 6. (a) synapse, (b) receptors; 7. (a) neurons, (b) central, (c) nerves, (d) peripheral, (e) regrow, (f) peripheral, (g) neurons; 8. (a) chemical gates, (b) resting, (c) sodium, (d) protein, (e) positive, (f) negative, (g) sodium pump; 9. (a) chemical gates, (b) sodium, (c) sodium, (d) action potential, (e) positive, (f) negative; 10. (a) nerve impulse, (b) all-or-none law; 11. (a) neurotransmitters, (b) receptors, (c) excitatory, (d) inhibitory, (e) anandamide; 12. (a) reflex, or reflex response, (b) sensory, or afferent, (c) motor, or efferent, (d) interneurons, (e) injury or harm, (f) physiological; 13. (a) phantom limb, (b) parts; 14. (a) reuptake, (b) curare, (c) mescaline; 15. (a) basal ganglia, (b) stereotaxic, (c) stem cells, (d) neurons*

Critical Thinking

Mirrors in Your Brain?

When we see someone yawn, we yawn too. When we watch a spider crawl up someone's leg, we get creepy sensations on our leg. When we see someone in danger, we experience a wave of fear. When we see someone's arm get jabbed with a sharp needle, the muscles in our arms tense up and our breathing intensifies. When we watch our favorite Olympic athlete near the finish line to win first place, our heart races with excitement.



How can simply observing others lead us to experience such intense responses so similar to those experienced by the people we are observing? The answer is found in our brain cells. A type of neuron, called a mirror neuron, helps explain how we effortlessly "read" other people's minds and empathize with them—feel what they do. Mirror neurons automatically put us in somebody else's shoes. Not convinced? Just consider brain scan research that finds romantic partners who observe loved ones in pain show similar activity in their emotional brain areas as that experienced by the loved ones. It turns out that when we empathize with someone's pain, on some level we actually feel pain!

One fascinating characteristic of mirror neurons is they are the only brain cells that are activated the same way whether we are "seeing" or "doing." These special neurons mirror what the other person is doing. For instance, when we see someone smiling, our mirror neurons for smiling get activated, which triggers neural activity leading to experiencing feelings associated with smiling, such as happiness. In other words, we get all the benefits of smiling without making even the slightest movement of our lips!

Mirror neurons also help us understand someone's intentions. They get activated when we watch someone do something, which helps us predict what their goal is and what they may do next. For example, if you see a boy begin to reach for candy on the counter in front of him, you have a copy of what he is doing in your brain, which helps you to understand his goal (getting the candy).

Research on mirror neurons is still in its infancy, and much has yet to be learned. But, for now, those of us who are embarrassed by our free-flowing tears during dramatic scenes in television programs, movies, and, yes, sometimes even commercials should be relieved to know that the emotions we experience may be out of our control; that is, we may not be able to contain our tears after all. (Adapted from Blakeslee, 2006a; Blakeslee & Blakeslee, 2007; Iacoboni, 2008a, 2008b; Iacoboni & Mazziotta, 2007; Ramachandran & Oberman, 2006; T. Singer et al., 2004; Winerman, 2005)

QUESTIONS

1 How might mirror neurons explain the social problems of people with autism?

2 In what type of research setting do brain scan studies take place? What are an advantage and disadvantage of this type of research setting?

3 How are mirror neurons different from nerves?

4 What would it be like to have no mirror neurons?

5 How might mirror neurons be involved in the enjoyment of watching pornography?

6 Which modern approaches to psychology are best suited to study mirror neurons?

Learning Activities

PowerStudy for Introduction to Psychology 4.5

PowerStudy 4.5™

Try out **PowerStudy's SuperModule** for the Brain's Building Blocks! In addition to the quizzes, learning activities, interactive Summary Test, key terms, module outline and abstract, and extended list of correlated websites provided for all modules, the DVD's **SuperModule** for the Brain's Building Blocks features:

- Self-paced, fully narrated learning with a multitude of animations.
- Video about Alzheimer's.
- Interactive versions of study resources, including the Summary Test on pages 62–63 and the critical thinking questions for the article on page 64.

CengageNOW!

www.cengage.com/login

Want to maximize your online study time? Take this easy-to-use study system's diagnostic pre-test and it will create a personalized study plan for you. The plan will help you identify the topics you need to understand better and direct you to relevant companion online resources that are specific to this book, speeding up your review of the module.

Introduction to Psychology Book Companion Website

www.cengage.com/psychology/plotnik

Visit this book's companion website for more resources to help you study, including learning objectives, additional quizzes, flash cards, updated links to useful websites, and a pronunciation glossary.

Study Guide and WebTutor

Work through the corresponding module in your Study Guide for tips on how to study effectively and for help learning the material covered in the book. WebTutor (an online Study Tool accessed through your eResources account) provides an interactive version of the Study Guide.

Suggested Answers to Critical Thinking

1. People with autism (see Module 1) struggle with social interactions because they do not understand other people's emotions well. Their reduced mirror neuron activity weakens their ability to experience what other people are experiencing. People with autism misunderstand verbal and nonverbal cues suggesting a variety of emotions felt by others, including happiness and anger.
2. Brain scan research takes place in a laboratory setting (see p. 35). An advantage of laboratory settings is that researchers can study individuals in a systematic and controlled setting while reducing error. A disadvantage is that the laboratory setting may be so controlled or artificial that the results are not meaningful in real-life situations.
3. Mirror neurons are brain cells located in the central nervous system; nerves are bundles of axons and dendrites that come from the spinal cord and are located in the peripheral nervous system. Neurons have a limited capacity for repair or regrowth, whereas nerves can regrow or reattach if damaged or severed.
4. Mirror neurons are essential for social interactions. Without them we would be blind to the actions, emotions, and intentions of others.
5. Mirror neurons have an important role in the enjoyment of pornography. For example, a heterosexual man watching another man have sex with a woman enjoys observing the pornography because his mirror neurons are highly activated. The observer anticipates the building of the man's excitement and his own excitement builds as well. In brief, the observer identifies with the male in the video and feels what he feels.
6. The modern approaches best suited to study mirror neurons are the biological and cognitive neuroscience approaches (see pp. 6–7). These approaches study how our brains interact with our environment to influence such things as emotions and a variety of cognitive processes, such as understanding one's intentions.

Identical Twins: Genetic Differences

Identical twins may look the same, but their genes may not be identical.

Identical twins are so fascinating. We occasionally hear of identical twins separated at birth and reunited as adults discovering similarities that chance alone cannot possibly explain. We've long believed that identical twins are genetically the same. This has led to very interesting dilemmas. For instance, what if a man commits a crime and police gather DNA evidence that matches his DNA but find out he has an identical twin? If neither twin confesses to the crime, could one have committed the "perfect crime"? This scenario occurred with identical twins Hassan and Abbas O. One twin carried out a heist and his DNA was found at the crime scene, but both twins were let go because police could not identify which twin committed the crime (Himmelreich, 2009).

Researchers are now discovering how different identical twins can be. It turns out identical twins have slightly varying genes (Bruder et al., 2008). With future advances in genetic testing, we may be able to determine which twin committed the crime. In this module, we'll talk about genetic differences in identical twins and learn about uses for genetic testing.

Ming's Brain: Wrong Instructions

Ming has a genetic defect that affects his functioning.

When Ming was born, he weighed about 9 pounds and his doctor stated he was a very healthy baby. Everything was fine at first as Ming often smiled and cooed, and he slept and ate well. But soon Ming's parents began to worry because he was not reaching many of his developmental milestones on time, such as sitting and crawling.

As Ming got older, more problems became evident. He was hyperactive and had frequent, uncontrollable tantrums. Also, he didn't begin speaking until age 3, and he continued to fall behind in school. An examination of Ming's genetic makeup revealed that he had inherited fragile X syndrome, which is the most common cause of an inherited developmental disorder (B. O. Berg, 2007; Ropper & Samuels, 2009).

We'll use Ming's problem to explain how genetic instructions are written and what happens when they have errors.

Phillipa's Brain: Cruel Fate

What happened to Phillipa's brain that made her yell and swear at strangers?

Phillipa was a healthy, intelligent, well-educated woman who loved her job as a school teacher. She was a positive, pleasant person who never seemed to get irritated, even when her children would act up while she still had hours of lesson planning remaining for the next morning.

But Phillipa changed in many drastic ways after she was brutally assaulted by a mugger as she was walking to her car after a late night of grading her students' papers. She was hit hard on the front of her head with a steel rod. After the assault, Phillipa would yell at random individuals, swear at anyone who left her side, and inappropriately undress in front of strangers. Her unusual behaviors had her family members very concerned (adapted from J. A. Ogden, 2005).

We'll use Phillipa's unsettling experience to illustrate some of the symptoms of brain damage and how neurologists can examine the living brain.

Baby Theresa's Brain: Fatal Flaw

Missing brain area

Baby Theresa was born with almost all of her brain missing.

The press called her Baby Theresa. She was born with the most dangerous malformation of the brain babies can have—a devastating condition called anencephaly (*an-in-CEPH-ah-lee*), which is usually fatal within the first week of life (Ropper & Samuels, 2009).

Baby Theresa was born with almost no brain and therefore would never develop the functions we associate with being human, such as talking, reasoning, and planning. She survived for 9 days because a very primitive part of her brain was functioning to keep her alive. This small, primitive brain area lies directly above the spinal cord and regulates vital reflexes, such as breathing, blood pressure, and heart rate. These vital reflexes kept Theresa alive for a short time.

We'll use Baby Theresa's tragic case to illustrate some of the different structures and functions of the brain.

What's Coming

The study of identical twins raises one very interesting question: Are their genes so similar that one twin can get away with committing a serious crime? The brains of Ming, Phillipa, and Baby Theresa raise a number of questions. Ming's brain raises the questions of how brains develop and how things can go wrong. Phillipa's brain brings up the questions of what happens when brains are damaged and how doctors can look inside living brains. Baby Theresa's brain raises the question of what it means to be human. We'll answer these questions as well as discuss all the major structures and functions of the human brain.

Let's begin with how genetic instructions are written.

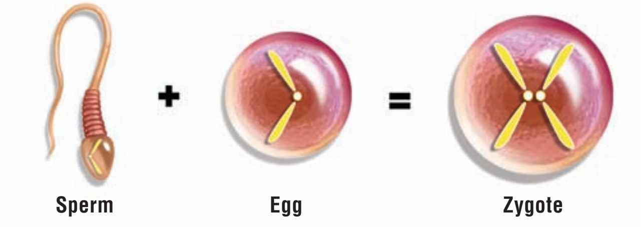
Photo Credit: © Royalty-Free/Masterfile

A. Genes & Evolution

What makes brains different?

Your brain and body developed according to complex chemical instructions that were written in a human cell no larger than a grain of sand. The reason brains and bodies have different shapes, colors, and abilities is that they develop from different instructions, which are written at the moment of fertilization.

1 Fertilization. Human life has its beginnings when a father's sperm, which contains 23 chromosomes, penetrates a mother's egg, which contains 23 chromosomes. The result is a fertilized cell called a zygote (shown below).



2 Zygote. A zygote (figure above), which is about the size of a grain of sand, is the largest human cell.

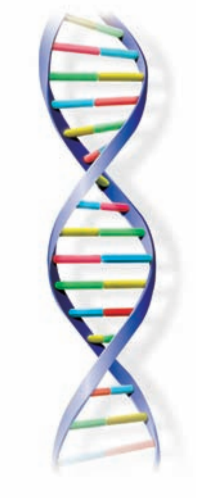
A ***zygote*** is a cell that results when an egg is fertilized. A zygote contains 46 chromosomes arranged in 23 pairs.

A zygote contains the equivalent of 300,000 pages of typewritten instructions. For simplicity, the zygote shown above has only 1 pair of chromosomes instead of the usual 23 pairs.

3 Chromosomes. Inside the very tiny zygote are 23 pairs of chromosomes, which contain chemical instructions for development of the brain and body.

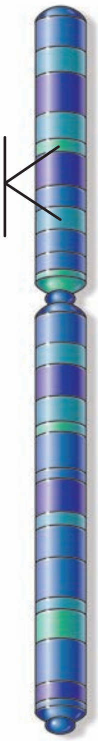
A ***chromosome*** is a short, rodlike, microscopic structure that contains tightly coiled strands of the chemical DNA, which is an abbreviation for deoxyribonucleic (*dee-ox-ee-RYE-bow-new-CLEE-ick*) acid. Each cell of the human body (except for the sperm and egg) contains 46 chromosomes arranged in 23 pairs.

For the sake of simplicity, the cell above contains only 2 pairs of chromosomes instead of the usual 23 pairs.



4 Chemical alphabet. Each chromosome contains a long, coiled strand of DNA, which resembles a ladder (left figure) that has been twisted over and over upon itself.

Each rung of the DNA ladder is made up of four chemicals. The order in which the four different chemicals combine to form rungs creates a microscopic chemical alphabet. This chemical alphabet is used to write instructions for the development and assembly of the 100 trillion highly specialized cells that make up the brain and body (R. J. Sternberg, 2001).



5 Genes and proteins. On each chromosome are specific segments that contain particular instructions. In the chromosome on the right, each segment represents the location of a gene.

A ***gene*** is a specific segment on the long strand of DNA that contains instructions for making proteins. Proteins are chemical building blocks from which all the parts of the brain and body are constructed.

For example, genes determine physical traits (eye color, shape of ear lobes) as well as contribute to the development of emotional, cognitive, and behavioral traits (Angier, 2003). When researchers discover a new gene, it means they have identified the exact location of the gene on its chromosome.

6 Polymorphic genes. Although there is only one version of about 99% of our genes, some of our genes have more than one version.

A ***polymorphic gene*** is a gene that has more than one version.

Polymorphic genes help explain some of the differences in physical appearance and behaviors in people. For example, there is a polymorphic gene that influences eye color. Depending on which combination of these genes each sibling receives from the parents, two siblings may have different eye colors.

7 Dominant and recessive genes. Because we can inherit different versions of genes for a particular characteristic (such as eye color) from each parent, conflicts between polymorphic genes can occur. The conflict is resolved by identifying the dominant and recessive genes. In terms of eye color, the gene for brown eyes is dominant and the gene for blue eyes is recessive.

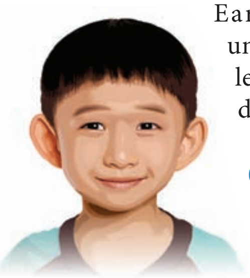
A ***dominant gene*** is a type of polymorphic gene that determines the development of a specific trait even if it is paired with a recessive gene. A ***recessive gene*** is a type of polymorphic gene that determines the development of a specific trait only when it is inherited from both parents.

If you inherit a gene for brown eyes from your father and a gene for blue eyes from your mother, the dominant gene will determine your eye color. The gene for brown eyes is dominant, so you will develop brown eyes.

8 Genome. Because genes determine a multitude of traits, scientists have long been interested in mapping all of our genes. The Human Genome Project, which began in 1995 and cost over $2.7 billion, reached its first goal in 2003 of mapping all the human genes (Mestel, 2003a). Unlike earlier estimates of 100,000 human genes, researchers found only 20,000–25,000 human genes on the 23 pairs of chromosomes (IHGSC, 2004). Researchers are now working to understand how humans develop physical and psychological traits, identify sources of genetic diseases, develop new drugs, and use gene therapy to treat genetic problems (Kolata, 2003, 2006, 2007). Next, we'll learn what happens when there are errors in genetic instruction.

Figure/Text Credit: (right) Chromosome drawing redrawn by permission from an illustration on page 126 by Michael Goodman in "DNA's New Twists," by John Rennie, *Scientific American*, March, 1993. All rights reserved.

Errors in Genetic Instructions



Ming has fragile X syndrome.

Earlier, we told you about Ming's unusual physical and behavioral problems. Ming has an inherited genetic disorder called fragile X syndrome.

Fragile X syndrome, an inherited developmental disability, is due to a defect in the X chromosome (the pinched end of the X chromosome). It can result in physical changes, such as a relatively large head with protruding ears, as well as mild to profound mental retardation.

Fragile X syndrome, which can include changes in both physical features and brain development, illustrates what happens when there is an error in the genetic instructions (Ropper & Samuels, 2009). Another example of an error in the genetic instructions is Down syndrome.

Down syndrome results from an extra 21st chromosome and causes abnormal physical traits (a fold of skin at the corner of each eye, a wide tongue, heart defects) and abnormal brain development, resulting in degrees of mental retardation.

Next, we'll discuss the uses of genetic testing, which includes identifying inherited genetic disorders, such as fragile X syndrome and Down syndrome.

Genetic Testing

Genetic testing is used to detect genes associated with a specific disease or disorder (such as fragile X syndrome and Down syndrome) as well as for paternal testing and forensics (NHGRI, 2008).

Genetic testing involves taking a sample from someone's blood, hair, skin, or other body parts and then examining the person's genes to look for signs that they may be at risk for specific diseases or disorders (NIH, 2006).

By using genetic testing, researchers have discovered genetic variations between identical twins (Bruder et al., 2008). These variations are called *copy number variations,* and with advances in genetic testing, researchers should be able to identify all of the copy number variations between identical twins.

The discovery of these genetic variations combined with advances in genetic testing may lead to a better chance of solving the dilemma of identifying a criminal suspect who is an identical twin, such as in the case of identical twins Hassan and Abbas O. discussed earlier (Bieber, 2008). They were released despite matching DNA collected at the crime scene.

Genetic testing and genetic research have a tremendous influence on psychology. One major goal for researchers is to understand how genes interact with the environment to result in mental retardation, personality traits, mental disorders, and various cognitive abilities (Rutter, 2006).

Next, we'll discuss how genetic changes are thought to have affected brain development over millions of years.

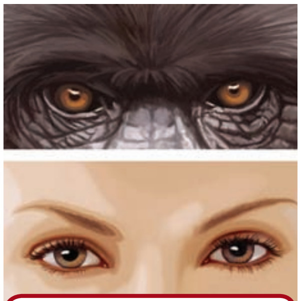
Evolution of the Human Brain

What is evolution?

In 1859, Charles Darwin stunned much of the Western world by publishing *Origin of Species,* a revolutionary book on how species originate, which was the basis for his now-famous theory of evolution.

The ***theory of evolution*** says that different species arose from a common ancestor and that those species that survived were best adapted to meet the demands of their environments.

Darwin's theory of evolution has received broad scientific support from fossil records and examination of genetic similarities and differences among species (Mayr, 2000; Zimmer, 2009). The belief of many scientists in the theory of evolution clashes with deeply held religious beliefs that place humans on a family tree of their own. According to evolution theory, present-day humans descended from a creature that split off from apes millions of years ago. Supporting this theory is the finding that humans and chimpanzees share at least 98% of their DNA or genetic instructions. Research suggests that when and how much genes are activated may be what helps set humans apart from chimpanzees (Ehrenberg, 2008). Other research suggests humans are more intelligent than chimpanzees not because of more sophisticated neurons; rather, an enormous number of basic neurons and countless more interactions between neurons are responsible for making humans so brainy (Sapolsky, 2006).



According to the theory of evolution, humans descended from a creature that split off from apes.

Two forces are thought to be responsible for the evolution of the human brain: (1) ***genetic mutations,*** which are accidental errors in genetic instructions that lead to a change, and (2) ***natural selection,*** which means the genes for traits that help an organism survive and reproduce ***(adaptive genes)*** will be selected and will continue in a species, whereas the genes for traits that prevent survival and reproduction ***(maladaptive genes)*** will not be selected and will be eliminated in a species (Balter, 2002; Toner, 2006).

The process of natural selection produces ***adaptations,*** which are common features of a species that provide it with improved function. Examples of adaptations include a behavior that helps the organism better escape a predator and a physical characteristic that provides it with an advantage, such as opposable thumbs for gripping.

A relatively new modern approach to psychology emerges from the theory of evolution and is called the evolutionary approach.

The ***evolutionary approach*** studies how evolutionary ideas, such as adaptation and natural selection, explain human behaviors and mental processes. This approach provides rather persuasive theories in sexual conflict, mating, sexuality, families, social conflict, aggression, morality, depression, and anxiety (Nesse, 2005; Pinker, 2002). In the case of sexual coercion, a type of sexual conflict, research suggests women have a variety of defenses, including the formation of female–female coalitions, selection of male friends who serve as "bodyguards," avoidance of risky activities, and fears of rape (Buss, 2003).

Research in evolutionary psychology relies on cognitive neuroscience (see p. 7), which means it uses pictures of the living brain (Tooby & Cosmides, 2006). We'll now describe how researchers study our modern brains through the use of impressive brain images.

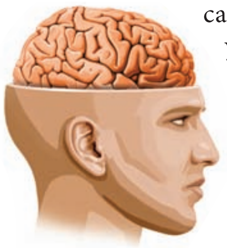
B. Studying the Living Brain

Brain Scans

Can we look inside the human skull?

We have explained how genetic instructions guide the development and assembly of billions of parts that make up the human brain. We have discussed genetic mutations and natural selection as the forces responsible for the evolution of the human brain. Now we begin exploring the structure and function of your own brain.

Looking at the skull on the right raises an interesting question: How can researchers look inside the half-inch-thick skull and study the living brain without causing any damage? The answer is that during the past 10 years, researchers have developed several brain-scanning techniques that can look through the thick skull and picture the brain with astonishing clarity yet cause no damage to the extremely delicate brain cells. By using these almost science-fiction techniques, researchers are mapping a variety of cognitive functions (attention, language, memory, motor skills) as well as sites of emotional feelings and appetite (Geliebter et al., 2006; Penn, 2006; Purves et al., 2008). We'll discuss several brain-scanning techniques that take pictures through the skull.



New techniques can take pictures through the skull.

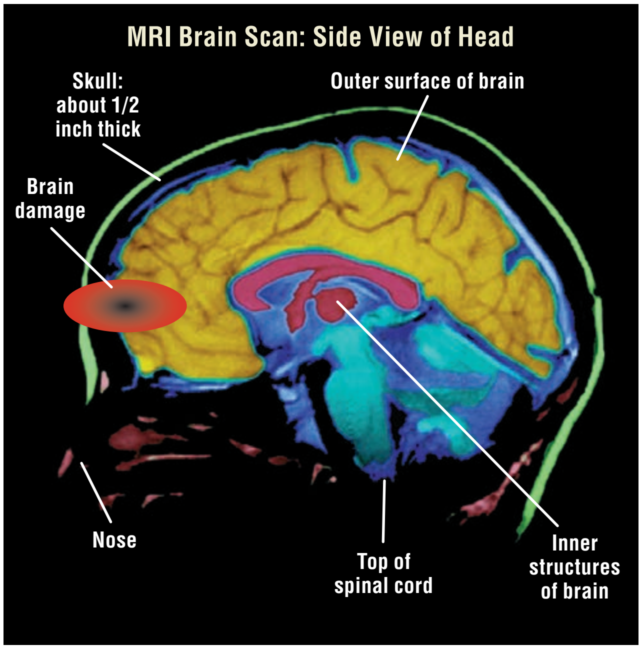
Brain Scans: MRI & fMRI

Why would Phillipa have an MRI?

At the beginning of this module, we told you about Phillipa, who was a school teacher. As she walked to her car one evening, she was approached by a mugger who used a steel rod to hit her head with a devastating blow. She was in excruciating pain and unable to move as she was taken to the hospital, unaware of the serious damage caused by the assault.

The neurologist at the hospital told Phillipa that the front part of her skull was shattered and the front area of her brain had serious, irreparable damage. The neurologist identified the exact location and extent of the damaged area by using a brain-scanning technique called MRI (photo below).

MRI, or ***magnetic resonance imaging,*** involves passing nonharmful radio frequencies through the brain. A computer measures how these signals interact with brain cells and transforms this interaction into an incredibly detailed image of the brain (or body). MRIs are used to study the structure of the brain.

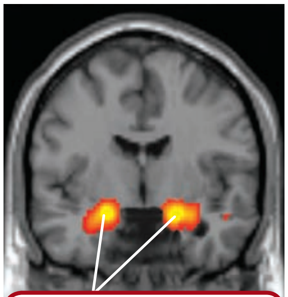


MRI Brain Scan: Side View of Head
Skull: about 1/2 inch thick
Outer surface of brain
Brain damage
Nose
Top of spinal cord
Inner structures of brain

During an MRI procedure, Phillipa would lie with her head in the center of a giant, donut-shaped machine. Reflections from the radio waves are computer analyzed and developed into very detailed pictures of the living brain, as shown in the photo (below left).

There is also a newer and different version of the MRI, called the fMRI. The "f" in ***fMRI*** (functional magnetic resonance imaging) stands for *functional* and measures the changes in activity of specific neurons that are functioning during cognitive tasks, such as thinking, listening, or reading.

For example, the fMRI on the right shows that while children were watching violence on TV, an increase in activity occurred in an area of the brain called the amygdala (p. 80), which researchers believe is involved in evaluating emotional situations, especially fear or threat (J. P. Murray et al., 2006). Notice that ***fMRI*** scans can map activities of neurons that are involved in various cognitive ***functions.*** In comparison, ***MRI*** scans show the location of ***structures*** inside the brain as well as identify tumors and sites of brain damage, as shown in the left photo.



Amygdala responds to watching televised violence.

Brain damage. During Phillipa's MRI scan, images of her brain—slice by slice—appeared on a television screen. Suddenly, standing out from the normal grayish image was a large unusual area that indicated a skull fracture and brain damage (red area on left of MRI scan). Because the damage was located in a brain area involved with carrying out motor movements, behaving normally in social situations, performing emotional behaviors, and maintaining a healthy personality, Phillipa had impaired motor movements, inappropriately yelled at others with rude remarks, and broke social guidelines (such as undressing herself in front of strangers). However, since only the front area of her brain was affected, many other functions, such as seeing, feeling, speaking, hearing, and understanding, were normal.

Advantage. The advantage of the two kinds of MRI scans is they use nonharmful radio frequencies and give very detailed views of structures and functions inside the living brain (Ropper & Samuels, 2009). The use of these two kinds of MRI scans has greatly increased our understanding of the brain.

We'll discuss one other brain-scanning technique, called the PET scan, which, similar to the fMRI, is also used to identify cognitive functions.

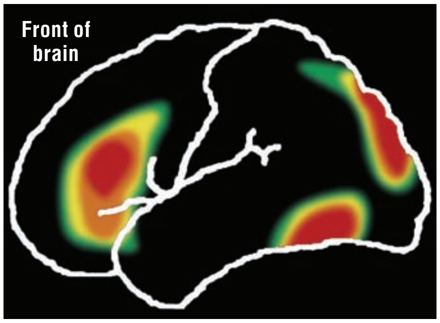
Brain Scans and Cognitive Neuroscience

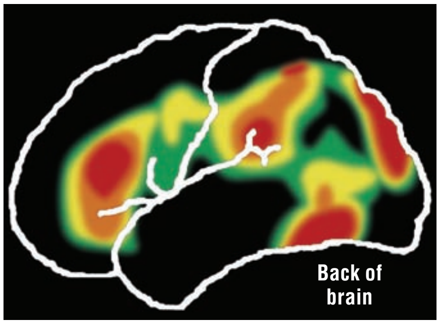
Are there pictures of thinking?

Currently, one of the most exciting areas in biological psychology is the study of cognitive neuroscience (p. 7), which involves using imaging techniques to literally light up your thoughts and feelings.

A ***PET scan,*** or positron emission tomography, involves injecting a slightly radioactive solution into the blood and then measuring the amount of radiation absorbed by brain cells called neurons. Very active neurons absorb more radioactive solution than less active ones. Different levels of absorption are represented by colors—red and yellow indicate maximum activity of neurons, while blue and green indicate minimal activity.



PET scan indicates that when you SPEAK a word, maximum neural activity—areas of red and yellow—occurs in 3 major areas of your brain.



PET scan indicates that when you SIGN a word, maximum neural activity occurs in the same areas as SPEAKING and 1 additional major area of your brain.

Pictures of speaking and signing. The PET scan at the top left shows that when subjects look at an object and identify it by speaking, most neural activity occurs in the areas of the brain responsible for speaking, seeing, and understanding. The PET scan at the bottom shows that when deaf people look at an object and identify it by signing, most neural activity occurs in the same areas as when speaking, but one area responsible for monitoring self-generated movements, such as signing, is also highly activated (Emmorey et al., 2007).

Neuroimaging. Both PET and fMRI scans identify and map the living brain's neural activity as a person performs complex behavioral and cognitive tasks, such as seeing, moving, thinking, speaking, trusting, and empathizing (McCarthy, 2005). PET scans are now being replaced by the newer fMRI scans because fMRI scans do not require the injection of slightly radioactive solutions (Ropper & Samuels, 2009).

Next, we'll discuss how brain scans were used to study an interesting puzzle in cognitive neuroscience.

Faces Versus Bodies

Same or different brain areas for recognizing faces and bodies?

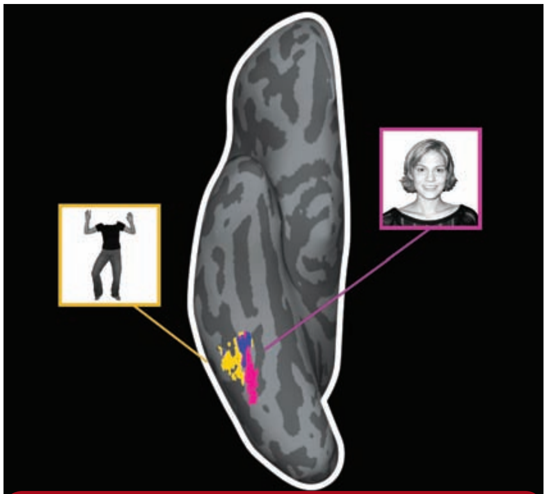
An interesting cognitive puzzle is whether our brain has specialized parts, each with a very specific function, or more generalized parts, with each carrying out a variety of functions without specializing in any. Solving this puzzle is a job for PET or fMRI scans.

Face and body recognition. An example of a specific function that has generally been believed to be a result of brain specialization is face recognition. Still, some researchers believe the same brain area that enables face recognition is also involved in recognizing bodies and body parts. Recently, a team of researchers used fMRI brain scans to carefully study the question of whether face recognition is a result of specialized brain function or in fact is made possible through generalized brain areas.

In this study, participants were placed in the fMRI machine while they were shown pictures of faces and bodies separately. fMRI scans showed maximum neural activity in two neighboring brain regions during these tasks. One area was mostly active when people saw faces (not bodies), and the other was mostly active when people saw bodies (not faces) (right photo). This finding suggests that, at least in the case of face and body recognition, one specific brain area is dedicated to one specific function (Delude, 2005; Schwarzlose et al., 2005).

As we discussed in Module 1 (p. 7), this study is an example of a relatively new area called ***cognitive neuroscience,*** which identifies and maps differences in neural activity to understand the bases for cognitive functions (Purves et al., 2008). Later on, we'll discuss a wide range of cognitive processes being studied using brain scans.

Conclusion. While many researchers are excited about using brain scans to understand the functions of our brain, some experts urge caution in interpreting the results from brain scan research. They say that, although brain scans can gradually help make sense of the complexities of the human brain, better technology and replication of findings are necessary to reach more accurate and less over-hyped conclusions (A. Grant, 2009; Vergano, 2008).



fMRI scan showing brain regions that specialize in recognizing faces (pink area) and in recognizing bodies (yellow area)

Now that you are familiar with ways to study the living brain, we can examine the brain's specific structures and interesting functions.

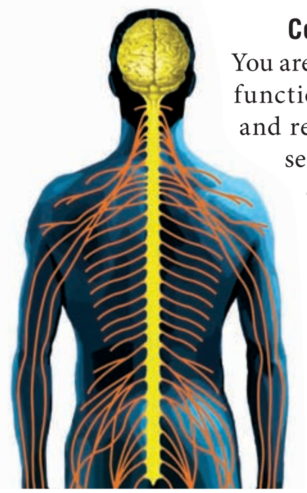
C. Organization of the Brain

Divisions of the Nervous System

How many nervous systems?

Because you have one brain, you may think that means you have one nervous system. In fact, your brain is much more complex: It has two major nervous systems, one of which has four subdivisions. We'll explain the overall organization of the brain's several nervous systems, beginning with its two major divisions: the central and peripheral nervous systems.

A. Major Divisions of the Nervous System

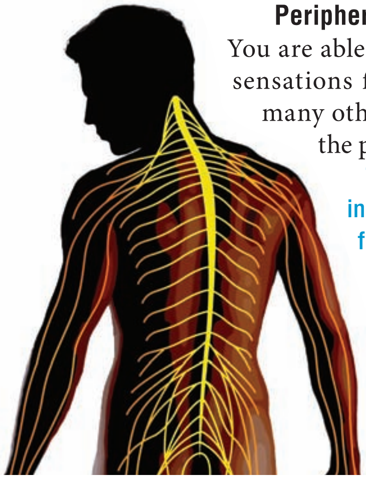


Central Nervous System—CNS

You are capable of many complex cognitive functions—such as thinking, speaking, and reading, as well as moving, feeling, seeing, and hearing—because of your central nervous system.

The ***central nervous system*** is made up of the brain and spinal cord. From the bottom of the brain emerges the spinal cord, which is made up of neurons and bundles of axons and dendrites that carry information back and forth between the brain and the body.

We'll discuss the major parts of the brain throughout this module.



Peripheral Nervous System—PNS

You are able to move your muscles, receive sensations from your body, and perform many other bodily responses because of the peripheral nervous system.

The ***peripheral nervous system*** includes all the nerves that extend from the spinal cord and carry messages to and from various muscles, glands, and sense organs located throughout the body.

The peripheral nervous system has two subdivisions: the somatic and autonomic nervous systems.

B. Subdivisions of the PNS

Somatic Nervous System

The ***somatic nervous system*** consists of a network of nerves that connect either to sensory receptors or to muscles that you can move voluntarily, such as muscles in your limbs, back, neck, and chest. Nerves in the somatic nervous system usually contain two kinds of fibers. Afferent, or sensory, fibers carry information from sensory receptors in the skin, muscles, and other organs to the spinal cord and brain. Efferent, or motor, fibers carry information from the brain and spinal cord to the muscles.

For example, this gymnast controls her muscles, knows where her arms and legs are located in space, and maintains her coordination and balance because the somatic nervous system sends electrical signals back and forth to her brain.

ANS—Autonomic Nervous System

The ***autonomic nervous system*** regulates heart rate, breathing, blood pressure, digestion, hormone secretion, and other functions. The autonomic nervous system usually functions without conscious effort, which means that only a few of its responses, such as breathing, can also be controlled voluntarily.

The autonomic nervous system also has two subdivisions: the sympathetic and parasympathetic divisions.

C. Subdivisions of the ANS

Sympathetic Division

The ***sympathetic division,*** which is triggered by threatening or challenging physical or psychological stimuli, increases physiological arousal and prepares the body for action.

For example, the sight of a frightening snake would trigger the sympathetic division, which, in turn, would arouse the body for action, such as fighting or fleeing.

Parasympathetic Division

The ***parasympathetic division*** returns the body to a calmer, relaxed state and is involved in digestion.

For example, when you are feeling calm and relaxed or digesting food, your parasympathetic system is activated.

Now that you know the overall organization of the nervous system, we'll focus on major parts of the brain.

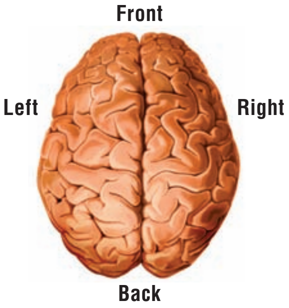
Major Parts of the Brain

Can someone be shot in the head but not die?

A human brain (right figure), which can easily be held in one hand, weighs about 1,350 grams, or 3 pounds, and has the consistency of firm JELL-O. The brain is protected by a thick skull and covered with thin, tough, plasticlike membranes. If shot in the head, a person may or may not die depending on which area was damaged. For example, damage to an area in the forebrain would result in paralysis, damage to an area in the midbrain would result in coma, but damage to an area in the hindbrain would certainly result in death.

We'll begin our exploration of the brain by looking at its three major parts—forebrain, midbrain, and hindbrain—beginning with the forebrain.



1 Forebrain

When you look at the brain, what you are actually seeing is almost all forebrain (figure above).

The ***forebrain,*** which is the largest part of the brain, has right and left sides that are called hemispheres. The hemispheres, connected by a wide band of fibers, are responsible for an incredible number of functions, including learning and memory, speaking and language, having emotional responses, experiencing sensations, initiating voluntary movements, planning, and making decisions.

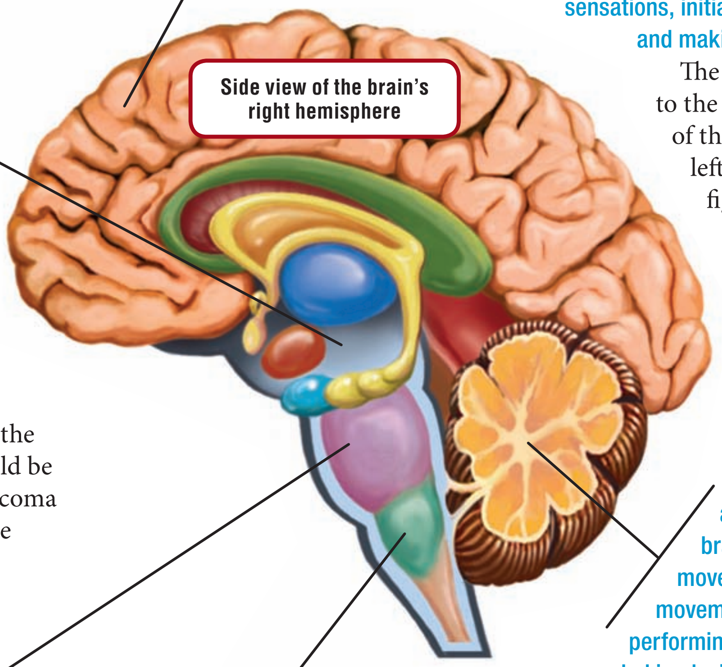
The large structure outlined in orange to the left shows only the right hemisphere of the forebrain. The forebrain's right and left hemispheres are both shown in the figure at the top right. The forebrain is very well developed in humans.

2 Midbrain

If a boxer is knocked unconscious, part of the reason lies in the midbrain.

The ***midbrain*** has a reward or pleasure center, which is stimulated by food, sex, money, music, attractive faces, and some drugs (cocaine); has areas for visual and auditory reflexes, such as automatically turning your head toward a noise; and contains the reticular formation, which arouses the forebrain so that it is ready to process information from the senses (Holroyd & Coles, 2002).

If the reticular formation were seriously damaged—by a blow to the head, for example—a person would be unconscious and might go into a coma because the forebrain could not be aroused (Bleck, 2007).



3 Hindbrain

The structures and functions of the hindbrain, which are found in very primitive brains, such as the alligator's, have remained constant through millions of years of evolution. The ***hindbrain*** has three distinct structures: the pons, medulla, and cerebellum.

3a Pons

If someone has a serious sleep disorder, it may involve the pons. In Latin, *pons* means "bridge," which suggests its function.

The ***pons*** functions as a bridge to transmit messages between the spinal cord and brain. The pons also makes the chemicals involved in sleep (Monti et al., 2008).

3b Medulla

If someone dies of a drug overdose, the cause of death probably involved the medulla.

The ***medulla,*** which is located at the top of the spinal cord, includes a group of cells that control vital reflexes, such as respiration, heart rate, and blood pressure.

Large amounts of alcohol, heroin, or other depressant drugs suppress the functions of cells in the medulla and cause death by stopping breathing.

3c Cerebellum

A person suspected of drunken driving may fail the test of rapidly touching a finger to the nose because of alcohol's effects on the cerebellum.

The ***cerebellum,*** which is located at the very back and underneath the brain, is involved in coordinating motor movements but not in initiating voluntary movements. The cerebellum is also involved in performing timed motor responses, such as those needed in playing games or sports, and in automatic or reflexive learning, such as blinking the eye to a signal, which is called classical conditioning (discussed in Module 9) (Gerwig et al., 2008).

Because alcohol is a depressant drug and interferes with the functions of the cerebellum, an intoxicated person would experience decreased coordination and have difficulty rapidly touching a finger to the nose, which is one test for being drunk (Oscar-Berman & Marinkovic, 2007).

Of the brain's three parts, the forebrain is the largest, most evolved, and most responsible for an enormous range of personal, social, emotional, and cognitive behaviors. For those reasons, we'll examine the forebrain in more detail.

D. Control Centers: Four Lobes

Overall View of the Cortex

How do you package 1 trillion cells?

How would you design a brain to hold 1 trillion cells (100 billion neurons and 900 billion glial cells) and be no bigger than a small melon and weigh no more than 3 pounds? You would need to make the cells microscopic in size, which they are, and to organize the billions of cells into different but interconnected areas, which they are. But would you have thought to make the brain's surface very wrinkled? Here's why.

Wrinkled Cortex

In the photo below, you see a computer-enhanced picture of the outside of an adult human brain, which has a very wrinkled surface that is called the cortex (in Latin, *cortex* means "cover").

Brain's surface shows its wrinkled cortex.

The ***cortex*** is a thin layer of cells that essentially covers the entire surface of the forebrain. The vast majority of our neurons are located in the cortex, which folds over on itself so that it forms a large surface area.

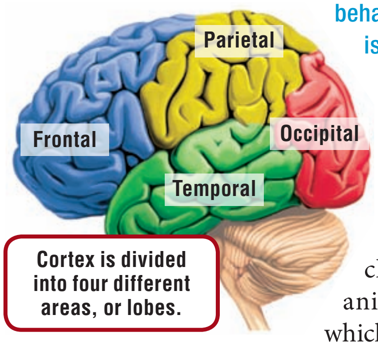
To understand the advantage of having a wrinkled cortex, just imagine having to put a large sheet of paper about 18 inches square into a small match box that is 3 inches square. One solution is to crumple (wrinkle) the sheet of paper until it easily fits into the tiny match box. Similarly, imagine many billions of neurons laid on a sheet of paper about 18 inches square. When this large sheet of neurons is wrinkled, the cortex can fit snugly into our much smaller, rounded skulls.

Early researchers divided the wrinkled cortex into four different areas, or lobes, each of which has different functions.

Four Lobes

As you look at the brain's cortex, you see a wrinkled surface of peaks and valleys with very few distinguishing features. However, the cortex's appearance is deceiving because its hundreds of different functions are organized into four separate areas called lobes.

The cortex is divided into four separate areas, or ***lobes,*** each with different functions: the ***frontal lobe*** is involved with personality, emotions, and motor behaviors; the ***parietal*** *(puh-RYE-it-all)* ***lobe*** is involved with perception and sensory experiences; the ***occipital*** *(ock-SIP-pih-tull)* ***lobe*** is involved with processing visual information; and the ***temporal*** *(TEM-purr-all)* ***lobe*** is involved with hearing and speaking.



Cortex is divided into four different areas, or lobes.

The one brain structure that most clearly distinguishes you from other animals is your well-developed cortex, which allows you to read, understand, talk about, and remember the concepts in this text. To understand what life would be like without a cortex, we'll return to the case of Baby Theresa, who was born without any lobes and thus no cortex.

Baby Theresa's Brain: A Fatal Defect

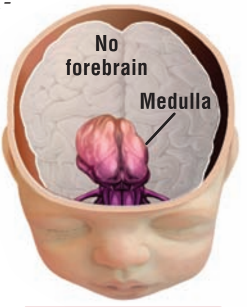
At the beginning of this module, we told you about Baby Theresa, who was born with almost no brain and died only 9 days after birth. This rare condition, caused by errors in genetic instructions, is called anencephaly (Ropper & Samuels, 2009).

Anencephaly *(an-in-CEPH-ah-lee)* refers to the condition of being born with little or no brain. If some brain or nervous tissue is present, it is totally exposed and often damaged because the top of the skull is missing. Survival is usually limited to days; the longest has been two months.

Theresa had anencephaly, meaning little or no brain.

Anencephaly is always fatal because it also includes other serious physical defects, such as damage to the skull (R. J. Cook et al., 2008). Baby Theresa (photo above), who survived only nine days, had almost no brain tissue and almost no skull (bandaged area above eyes). Lacking most of a brain means that she would be incapable of perceiving, thinking, speaking, planning, or making decisions.

The figure below shows that a baby born with anencephaly has no forebrain. One reason babies with anencephaly may survive for days or weeks is that they may have parts of their hindbrain. As discussed earlier, the hindbrain contains the pons and medulla. The medulla controls vital reflexes, such as breathing, heart rate, and blood pressure, which together can maintain life for a period of time.



The medulla kept Theresa alive.

This example of anencephaly shows that without the forebrain, a baby may be physiologically alive but show no signs of having a mind or possessing cognitive abilities associated with being human. In a real sense, it is the functions of the forebrain's four lobes that define us as human and distinguish us from all other creatures.

Because the four lobes are vital to our existence as humans, we'll discuss each lobe in turn. We'll begin with the frontal lobe and a tragic accident.

Photo Credits: top left, Wadsworth Publishing; top right, © Patrick Farrell/*Miami Herald* photo

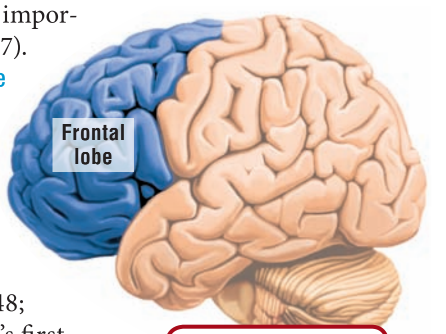
Frontal Lobe: Functions

What does the biggest lobe do?

The frontal lobe (right figure) is the largest of the brain's lobes and has many important functions (J. H. Friedman & Chou, 2007; B. L. Miller & Cummings, 2007).

The ***frontal lobe,*** which is located in the front part of the brain, includes a huge area of cortex. The frontal lobe is involved in many functions: performing voluntary motor movements, interpreting and performing emotional behaviors, behaving normally in social situations, maintaining a healthy personality, paying attention to things in the environment, making decisions, and executing plans. Because the frontal lobe is involved in making decisions, planning, reasoning, and carrying out behaviors, it is said to have executive functions, much like the duties of a company's executive officer.

Our first clue about the functions of the frontal lobe came from an unusual accident in 1848; our more recent knowledge comes from research using brain scans (fMRI and PET scans). Let's first go back in time and meet Phineas Gage, whose accident led to the discovery of one of the frontal lobe's important functions.



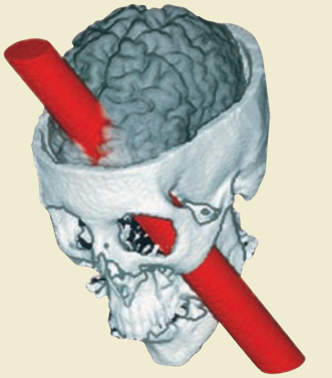
Frontal lobe has executive functions.

A Terrible Accident

The accident occurred at about half past four on the afternoon of September 13, 1848, near the small town of Cavendish, Vermont. Railroad crewmen were about to blast a rock that blocked their way. Foreman Phineas Gage filled a deep, narrow hole in the rock with powder and rammed in a long iron rod to tamp down the charge before covering it with sand. But the tamping iron rubbed against the side of the shaft, and a spark ignited the powder. The massive rod—3½ feet long, 1¼ inches in diameter, and weighing 13 pounds—shot from the hole under the force of the explosion. It struck Phineas just beneath his left eye and tore through his skull. It shot out the top of his head and landed some 50 yards away.

Phineas survived, but, following the accident, his personality changed: He went from being a popular, friendly foreman to acting impatient, cursing his workers, and refusing to honor his promises.

A massive rod (right image) weighing 13 pounds was accidentally driven through the front part of Phineas Gage's frontal lobe. The result, which was similar to having a frontal lobotomy, caused Phineas to have emotional outbursts and problems in making decisions, something he did not experience before this accident.



Researchers recently used Phineas's preserved skull to reconstruct the site and extent of his brain damage. As the figure above shows, the iron rod had passed through and extensively damaged Phineas's frontal lobe. Researchers concluded that Phineas had suffered a crude form of frontal lobotomy, which caused deficits in processing of emotion and decision making that result after damage to the frontal lobe (H. Damasio et al., 1994).

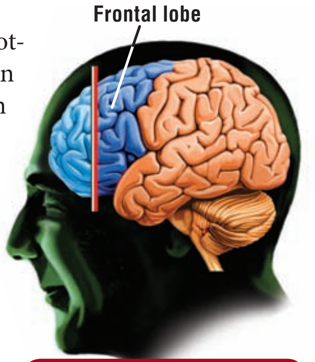
Beginning in the 1930s, doctors performed thousands of lobotomies to treat various mental and behavioral problems.

Frontal Lobotomy

In 1936, Egas Moniz, a Portuguese neurologist, used an untested surgical treatment, frontal lobotomy, to treat individuals with severe emotional problems (Tierney, 2000; A. P. Weiss et al., 2007).

A ***frontal lobotomy*** was a surgical procedure in which about one-third of the front part of the frontal lobe (figure below) was cut away from the rest of the brain.

Moniz first reported that frontal lobotomies did reduce emotional problems in about 35% of severely agitated human patients, although he did no controlled or follow-up studies to check long-term effects (D. R. Weinberger et al., 1995). Based on Moniz's reports of success, about 18,000 frontal lobotomies were performed in the 1940s and 1950s on emotionally disturbed patients who were primarily confined to state mental hospitals that had no other treatments.



Red line indicates where lobe was severed.

Results of Lobotomies

Initially, neurologists reported good short-term effects, but better controlled, long-term studies on frontal lobotomies found mixed results: Some patients did become less violent, but others showed no improvement and some became worse. Even those whose social-emotional behaviors improved were often left with serious problems in other areas, such as having difficulty in making and carrying out plans, adjusting to new social demands, or behaving with appropriate emotional responses in social situations (Mashour et al., 2005).

Two things happened in the early 1950s that ended the use of frontal lobotomies to treat social-emotional problems. First, follow-up research indicated that lobotomies were no more successful in relieving social-emotional problems than doing nothing. Second, antipsychotic drugs were discovered and showed greater success in treating serious social-emotional problems (Mashour et al., 2005).

From using frontal lobotomies as treatment, researchers learned two things: (1) careful follow-up work is essential before declaring a treatment successful, and (2) the frontal lobe has many different, important functions, which we'll look at next.

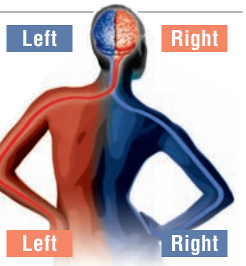
D. Control Centers: Four Lobes

Frontal Lobe: Functions

How do you move your right hand?

The organization of the frontal lobe is somewhat confusing because it has such a wide range of functions, from motor movements to cognitive processes. We'll first focus on motor movements, which have a very unusual feature.

In the figure on the right, notice that nerves from the left hemisphere (blue) cross over and control the movements of the right hand and right side of the body; nerves from the right hemisphere (red) cross over and control the movements of the left hand and left side of the body. The ability to move your hand or any other part of your body depends on the motor cortex in the right and left frontal lobes.

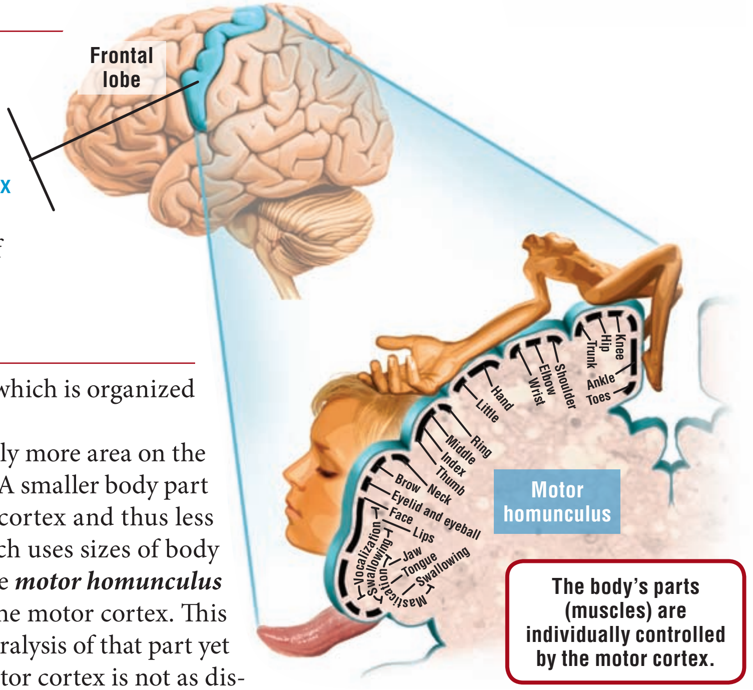


Location of Motor Cortex

To move your right hand, you will use the motor cortex in your left frontal lobe.

The ***motor cortex*** is a narrow strip of cortex that is located on the back edge of the frontal lobe and extends down its side. The motor cortex is involved in the initiation of all voluntary movements. The right motor cortex controls muscles on the left side of the body, and vice versa.

You can move any individual part of your body at will because of how the motor cortex is organized.



The body's parts (muscles) are individually controlled by the motor cortex.

Organization and Function of Motor Cortex

The figure on the right shows an enlarged part of the motor cortex, which is organized in two interesting ways.

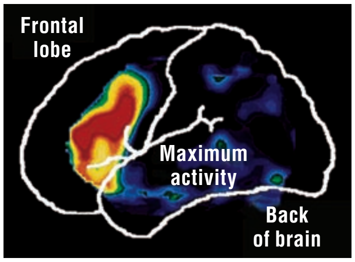
First, a larger body part (notice huge hand area) indicates relatively more area on the motor cortex and thus more ability to perform complex movements. A smaller body part (notice small knee area) indicates relatively less area on the motor cortex and thus less ability to perform complex movements. This unusual drawing, which uses sizes of body parts to show the ability to perform complex movements, is called the ***motor homunculus*** *(ho-MONK-you-luss).* **Second,** each body part has its own area on the motor cortex. This means that damage to one part of the motor cortex could result in paralysis of that part yet spare most other parts. However, recent studies indicate that the motor cortex is not as discretely organized as once believed. Instead of each body part having a different discrete area, there is considerable overlap between body parts in the motor cortex (Purves et al., 2008). Finally, notice that the motor cortex makes up only a relatively small part of the entire frontal lobe.

In a surprising finding, there was vigorous activity in the motor cortex when people did nothing more than silently read action words. For example, when people read the word *lick,* activity occurred in parts of the motor cortex associated with the tongue and mouth (Hauk et al., 2004). This means that besides triggering voluntary movements, the motor cortex responds to simply hearing action words, such as *kick, hit,* or *run.* Next, we'll explain the frontal lobe's other functions.

Other Functions of Frontal Lobe

Executive function. Much of our knowledge of other frontal lobe functions comes from brain scans on both individuals who had damage to that area and healthy individuals. Researchers have found that the frontal lobes are involved in paying attention, organizing, planning, deciding, and carrying out cognitive and social-emotional behaviors, including self-control. Frontal lobes are said to have an **executive function**—that is, act similar to a smart, successful executive of a large organization (B. L. Miller & Cummings, 2007; von Hippel, 2007).

Memory. Brains scans used on individuals without brain damage have led to interesting discoveries about frontal lobe functions. For example, after subjects were shown a series of word pairs, such as *ordeal* and *roach,* they were shown one word from each pair *(ordeal)* and asked to either think about or avoid thinking about the associated word *(roach).* Brain scans, such as the one shown below, indicated that people who best avoided thinking about the associated word had maximum activity in the frontal lobe. This means the frontal lobe is involved in memory, specifically intentional forgetting (M. C. Anderson et al., 2004).



Aging. The frontal lobes shrink as we age, creating impairment in our executive functions, such as inhibiting unwanted speech (a type of self-control). Although older adults understand social rules, they often inappropriately ask others embarrassing questions in public settings and talk at great length about topics irrelevant to a conversation, both of which demonstrate executive function impairments (Begley, 2007b; von Hippel, 2007).

Immediately behind the frontal lobe is the parietal lobe, which, among other things, keeps track of your body's limbs.

Photo Credit: bottom, Courtesy of J.A. Fiez, Dept. of Neurology, Washington University School of Medicine

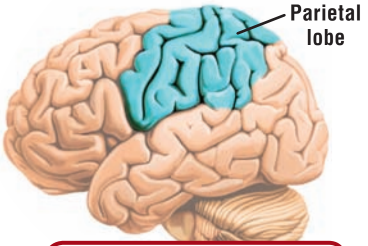
Parietal Lobe: Functions

How do you know where your feet are?

Every second of every minute of every day, your brain must keep track of what's touching your skin, where your feet and hands are, and whether you're walking or running. All this is automatically and efficiently done by your parietal lobe (right figure).

The ***parietal lobe*** is located directly behind the frontal lobe. The parietal lobe's functions include processing sensory information from body parts, which includes touching, locating positions of limbs, and feeling temperature and pain, and carrying out several cognitive functions, such as attending to and perceiving objects.

For example, the ability to know what you're touching involves the parietal lobe's somatosensory cortex.



Parietal lobe processes information from body parts.

Location of Somatosensory Cortex

Knowing what you're touching or how hot to make the water for your shower involves the somatosensory cortex.

The ***somatosensory cortex*** is a narrow strip of cortex that is located on the front edge of the parietal lobe and extends down its side. The somatosensory cortex processes sensory information about touch, location of limbs, pain, and temperature. The right somatosensory cortex receives information from the left side of the body, and vice versa.

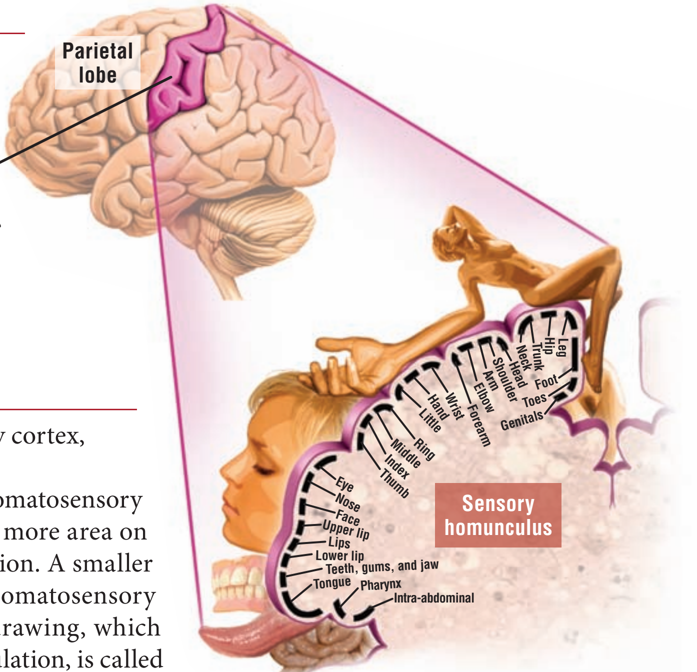
Your lips are much more sensitive than your elbows because of the way the somatosensory cortex is organized.

Organization of Somatosensory Cortex

The large figure on the right shows an enlarged part of the somatosensory cortex, which is also cleverly organized.

First, notice the different sizes of the body parts drawn on top of the somatosensory cortex. A larger body part (notice large area for lips) indicates relatively more area on the somatosensory cortex and thus more sensitivity to external stimulation. A smaller body part (notice small nose area) indicates relatively less area on the somatosensory cortex and thus less sensitivity to external stimulation. This unusual drawing, which uses sizes of body parts to indicate amount of sensitivity to external stimulation, is called the ***sensory homunculus*** *(ho-MONK-you-luss).* In Latin, *homunculus* means "little man." Notice that the somatosensory cortex makes up only a small part of the parietal lobe.

Second, notice that each body part has its own area on the somatosensory cortex. This means that damage to one part of the somatosensory cortex could result in loss of feeling to one part of the body yet spare all others. Next, we'll explain the parietal lobe's other functions.

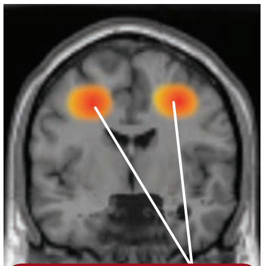


Information from body parts (skin, muscles, etc.) is individually processed by the somatosensory cortex.

Other Functions of Parietal Lobe

Sensory integration. When you put your hand in your pocket, you can easily distinguish a key from a stick of chewing gum because your parietal lobe digests information about texture, shape, and size and "tells you" what the object is. However, patients with damage to the back of their parietal lobes cannot recognize common objects by touch or feel (Bear et al., 1996). Evidence that the parietal lobes are involved in other cognitive processes comes from studies using brain scans.

Spatial orientation. The parietal lobe is involved in processing spatial information (P. H. Weiss et al., 2006). For example, when you are judging the location and distance you must throw a football, your parietal lobe is working to enable you to complete a successful throw.



Maximum activity in parietal lobe.

Language abilities. Subjects were asked to participate in a writing exercise while researchers investigated changes in their brain activity. fMRI scans, such as the one shown here, indicated that maximum activity during this task occurred in the parietal lobe (Menon & Desmond, 2001). Another fMRI study on people who fluently speak a second language indicated the parietal lobe was more developed (or larger) than in those who spoke only one language (Mechelli et al., 2004).

Other functions. Research using brain scans shows that the parietal lobes are involved in additional cognitive functions, such as visual and auditory attention, memory, and numerical processing (counting) (Hao et al., 2005; Hubbard et al., 2005; Shomstein & Yantis, 2006; Simons et al., 2008).

Immediately below the parietal lobe is the temporal lobe, which we'll examine next.

D. Control Centers: Four Lobes

Temporal Lobe: Functions

Did you hear your name?

You recognize your name when you hear it spoken; because of the way sound is processed in the temporal lobe, you know it's not just some meaningless noise.

The ***temporal lobe*** is located directly below the parietal lobe and is involved in hearing, speaking coherently, and understanding verbal and written material.

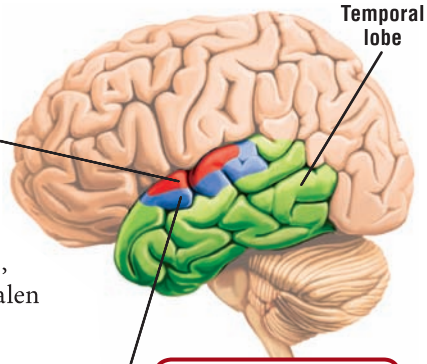
As you'll see, the process of hearing and recognizing your name involves two steps and two different brain areas.

Primary Auditory Cortex

The first step in hearing your name occurs when sounds reach specific areas in the temporal lobe called the primary auditory (hearing) cortex; there is one in each lobe.

The ***primary auditory cortex*** (shown in red), which is located on the top edge of each temporal lobe, receives electrical signals from receptors in the ears and transforms these signals into meaningless sound sensations, such as vowels and consonants.

At this point, you would not be able to recognize your name because the primary auditory cortex only changes electrical signals from the ears into basic sensations, such as individual sounds, clicks, or noises. For these meaningless sound sensations to become recognizable words, they must be sent to another area in the temporal lobe, called the auditory association area (Whalen et al., 2006).



Temporal lobe processes auditory (hearing) information.

Auditory Association Area

The second step in recognizing your name is when the primary auditory cortex sends its electrical signals to the auditory association area; there is one in each lobe.

The ***auditory association area*** (shown in blue), which is located directly below the primary auditory cortex, transforms basic sensory information, such as noises or sounds, into recognizable auditory information, such as words or music.

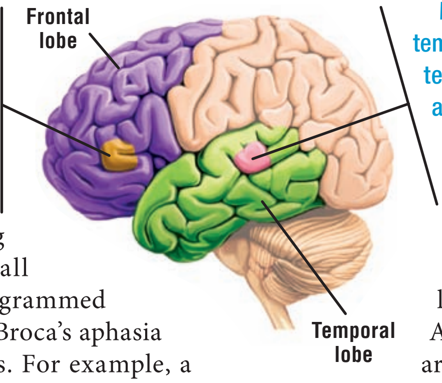
It is only after auditory information is sent by the primary auditory cortex to the auditory association area that you would recognize sounds as your name, or words, or music (D.H. Whalen et al., 2006). So, it is safe to say that you hear with your brain rather than your ears.

Besides being involved in hearing, the temporal lobe has other areas that are critical for speaking and understanding words and sentences.

Broca's Area—Frontal Lobe

Just as hearing your name is a two-step process, so is speaking a sentence. The first step is putting words together, which involves an area in the frontal lobe called Broca's *(BROKE-ahs)* area.

Broca's area, which is usually located in the left frontal lobe, is necessary for combining sounds into words and arranging words into meaningful sentences. Damage to this area results in ***Broca's aphasia*** *(ah-PHASE-zz-ah),* which means a person cannot speak in fluent sentences but can understand written and spoken words.



The reason that saying words and putting words into sentences come naturally to small children is that Broca's area is genetically programmed to do this task. If it is damaged, people with Broca's aphasia have difficulty putting words into sentences. For example, a patient was asked, "What have you been doing in the hospital?" The patient answered, "Yes, sure. Me go, er, uh, P.T. non o'cot, speech . . . two times . . . read . . . wr . . . ripe, er, rike, er, write . . . practice . . . get-ting better" (H. Gardner, 1976, p. 61). The patient was trying to say, "I go to P.T. (physical therapy) at one o'clock to practice speaking, reading, and writing, and I'm getting better."

A patient with Broca's aphasia cannot speak fluently but can still understand words and sentences because of a second area in the temporal lobe—Wernicke's area (Swanberg et al., 2007).

Wernicke's Area—Temporal Lobe

The first step in speaking is using Broca's area to combine sounds into words and arrange words into sentences. The second step is to understand sentences, which involves Wernicke's *(VERN-ick-ees)* area.

Wernicke's area, which is usually located in the left temporal lobe, is necessary for speaking in coherent sentences and for understanding speech. Damage to this area results in ***Wernicke's aphasia,*** which is a difficulty in understanding spoken or written words and in putting words into meaningful sentences.

For example, a patient with Wernicke's aphasia said, "You know, once in awhile I get caught up, I mention the tarripoi, a month ago, quite a little, I've done a lot well" (H. Gardner, 1976, p. 68). As this meaningless sentence shows, Wernicke's area is critical for combining words into meaningful sentences and being able to speak coherently (Mesulam, 2008).

Due to genetic factors, most right-handers (96%) and a majority of left-handers (70–80%) have Broca's and Wernicke's areas in the left hemisphere. In about 20% of left-handers, the language areas are in either the right hemisphere or both hemispheres (B. Bower, 2002).

Compared to many other animals, humans rely more heavily on visual information, which is processed in the occipital lobe, our next topic.

Occipital Lobe: Functions

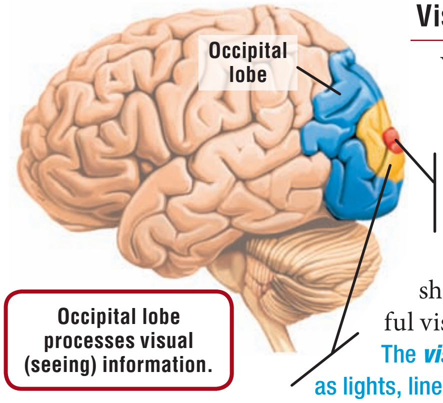
Can you see better than dogs?

Dogs have poor color vision and rely more on their sense of smell. In comparison, all primates, which include monkeys, apes, and humans, have a relatively poor sense of smell and rely more on vision for gathering information about their environments.

If you have ever been hit on the back of the head and saw "stars," you already know that vision is located in the occipital lobe.

The ***occipital lobe*** is located at the very back of the brain and is involved in processing visual information, which includes seeing colors and perceiving and recognizing objects, animals, and people.

Although you see and recognize things with great ease, it is actually a complicated two-step process. Here, we'll give only an overview of that process; we'll go into more detail in Module 5.



Occipital lobe processes visual (seeing) information.

Vision

When you look in the mirror and see your face, you don't realize that seeing your face involves two steps and two different areas in the occipital lobe (Maldonado et al., 1997). The first step in seeing your face involves the primary visual cortex.

The ***primary visual cortex,*** which is located at the very back of the occipital lobe, receives electrical signals from receptors in the eyes and transforms these signals into meaningless basic visual sensations, such as lights, lines, shadows, colors, and textures.

Since the primary visual cortex produces only meaningless visual sensations (lights, lines, shadows), you do not yet see your face. Transforming meaningless visual sensations into a meaningful visual object occurs in the visual association area (Kiernan, 2008).

The ***visual association area,*** which is located next to the primary visual cortex, transforms basic sensations, such as lights, lines, colors, and textures, into complete, meaningful visual perceptions, such as persons, objects, or animals.

When the second step works properly, there is increased activity in the visual association area and decreased activity in the primary visual cortex as basic sensations are turned into meaningful perceptions (S. O. Murray et al., 2002). If there are problems in the second step, the person can still see parts of objects but has difficulty combining the parts and recognizing the whole object (Osborne et al., 2007; Purves et al., 2008).

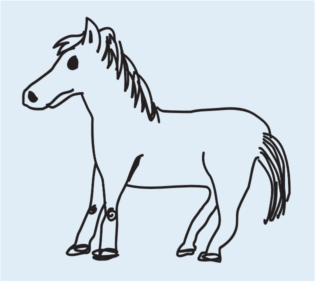
We'll discuss two unusual visual problems that result from damage to association areas.

Visual Agnosia

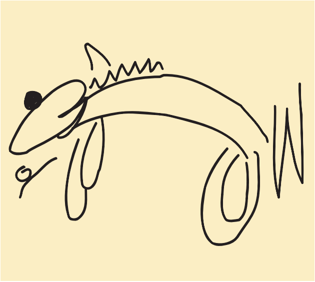
Since the visual association area is critical for recognizing faces, shapes, and objects, damage to this area results in difficulties of recognition, a condition called visual agnosia *(ag-NO-zee-ah).*

In ***visual agnosia,*** the individual fails to recognize some object, person, or color, yet has the ability to see and even describe pieces or parts of some visual stimulus.

Here's what happened when a patient with damage to the visual association area was asked to simply copy an object.



A patient who has visual agnosia was asked to make a copy of this horse, something most everyone can do.



The patient drew each part of the horse separately and could not combine individual parts into a meaningful image.

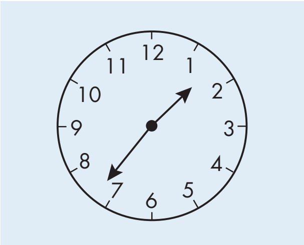
Patients with visual agnosia can see individual parts of an object, such as a horse's leg, but, because of damage to visual association areas, have great difficulty combining parts to perceive or draw a complete and recognizable image, such as a complete horse (Farah, 2004; Maratsos & Matheny, 1994). Damage to association areas can also result in seeing only half of one's world.

Neglect Syndrome

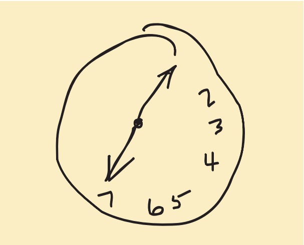
Individuals who have damage to association areas, usually in occipital and parietal lobes, and usually in the right hemisphere, experience a very strange problem called the neglect syndrome.

The ***neglect syndrome*** refers to the failure of a patient to see objects or parts of the body on the side opposite the brain damage. Patients may dress only one side of their body and deny that opposite body parts are theirs ("that's not my leg").

Here's how a patient with neglect syndrome drew an object.



A patient with neglect syndrome caused by right-sided brain damage was asked to copy this clock.



The patient drew only the right side of the clock because he did not see or recognize things on his left side.

After a stroke or other damage, usually to the occipital and parietal association areas in the right hemisphere, patients may behave as if the left sides of objects or their own bodies no longer exist: they may not shave or dress the left sides of their bodies, which they do not recognize. Neglect syndrome shows the important function of association areas in recognizing things (Danckert & Ferber, 2006).

Now we'll journey beneath the cortex and explore a group of structures that existed in evolutionarily very old, primitive brains.

Matheny, 1994, *Annual Review of Psychology, 45,* 487–516; (bottom right) Adapted from *Left Brain, Right Brain,* by S. P. Springer and G. Deutsch, 4/e, 1989. W. H. Freeman Company.

E. Limbic System: Old Brain

Structures and Functions

How are you like an alligator?

Your cortex is involved in numerous cognitive functions, such as thinking, deciding, planning, and speaking, as well as other sensory and motor behaviors. But what triggers your wide range of emotional experiences, such as feeling happy, sad, or angry? The answer lies deeper inside the brain, where you'll find a number of interconnected structures that are involved in emotions and are called the limbic system (J. H. Friedman & Chou, 2007; Ropper & Samuels, 2009).

The ***limbic system*** refers to a group of about half a dozen interconnected structures that make up the core of the forebrain. The limbic system's structures are involved with regulating many motivational behaviors such as obtaining food, drink, and sex; with organizing emotional behaviors such as fear, anger, and aggression; and with storing memories.

Alligators and humans have limbic systems.

The limbic system is often referred to as our primitive, or animal, brain because its same structures are found in the brains of animals that are evolutionarily very old, such as alligators. The alligator's limbic system, which essentially makes up its entire forebrain, is involved in smelling out prey, defending territory, hunting, fighting, reproducing, eating, and remembering. The human limbic system, which makes up only a small part of our forebrain, is involved in similar behaviors.

We'll discuss some of the major structures and functions of the limbic system. The drawing below shows the right hemisphere (the left hemisphere is cut away). Notice that the limbic structures are surrounded by the forebrain, whose executive functions regulate the limbic system's emotional and motivational behaviors.

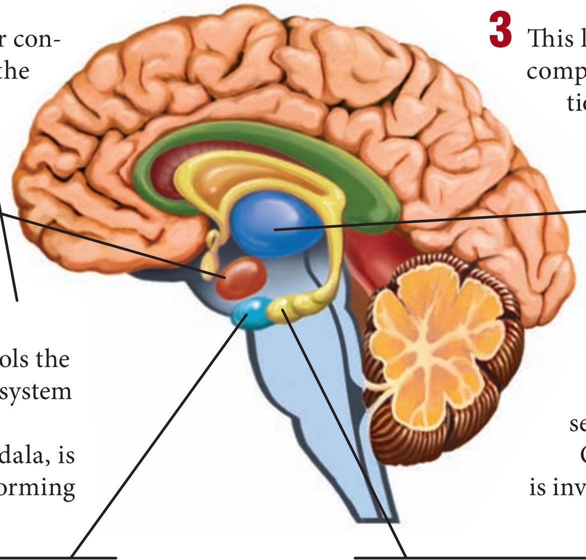
Important Parts of the Limbic System

1 One limbic structure that is a master control for many emotional responses is the hypothalamus *(high-po-THAL-ah-mus).*

The ***hypothalamus*** regulates many motivational behaviors, including eating, drinking, and sexual responses; emotional behaviors, such as arousing the body when fighting or fleeing; and the secretion of hormones, such as occurs at puberty.

In addition, the hypothalamus controls the two divisions of the autonomic nervous system discussed on the next page.

The next limbic structure, the amygdala, is also involved in emotions but more in forming and remembering them.



2 The ***amygdala*** *(ah-MIG-duh-la),* located in the tip of the temporal lobe, receives input from all the senses. It plays a major role in evaluating the emotional significance of stimuli and facial expressions, especially those involving fear, distress, or threat.

When the amygdala is damaged, patients had difficulty recognizing emotional facial expressions and animals did not learn to fear or avoid dangerous situations. Brain scans indicate that the amygdala is involved in identifying emotional facial expressions (Hooker et al., 2006). Researchers report that the amygdala is critical in recognizing emotional facial expressions, including happy faces but especially faces indicating fear, distress, or threat; evaluating emotional situations, especially involving threat or danger; and adding emotional feelings to happy or sad events (remembering a joke, going to a funeral) (R. J. Dolan, 2002).

3 This limbic structure, which is like a miniature computer that gathers and processes information from all of your senses (except smell), is called the thalamus *(THAL-ah-mus).*

The ***thalamus*** is involved in receiving sensory information, doing some initial processing, and then relaying the sensory information to areas of the cortex, including the somatosensory cortex, primary auditory cortex, and primary visual cortex.

For example, if the thalamus malfunctions, you might have difficulty processing sensory information (hearing or seeing).

Our last limbic structure, the hippocampus, is involved in saving your memories.

4 The ***hippocampus,*** which is a curved structure inside the temporal lobe, is involved in saving many kinds of fleeting memories by putting them into permanent storage in various parts of the brain.

For example, humans with damage to the hippocampus have difficulty remembering new facts, places, faces, or conversations because these new events cannot be placed into permanent storage (Rolls, 2007). Think of the hippocampus, which is involved in saving things in long-term storage (see p. 268), as functioning like the "Save" command on your computer.

Limbic system versus frontal lobe. Some of the basic emotional feelings triggered by the limbic system (anger, rage, fear, panic) carry the potential for self-injury or injury to others. Researchers found that our larger and evolutionarily newer frontal lobe, which is involved in thinking, deciding, and planning, plays a critical role in controlling the limbic system's powerful urges (Banks et al., 2007; Rosenkranz et al., 2003).

One particular structure in the limbic system, the hypothalamus, also has an important role in regulating the autonomic nervous system, which we'll examine next.

Autonomic Nervous System

Why don't you worry about breathing?

You are unaware of what regulates your breathing, heart rate, hormone secretions, or body temperature. You're not concerned about these vital functions because they are usually controlled by a separate nervous system, called the autonomic nervous system, which, in turn, is regulated by a master control center, the hypothalamus (discussed on the preceding page).

The autonomic nervous system, which regulates numerous physiological responses, has two divisions: the sympathetic and parasympathetic nervous systems. The sympathetic division is activated when you suddenly see a snake; then the parasympathetic division helps you relax (Purves et al., 2008). We'll explain some of the specific and automatic functions of the sympathetic and parasympathetic divisions.

Sympathetic Nervous System

If you were on a nature hike and suddenly saw a snake, your cortex would activate the hypothalamus, which in turn would trigger the sympathetic division of the autonomic nervous system (A. Siegal & Sapru, 2007).

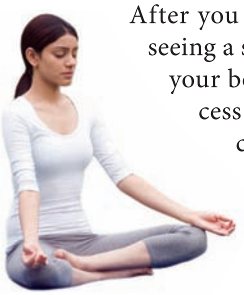
The ***sympathetic division,*** which is one part of the autonomic nervous system, is triggered by threatening or challenging physical stimuli, such as a snake, or by psychological stimuli, such as the thought of having to give a public speech. Once triggered, the sympathetic division increases the body's physiological arousal.

All of the physiological responses listed in the left-hand column under ***Sympathetic,*** such as increased heart rate, inhibited digestion, and dilated pupils, put your body into a state of heightened physiological arousal, which is called the fight-flight response.

The ***fight-flight response,*** which is a state of increased physiological arousal caused by activation of the sympathetic division, helps the body cope with and survive threatening situations.

You have no doubt experienced the fight-flight response many times, such as when you felt your heart pound and your mouth go dry. Later, we'll discuss the role of the fight-flight response in stressful situations and in psychosomatic diseases (pp. 484–489).

Parasympathetic Nervous System



After you have been physiologically aroused by seeing a snake, it usually takes some time before your body returns to a calmer state. The process of decreasing physiological arousal and calming down your body is triggered by the hypothalamus, which activates the parasympathetic division.

The ***parasympathetic division,*** which is the other part of the autonomic nervous system, decreases physiological arousal and helps return the body to a calmer, more relaxed state. It also stimulates digestion during eating.

As shown in the right column under the heading ***Parasympathetic,*** the parasympathetic division, once activated, decreases physiological arousal by decreasing heart rate, stimulating digestion, and constricting pupils. These responses result in the body returning to a more relaxed state.

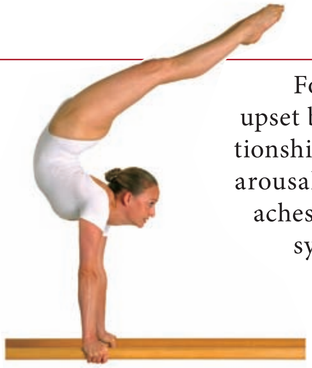
In dealing with stress, we'll discuss many relaxation techniques (pp. 502–503), such as the relaxation response, various forms of meditation, and biofeedback, which help increase parasympathetic activity, decrease body arousal, and thus help you calm down after stressful experiences.

Sympathetic		Parasympathetic
Pupils dilated, dry; far vision	*Eyes*	Pupils constricted, moist; near vision
Dry	*Mouth*	Salivation
Goose bumps	*Skin*	No goose bumps
Sweaty	*Palms*	Dry
Passages dilated	*Lungs*	Passages constricted
Increased rate	*Heart*	Decreased rate
Supply maximum to muscles	*Blood*	Supply maximum to internal organs
Increased activity	*Adrenal glands*	Decreased activity
Inhibited	*Digestion*	Stimulated
Climax	*Sexual functions*	Arousal

Homeostasis

One problem that some students face is becoming too stressed or upset by life's events. Because it is potentially harmful to your body to stay stressed or aroused, the autonomic nervous system tries to keep the body's arousal at an optimum level, a state called homeostasis.

Homeostasis *(ho-me-oh-STAY-sis)* means that the sympathetic and parasympathetic systems work together to keep the body's level of arousal in balance for optimum functioning.



Homeostasis—physiological arousal kept in balance

For instance, your body's balance, or homeostasis, may be upset by the continuous stress of final exams or a difficult relationship. Such stress usually results in continuous physiological arousal and any number of physical problems, including headaches, stomachaches, tight muscles, or fatigue. These physical symptoms, which are called psychosomatic problems, may result in real pain. We'll discuss these problems in Module 21: Health, Stress & Coping (pp. 480–507).

Besides triggering your autonomic nervous system, the hypothalamus is also involved in regulating a complex hormonal system, which we'll examine next.

F. Endocrine System

Definition

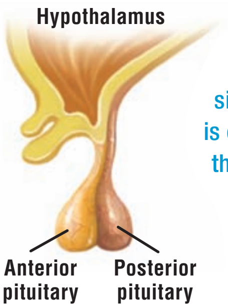
What is your chemical system?

You have two major systems for sending signals to the body's muscles, glands, and organs. We have already discussed the nervous system, which uses neurons, nerves, and neurotransmitters to send information throughout the body. The second major system for sending information is called the endocrine system.

The ***endocrine system*** is made up of numerous glands that are located throughout the body. These glands secrete various chemicals, called ***hormones,*** which affect organs, muscles, and other glands in the body.

The location and function of some of the endocrine system's glands are shown in the figure below.

Control Center



In many ways, the ***hypothalamus,*** which is located in the lower middle part of the brain, controls much of the endocrine system by regulating the pituitary gland, which is located directly below and outside the brain. The hypothalamus is often called the control center of the endocrine system.

The drawing on the left shows that the hypothalamus is connected to the pituitary gland.

Other Glands

We'll describe some of the endocrine system's major glands as well as their dysfunctions.

The ***pituitary gland,*** a key component of the endocrine system, hangs directly below the hypothalamus, to which it is connected by a narrow stalk. The pituitary gland is divided into anterior (front) and posterior (back) sections.

Posterior pituitary. The rear portion of the pituitary regulates water and salt balance.

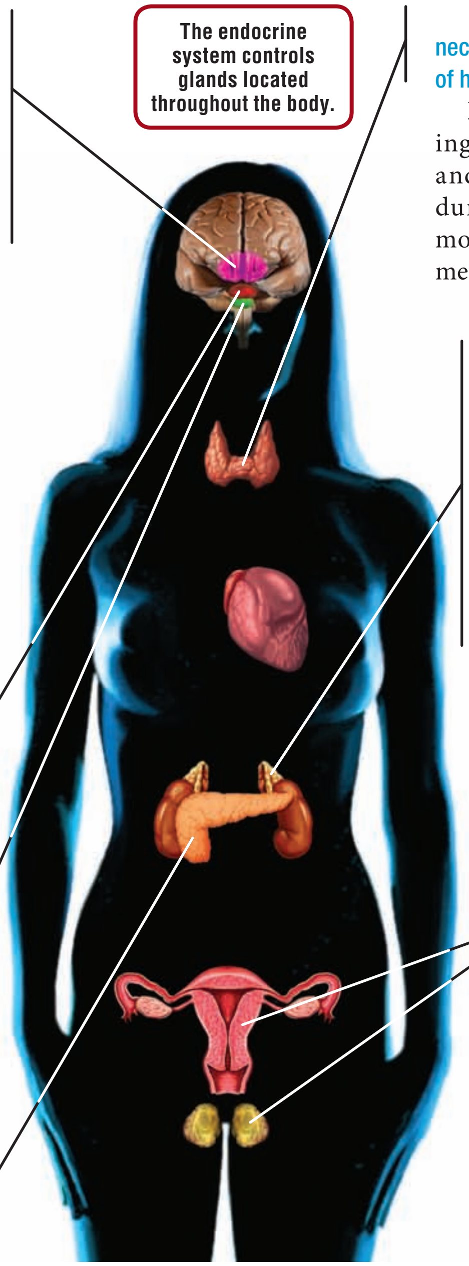
Dysfunction: Lack of hormones causes a less common form of diabetes.

Anterior pituitary. The front part of the pituitary regulates growth through secretion of growth hormone and produces hormones that control the adrenal cortex, pancreas, thyroid, and gonads.

Dysfunction: Too little growth hormone produces dwarfism; too much causes gigantism. Other problems in the pituitary cause problems in the glands it regulates.

Pancreas. This organ regulates the level of sugar in the bloodstream by secreting insulin.

Dysfunction: Lack of insulin results in the more common form of diabetes, while too much causes hypoglycemia (low blood sugar).



The endocrine system controls glands located throughout the body.

Thyroid. This gland, which is located in the neck, regulates metabolism through the secretion of hormones.

Dysfunction: Hormone deficiency during development leads to stunted growth and mental retardation. Undersecretion during adulthood leads to reduction in motivation. Oversecretion results in high metabolism, weight loss, and nervousness.

Adrenal glands. The adrenal cortex (outside part) secretes hormones that regulate sugar and salt balances and help the body resist stress; they are also responsible for growth of pubic hair, a secondary sexual characteristic. The adrenal medulla (inside part) secretes two hormones that arouse the body to deal with stress and emergencies: epinephrine (adrenaline) and norepinephrine (noradrenaline).

Dysfunction: With a lack of cortical hormones, the body's responses are unable to cope with stress.

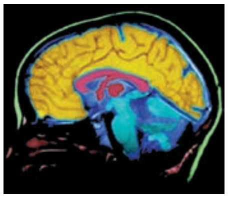
Gonads. In females, the ovaries produce hormones that regulate sexual development, ovulation, and growth of sex organs. In males, the testes produce hormones that regulate sexual development, production of sperm, and growth of sex organs.

Dysfunction: Lack of sex hormones during puberty results in lack of secondary sexual characteristics (facial and body hair, muscles in males, breasts in females).

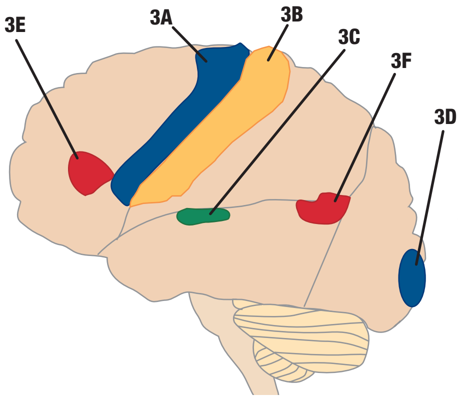
Up to this point, we have examined many of the structures and functions that make up the incredible nervous and endocrine systems. After the Concept Review, we'll discuss a question that students often ask: Do the brains of males differ from those of females?

Concept Review

1. A hairlike structure that contains tightly coiled strands of the chemical DNA (deoxyribonucleic acid) is called a (a) ________________. A specific segment on the strand of DNA that contains instructions for making proteins is called a (b) ________________. A theory that different species arose from a common ancestor and that those species survived that were best adapted to meet the demands of their environments is called the theory of (c) ________________.



2. There are several techniques for studying the living brain. One method for identifying structures in the brain involves measuring nonharmful radio frequencies as they pass through the brain; this is called an (a) ________________ scan. Another method that is used to study functions of the brain involves measuring the amounts of low-level radioactive substances absorbed by brain cells; this is called a (b) ________________ scan.



The numbers/letters on the drawing match those of the questions below.

3A. The cortical area that controls voluntary movements is called the (a) ________________ and is located in the (b) ________________ lobe.

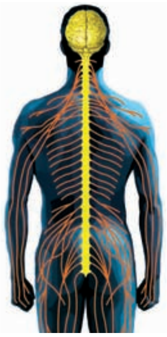
3B. The cortical area that receives input from sensory receptors in the skin, muscles, and joints is called the (a) ________________ and is located in the (b) ________________ lobe.

3C. The cortical area that receives input from sensory receptors in the ears is called the (a) ________________ and is located in the (b) ________________ lobe.

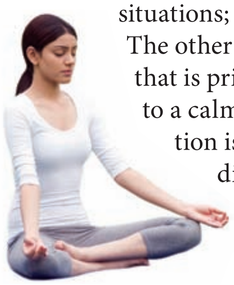
3D. The cortical area that receives input from sensory receptors in the eyes is called the (a) ________________ and is located in the (b) ________________ lobe.

3E. The cortical area that is necessary to produce words and arrange them into sentences is called (a) ________________ and is located in the (b) ________________ lobe.

3F. The cortical area that is necessary for understanding spoken and written words and putting words into meaningful sentences is called (a) ________________ and is located in the (b) ________________ lobe.



4. The two major divisions of the nervous system are the (a) ________________ and the (b) ________________. In turn, the peripheral nervous system has two parts: one part is a network of nerves that are connected either to sensory receptors or to muscles that you can move voluntarily and is called the (c) ________________; another part regulates heart rate, breathing, blood pressure, digestion, secretion of hormones, and other functions and is called the (d) ________________. The brain itself is divided into three major parts: (e) ________________, ________________, and ________________.



5. The old brain that is involved with many motivational and emotional behaviors is called the (a) ________________. One structure of the limbic system, the hypothalamus, controls the autonomic nervous system, which has two divisions. The division that responds by increasing the body's physiological arousal is called the (b) ________________. This division triggers an increased state of physiological arousal so that the body can cope with threatening situations; this state is called the (c) ________________. The other division of the autonomic nervous system that is primarily responsible for returning the body to a calm or relaxed state and is involved in digestion is called the (d) ________________. These two divisions work together to keep the body in physiological balance so that it remains or returns to a state of optimal functioning; this state is called (e) ________________.

6. A system made up of numerous glands that are located throughout the body and that secrete various hormones is called the (a) ________________. The brain area that can be considered the master control for this system is the (b) ________________. This brain area is connected to and controls one of the endocrine system's major glands that has an anterior and posterior part and is collectively called the (c) ________________.

Answers: 1. (a) chromosome, (b) gene, (c) evolution; 2. (a) MRI, (b) PET; 3A. (a) motor cortex, (b) frontal; 3B. (a) somatosensory cortex, (b) parietal; 3C. (a) primary auditory cortex, (b) temporal; 3D. (a) primary visual cortex, (b) occipital; 3E. (a) Broca's area, (b) frontal; 3F. (a) Wernicke's area, (b) temporal; 4. (a) central nervous system, (b) peripheral nervous system, (c) somatic nervous system, (d) autonomic nervous system, (e) forebrain, midbrain, hindbrain; 5. (a) limbic system, (b) sympathetic nervous system, (c) fight-flight response, (d) parasympathetic nervous system, (e) homeostasis; 6. (a) endocrine system, (b) hypothalamus, (c) pituitary gland

G. Research Focus: Sex Differences in the Brain?

Scientific Debate

Is this kind of research sexist?

Throughout history, the issue of sex differences in the brain has received much attention and debate. In the 1980s and 1990s, research on sex differences was criticized as "sexist" because it went against the "politically correct" belief that male and female brains are essentially the same (Azar, 1997). More recently, then Harvard University President Lawrence Summers announced that women are less likely than men to succeed in science and mathematics primarily because fewer females have "innate ability" in these fields. Immediately following this statement, a national debate took place about whether sex differences in the brain explained why fewer women reached high levels of success in science and mathematics (B. Bower, 2007; Halpern et al., 2007).

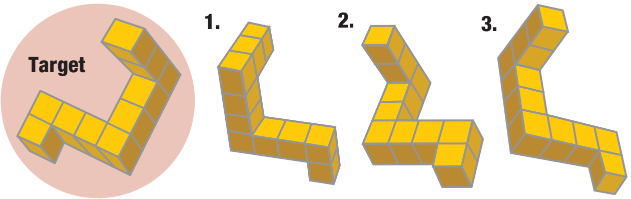
To examine the differences in the structure and function of male and female brains, which are called sex differences, researchers use brain scans (Cahill, 2005; Carne et al., 2006).

Sex, or ***gender, differences*** refer to structural or functional differences in cognitive, behavioral, or brain processes that arise from being a male or a female.

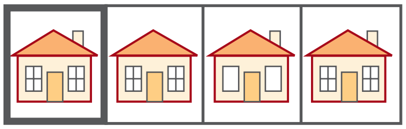
Here are some interesting sex differences.

Differences in Solving Problems

The rotating figure problem is a rather difficult spatial problem, as follows. First, study the target figure on the left. Then, from the three choices at the right, identify the same figure, even though it has been rotated.



The key to solving this problem is the ability to rotate the target figure in your mind until it matches the rotation of one of the three choices. Researchers consistently report faster or more accurate performance by males than by females in solving rotating figure problems, even as early as infancy (B. Bower, 2008f; Halpern et al., 2007). (Correct answer is 1.) There are other tasks at which women perform better than men.



For example, look at the house outlined in black (figure above) and find its twin among the three choices. Women are generally faster on these kinds of tests, which measure perceptual speed. In addition, women usually score higher on tests of verbal fluency, in which you must list as many words as you can that begin with the same letter, as in the figure at right (Halpern, 2000).

L___ Limp, Livery, Love, Laser, Liquid, Low, Like, Lag, Live, Lug, Light, Lift, Liver, Lime, Leg, Load, Lap, Lucid, . . .

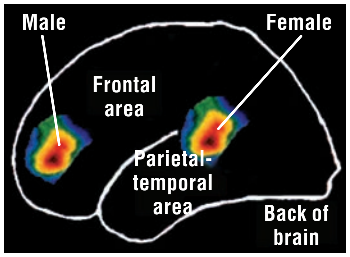
These sex differences may be explained by differences in socialization and learning, or as a result of evolving from different skills needed by early humans. Males with good spatial skills, for instance, had an advantage in hunting, and females with good communication skills had an advantage in child-rearing (B. Bower, 2007; Springer & Deutsch, 1997).

Researchers have now begun to look for sex differences in how the brain itself functions.

Differences between Female and Male Brains

To check for sex differences between male and female brains, researchers took brain scans while subjects were solving rotating figure problems.

Problem solving. As seen in the right figure, brain scans taken during problem solving showed that maximum neural activity in ***males*** occurred in the right frontal area. In contrast, maximum neural activity in ***females*** occurred in the right parietal-temporal area. Researchers concluded that solving rotating figure problems showed a significant sex difference in terms of which brain areas were activated, which in turn may be the basis for sex differences in performance on this task (Alivisatos & Petrides, 1997).



Emotional memories. How do men and women remember intense emotional experiences? Brain scans (fMRI) were taken while men and women viewed images they rated as ranging from emotionally neutral to highly arousing. Two weeks later, subjects were asked to pick out images they had seen earlier. Men with better memories for emotionally arousing images had greater activity in the right hemisphere amygdala, whereas women with better memories for emotionally arousing images had greater activity in the left hemisphere amygdala. Researchers concluded that there are sex differences in how the amygdala remembers emotionally arousing experiences (Cahill et al., 2004).

Movement and coordination. Researchers recently found a difference in how male and female brains make a major neurotransmitter (dopamine), which is responsible for controlling movement and coordination. This may help explain why men are more likely than women to develop Parkinson's disease (p. 60) (Gramling, 2006).

Depression. The production of another major neurotransmitter, serotonin, has been found to be 52% higher in men than in women. This may help explain why women are more likely than men to develop depression, a mental disorder treated with medication that increases serotonin production (Cahill, 2006; Nishizawa et al., 1997).

Conclusion. Researchers warn that although there are sex differences in the brain, we may not conclude that this is the only cause of differences in ability between males and females. After all, environmental experiences influence the development of the brain, and it is entirely possible that sex differences in the brain are due to differences in life experiences between males and females (Halpern et al., 2007).

Figure/Text Credits: (houses and letter L) Based on data from *Sex Differences in Cognitive Abilities*, by D. F. Halpern, 2000. Lawrence Erlbuam Associates; (left) Figures adapted from "Sex Differences in the Brain," by D. Kimura, 1992, *Scientific American, 267,* 119–125.

H. Cultural Diversity: Brain Size & Racial Myths

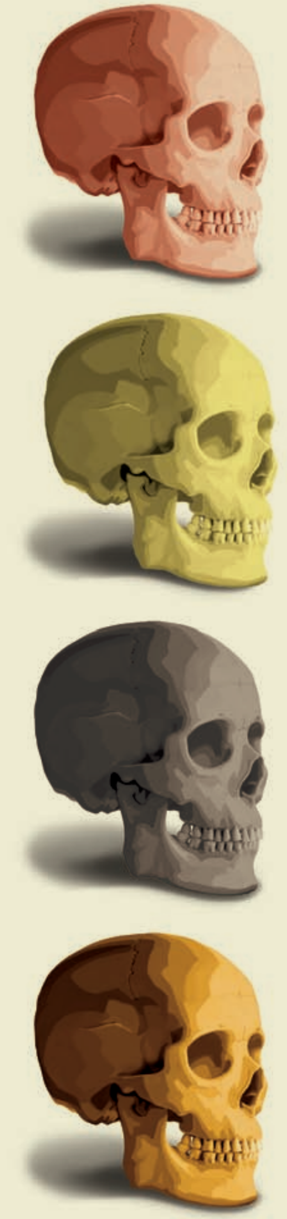
Skull Size and Intelligence

Which race had the biggest brain?

When he died in 1851, *The New York Times* proudly said that Samuel George Morton, scientist and physician, had one of the best reputations among scholars throughout the world. Morton had spent his lifetime collecting skulls of different races to determine which race had the biggest brain. During Morton's time, it was generally accepted that a bigger brain meant greater intelligence and innate mental ability.

Results in 1839. Morton estimated the size of a brain by pouring tiny lead pellets (the size of present-day BBs) into each skull and then measuring the pellets. By using this procedure, he arrived at the following ranking of brain size in different races, from biggest to smallest (see skulls on left): 1, White (Caucasian); 2, yellow (Mongolian); 3, brown (American Indian); and 4, Black (Negro). Along with his racial ranking of decreasing brain size, Morton also believed there was a corresponding decrease in behavioral and cognitive skills (Morton, 1839, cited in S. J. Gould, 1981).

No significant differences in brain size among races



Reanalyzed in 1980. Stephen Jay Gould, a renowned evolutionary biologist, reanalyzed Morton's data on brain size and, unlike Morton's findings, found ***no significant difference*** in brain size among the four races. Furthermore, Gould concluded that Morton's strong biases that Caucasians should have the biggest brains had unknowingly swayed his scientific judgment to fit his racial prejudices of the 1800s (S. J. Gould, 1981).

Major error. Morton's major error was that he included skulls that matched his personal biased expectations and omitted skulls that did not support his racial beliefs. That is, Morton chose bigger skulls to match his bias of Whites being more intelligent and smaller skulls for other races, whom he considered to be less intelligent (S. J. Gould, 1994).

Although Morton had the reputation for being a respected scholar and although he had asked a legitimate research question—Are there differences in brain size?—he was unable to prevent his strong personal beliefs from biasing his research and finding what he strongly but mistakenly believed.

One way current researchers guard against the problem of biasing their results is by having scientists in other laboratories repeat their studies. If the original findings are repeated in other laboratories, then scientists can be reasonably confident that their original results are valid.

Brain Size and Intelligence

What do brain scans show?

Researchers have studied the relationship between brain size and IQ scores by using brain scans (p. 70), which precisely measure the size of the human brain. For example, researchers found a moderate correlation (+0.45) between the number of neurons in the frontal lobe, which has an executive function (p. 76), and IQ scores (P. M. Thompson et al., 2001). This positive correlation means that, generally, the more neurons in the frontal lobe, the higher the IQ scores.

Female brains. If there is a positive correlation between number of neurons in the frontal lobe and IQ scores, we might expect women to have lower IQ scores than men, since their brains, as well as their heads, are about 9–12% smaller than men's (Witelson et al., 2006). Because there is no evidence that women have lower IQ scores than men, how do we explain this contradiction?

Women's heads and brains are about 10% smaller than men's.

Although women's brains are smaller, they have 15–20% more neurons than men's larger brains, and the brain cells of women are more tightly packed together (Halpern et al., 2007; L. M. Williams et al., 2005). Women even have more folds in some parts of the cortex than men do, which may compensate for their smaller brain size (Luders et al., 2004). Last, blood flow to the brain is faster in women than in men, which may reduce the loss of cognitive abilities due to aging (Halpern et al., 2007; L. M. Williams et al., 2005).

Correlations. Since studies report a positive correlation between brain size and IQ scores, we'll briefly review what *correlation* means. A correlation indicates only the existence of a relationship between two events; it does not identify the cause and effect. For example, being in a stimulating environment may promote brain growth and result in higher IQ scores, or being born with a larger brain may allow one to absorb more from one's environment and score higher on IQ tests. Thus, a positive correlation between brain size and intelligence may be scientifically interesting but has little practical application.

Before we complete our journey through the brain, we'll take you on one last trip, perhaps the most interesting of all. We'll see what happens when the brain is literally cut in two.

I. Application: Split Brain

Definition and Testing

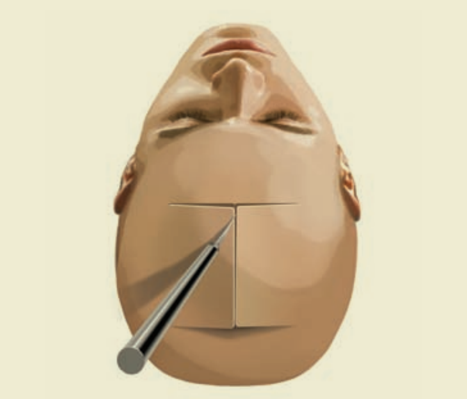
Why did Victoria choose a split brain?

Since about the age of 6, Victoria had seizures (also called epileptic seizures). During the seizures, she would lose consciousness and fall to the floor. Although her muscles would jerk uncontrollably, she felt no pain and would remember nothing of the experience. She was given anticonvulsant medicine, which prevented any further seizures until she was 18.

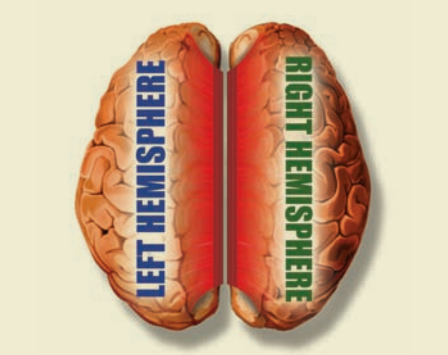
Split-brain operation. When Victoria was 18, for some unknown reason, her seizures returned with greater intensity. And to her dismay, anticonvulsant medication no longer had any effect. The seizures continued for ten years. Finally, when she was 27, she decided that her best chance of reducing her frightening, uncontrollable seizures was to have an operation that had a high probability of producing serious side effects. In this operation, a neurosurgeon would sever the major connection between her right and left hemispheres, leaving her with what is called a split brain (figure below).

Having to choose between a future of uncontrollable seizures and the potential problems of having a split brain, Victoria chose the operation (Sidtis et al., 1981).

In addition to Victoria (identified as V.P. in published reports), dozens of other individuals have also chosen to have a split-brain operation when they found that medicine no longer prevented their severe, uncontrollable seizures (Gazzaniga, 2008b).



In a split-brain operation, the neurosurgeon opens the patient's skull and separates the two hemispheres by cutting the corpus callosum.



After the corpus callosum is cut, the right and left hemisphere function relatively independently.

A ***split-brain operation*** involves cutting the wide band of fibers, called the corpus callosum, that connects the right and left hemispheres (figure above). The corpus callosum has 200 million nerve fibers that allow information to pass back and forth between the hemispheres.

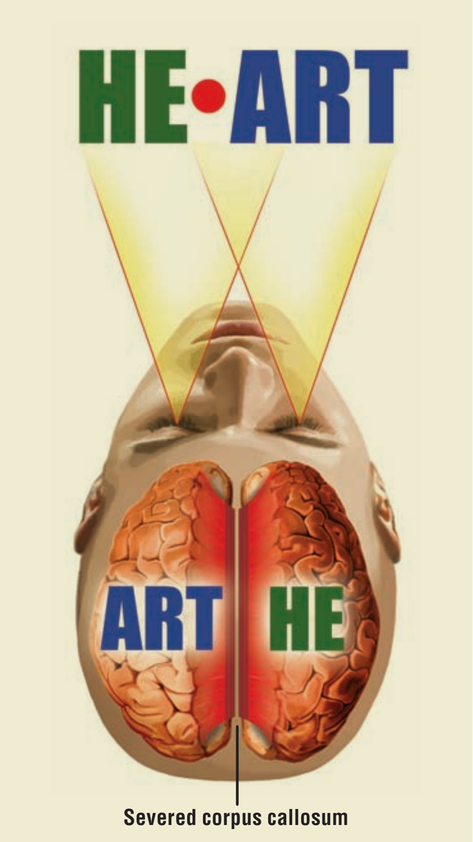
A split-brain operation not only disrupts the major pathway between the hemispheres but also, to a large extent, leaves each hemisphere functioning independently. In many split-brain patients, severing the corpus callosum prevented the spread of seizures from one hemisphere to the other and thus reduced their frequency and occurrence (Gazzaniga, 2008b).

Major breakthrough. It was 1961 when researcher Michael S. Gazzaniga and his colleagues tested the first split-brain patient, known as W.J. in the literature. Researchers first flashed on a screen a number of colors, letters, and pictures of objects. These stimuli were flashed so that they went only to W.J.'s left hemisphere, and he had no difficulty naming them. Then researchers flashed the same stimuli so that they went only to W.J.'s right hemisphere, and W.J. seemed to see nothing, to be blind (Gazzaniga et al., 1962). Gazzaniga calls the discovery that W.J.'s right hemisphere was saying nothing "one of those unforgettable moments in life." Was it true that W.J.'s left hemisphere could talk but not his right?

Testing a patient. To determine what each hemisphere can and cannot do, we can watch as Gazzaniga tests Victoria after her split-brain operation.

Victoria is asked to stare at the black dot between *HE* and *ART* as the word *HEART* is displayed on a screen. Because Victoria's hemispheres are split, information from each side of the black dot will go only to the opposite hemisphere (figure below). This means that Victoria's left hemisphere will see only the word *ART* and her right hemisphere will see only the word *HE*.

When asked, "What did you see?" Victoria says that she saw the word *ART* because it was projected to the left hemisphere, which has the ability to speak.



Although Victoria's right hemisphere saw the word *HE*, the right hemisphere turns out to be mute, meaning that it cannot say what it saw. However, Victoria can point with her left hand to a photo of a man *(HE)*, indicating that the right hemisphere understood the question and saw the word *HE*. (Victoria points with her left hand because her right hemisphere controls the left side of the body.) Although the effects of having a split brain are obvious under special testing, the effects are not so apparent in everyday life.

Behaviors Following Split Brain

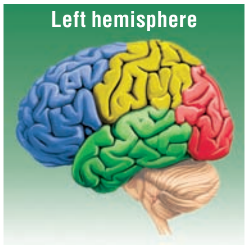
How does a split brain affect behavior?

Initially after her operation, Victoria reported that when she would choose clothes from her closet, her right hand would grab a blouse but then her left hand would put it back. However, these obvious conflicts between hemispheres are rare and disappear with time.

Four months after her operation, Victoria was alert and talked easily about past and present events. She could read, write, reason, and perform everyday functions such as eating, dressing, and walking, as well as carry on normal conversations. For Victoria with her split brain, as well as for most of us with normal brains, only the left hemisphere can express itself through the spoken word (Gazzaniga, 2000). If the speech area is in the left hemisphere, the right hemisphere is usually mute. (For a small percentage of left-handers, the speech area is in the right hemisphere and the left hemisphere is usually mute.) After testing split-brain patients, researchers discovered that each hemisphere is specialized for performing certain tasks (Gazzaniga, 2005, 2008a).

Different Functions of Hemispheres

Before observing split-brain patients, researchers knew very little about how each hemisphere functioned. But after studying the behaviors of split-brain patients, researchers gained a whole new understanding of what task each hemisphere does best.

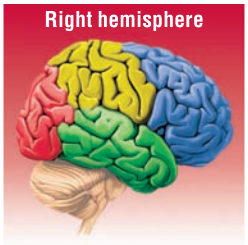


Verbal. Left hemisphere is very good at all language-related abilities: speaking, understanding language, carrying on a conversation, reading, writing, and spelling.

Mathematical. Left hemisphere is very good at mathematical skills: adding, subtracting, multiplying, dividing, solving complex problems in calculus and physics, and so on. Generally, the right hemisphere can perform simple addition and subtraction but not more complex mathematics (Sperry, 1974).

Analytic. Left hemisphere appears to process information by analyzing each separate piece that makes up a whole. For example, the left hemisphere would recognize a face by analyzing piece by piece its many separate parts: nose, eyes, lips, cheeks, and so on—a relatively slow process (J. Levy & Trevarthen, 1976).

Recognizing self. Left hemisphere is primarily involved in identifying one's own face, distinguishing one's face from others, as well as in memories and knowledge of oneself. Thus, the left brain contributes to the conscious understanding of oneself (Turk, 2002).



Nonverbal. Although usually mute, the right hemisphere has a childlike ability to read, write, spell, and understand speech (Gazzaniga, 1998). For example, when spoken to, the right hemisphere can understand simple sentences and read simple words.

Spatial. Right hemisphere is very good at solving spatial problems, such as arranging blocks to match a geometric design. Because the hemispheres control opposite sides of the body, the left hand (right hemisphere) is best at arranging blocks, a spatial task.

Holistic. Right hemisphere appears to process information by combining parts into a meaningful whole. For this reason, the right hemisphere is better at recognizing and identifying whole faces (J. Levy et al., 1972). The right hemisphere is also good at recognizing emotions in people's gestures and tone of voice (Adolphs et al., 2002).

Recognizing others. Right hemisphere is involved in recognizing familiar faces but not in recognizing one's own face, which primarily involves the left hemisphere (Turk, 2002).

After comparing the left and right hemispheres' functions, you can see that each hemisphere has specialized skills and is better at performing particular tasks. Some hemisphere specializations begin very early in life. For example, left-brain specialization for language appears as early as 2 to 3 months of age (B. Bower, 2003a). These differences raise a popular question: Am I right-brained or left-brained?

Left- or Right-Brained?

The popular press has exaggerated the idea that you are either "right-brained"—creative and intuitive—or "left-brained"—reasonable, logical, and rational.

According to Jerre Levy (1985), who has devoted her career to studying how the brain's hemispheres interact, these distinctions are much too simple. She believes that we are constantly using both hemispheres, since each hemisphere is specialized for processing certain kinds of information. For example, when you read a novel, you are probably using programs in the left hemisphere that allow you to understand language in written form. But at the same time, you are using programs in the right hemisphere to keep track of the overall story, appreciate its humor and emotional content, and interpret any illustrations. Although hemispheres may sometimes work alone, they share much of their information by passing it quickly back and forth through the corpus callosum.

How is my brain organized? Michael Gazzaniga (1998, 2008a), a cognitive neuroscientist who has studied split-brain patients for over 45 years, believes that each hemisphere of the brain has many different mental programs, such as sensing, thinking, learning, feeling, and speaking, all of which can function simultaneously. For example, when you see someone smile, your brain uses dozens of mental programs from each hemisphere to receive, interpret, and respond to this relatively simple emotional facial expression.

According to Gazzaniga, the brain and mind are built from separate units or modules that are interconnected and work together to carry out specific functions, much as your computer uses many separate programs to perform many different tasks.

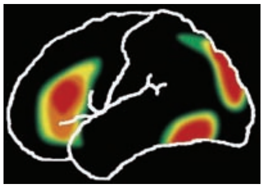
Summary Test

A. Genes & Evolution

1. A fertilized egg, which is called a (a) ______________, contains 46 chromosomes arranged in 23 pairs. A hairlike structure that contains tightly coiled strands of the chemical DNA (deoxyribonucleic acid) is called a (b) ______________. A specific segment on the strand of DNA that contains instructions for making proteins is called a (c) ______________.

2. In 1859, Charles Darwin published the revolutionary theory of (a) ______________, which said that different species arose from a common (b) ______________ and that those species survived that were best adapted to meet the demands of their (c) ______________.

B. Studying the Living Brain



3. There are several recently developed techniques for studying the living brain. One technique, which measures non-harmful radio frequencies as they pass through the brain, is called an (a) ______________ and is used to identify structures in the living brain. Another technique measures how much of a radioactive substance is taken up by brain cells and is called a (b) ______________. This kind of scan is used to study brain function and identify the most and least active parts.

C. Organization of the Brain

4. The human nervous system is divided into two major parts. The brain and spinal cord make up the (a) ______________. The network of nerves outside the brain and spinal cord makes up the (b) ______________.

5. The peripheral nervous system is further divided into two parts. One part is made up of a network of nerves that either carry messages to muscles and organs throughout the body or carry input from sensory receptors to the spinal cord; this is called the (a) ______________. The second part of the peripheral nervous system, which regulates heart rate, breathing, digestion, secretion of hormones, and related responses, is called the (b) ______________.

6. The human brain is divided into three major parts. The largest part is involved in cognitive responses that we characterize as most human. This part is called the (a)______________, which is divided into right and left hemispheres. The part that is involved in controlling vital reflexes, sleeping, and coordinating body movements is called the (b)______________. The part that is involved in visual and auditory reflexes, as well as alerting the brain to incoming sensations, is called the (c)______________.

7. Beginning in the midbrain and extending downward is a long column of cells called the ______________ that alerts the forebrain to incoming sensory information.

8. The hindbrain consists of three structures. The structure that serves as a bridge to connect the brain and body and also manufactures chemicals involved in sleep is called the (a)______________. The structure that controls vital reflexes, such as heart rate, blood pressure, and respiration, is called the (b)______________. The structure that was assumed to be involved primarily in coordinating body movements but has recently been found to have a role in cognitive functions, such as short-term memory, following rules, and carrying out plans, is called the (c) ______________.

D. Control Centers: Four Lobes

9. The thin outside layer of cells that has a wrinkled look and covers almost the entire forebrain is called the (a) ______________. This layer of cells is divided into four separate areas or lobes: (b) ______________, ______________, ______________, and ______________.

10. The lobe that is involved in controlling social-emotional behaviors, maintaining a healthy personality, and making and carrying out plans is called the ______________ lobe.

11. At the back edge of the frontal lobe is a continuous strip called the ______________, which controls the movement of voluntary muscles. Body parts that have greater capacity for complicated muscle movement have more area on the motor cortex devoted to them.

12. Along the front edge of the parietal lobe is a continuous strip that receives sensations from the body and is called the ______________. Body parts with greater sensitivity have more area on the somatosensory cortex devoted to them.

13. An area on the upper edge of the temporal lobe that receives signals from receptors in the ears and changes them into basic auditory sensations is called the (a) ______________. For most individuals, an area in the left temporal lobe is involved in understanding and speaking coherently; it is called (b) ______________ area. Damage to this area results in inability to understand spoken and written speech or to speak coherently, a problem called (c) ______________. An area in the frontal lobe, called (d) ______________, is necessary for producing words and arranging them into fluent sentences. If this area is damaged, the result is a speech problem called (e) ______________.

14. An area at the very back of the occipital lobe that receives signals from receptors in the eyes and changes them into basic visual sensations is called the ______________.

15. The vast majority of the cortex making up the four lobes is involved in adding meaning, interpretations, and associations to sensory stimuli, as well as in many cognitive functions. Together, these areas are called ________ areas.

E. Limbic System: Old Brain

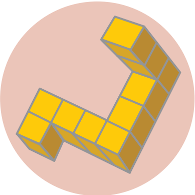
16. Inside the forebrain is a central core of interconnected structures known as the primitive, or "animal," brain or, more technically, the (a) ________. Four of the areas that make up the limbic system are the (b) ________, ________, ________, and ________, which are all involved in motivational and emotional behaviors.

17. One structure of the limbic system, the hypothalamus, controls the autonomic nervous system, which has two divisions. The one that arouses the body, increases physiological responses (such as heart rate and blood pressure), and prepares the body for the fight-flight response is called the (a) ________. The division that calms down the body and aids digestion is called the (b) ________. These two divisions work together to keep the body's internal organs in a balanced physiological state, which is called (c) ________.

F. Endocrine System

18. Besides the nervous system, a network of glands regulates organs through the secretion of hormones. This chemical system is called the (a) ________. A major gland that controls other glands in this system is the (b) ________ gland, which has an anterior and posterior parts.

G. Research Focus: Sex Differences in the Brain?

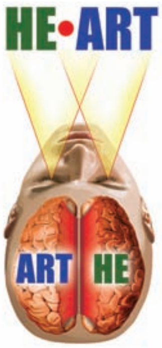


19. Structural or functional differences in the brain that arise from being male or female are called ________. One example of sex differences in the brain is that males primarily use the frontal area to solve spatial problems, while females use the parietal-temporal area.

H. Cultural Diversity: Brain Size & Racial Myths

20. In the 1800s, one scientist measured skull size and concluded that a larger brain indicated more intelligence and that the races could be ranked by brain size. However, further analysis of this researcher's data indicated that there was no basis for ranking races by (a) ________. More recent experiments that precisely measured brain size with MRI scans found a modest correlation between brain size and (b) ________. However, we do not know if a stimulating environment causes the brain to grow more or if a larger brain is able to absorb more from the environment.

I. Application: Split Brain



21. The two hemispheres are connected by a major bundle of fibers that is called the ________. Severing this structure produces a condition called a split brain.

22. For most individuals, mental programs for language, speech, and mathematics, as well as for distinguishing one's face from others and for memories and knowledge of oneself, are located in the (a) ________; mental programs for solving spatial problems, processing emotional responses, and recognizing familiar faces are located in the (b) ________. In addition, the hemispheres process information in different ways. The left hemisphere processes information in a more piece-by-piece fashion or (c) ________ way. In comparison, the right hemisphere processes information as a meaningful whole; that is, it uses a more (d) ________ approach.

23. One theory of brain organization says that your brain has many separate but interconnected ________ programs that function and work together so that you can perform many cognitive skills.

Answers: *1. (a) zygote, (b) chromosome, (c) gene; 2. (a) evolution, (b) ancestor, (c) environment; 3. (a) MRI scan, (b) PET scan; 4. (a) central nervous system, (b) peripheral nervous system; 5. (a) somatic nervous system, (b) autonomic nervous system; 6. (a) forebrain, (b) hindbrain, (c) midbrain; 7. reticular formation; 8. (a) pons, (b) medulla, (c) cerebellum; 9. (a) cortex, (b) frontal, parietal, temporal, occipital; 10. frontal; 11. motor cortex; 12. somatosensory cortex; 13. (a) primary auditory cortex, (b) Wernicke's, (c) Wernicke's aphasia, (d) Broca's area, (e) Broca's aphasia; 14. primary visual cortex; 15. association; 16. (a) limbic system, (b) hippocampus, hypothalamus, thalamus, amygdala; 17. (a) sympathetic division, (b) parasympathetic division, (c) homeostasis; 18. (a) endocrine system, (b) pituitary; 19. sex differences; 20. (a) brain size, (b) intelligence; 21. corpus callosum; 22. (a) left hemisphere, (b) right hemisphere, (c) analytic, (d) holistic; 23. mental*

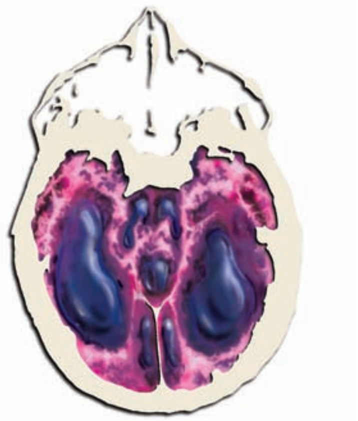
Critical Thinking

When Is a Person Brain-Dead?



Brain scan shows dark blue areas that are filled with fluid, which has replaced brain tissue.

Terri Schiavo, a 27-year-old woman, suffers a heart attack that results in her losing consciousness. During the next 15 years, she never regains consciousness and lives in nursing homes under constant care. Terri is fed and hydrated through tubes and has her diapers changed regularly. She can still breathe without a respirator and can even open her eyes. Terri will at times turn toward her mother's voice and smile, make sounds similar to laughter, and has seemingly followed a balloon with her eyes. Despite these abilities and movements, Terri remains completely unaware of her surroundings.

Doctors describe Terri's condition as a persistent vegetative state, meaning she has severe brain damage to the cortex resulting in long-term loss of cognitive function and awareness, but retains basic physiological functions, such as breathing and the sleep-wake cycle. Doctors say that her responses, including following an object with her eyes, are reflexive, not intentional, and commonly occur spontaneously with people in a vegetative state.

As a result of being in a vegetative state for over a decade, Terri's brain severely deteriorated. Brain scans (see top photo) show that much of her cortex is gone and is replaced with spinal fluid, a condition that is incurable. All that remains is enough of a brain stem (includes midbrain, pons, and medulla, p. 73) to keep certain basic life functions working (e.g., heart rate, breathing, arousal, visual and auditory reflexes). Many doctors conclude Terri will forever remain unconscious and be completely dependent on others, as she has been for the past 15 years.

Given the doctors' serious doubt that Terri's condition will ever improve, how long should she remain on a feeding tube? This question stirred tremendous debate between her husband, who wanted the feeding tube to be removed, and her parents, who wanted it to remain. The decision over Terri's future even received attention by the courts, the President, religious leaders, and many protestors arguing both sides of the debate. Some referred to removing the feeding tube as euthanasia, while others believed she died years ago following her heart attack.

Finally, after years of controversy, the court ordered the removal of the feeding tube. Terri died 13 days following its removal, and her autopsy showed she had massive and irreversible brain damage that shrunk her brain to about half of its expected size and she was blind. The medical examiner commented on Terri's potential for recovery by stating: "No amount of therapy or treatment would have regenerated the massive loss of neurons" (Associated Press, 2005d). (Adapted from Associated Press, 2005a, 2005d; Eisenberg, 2005; S. Russell, 2005; Schrock, 2007)

QUESTIONS

1 What part of the brain allows Terri to breathe?

2 How would Terri respond to being poked with a needle?

3 Which type of brain scan would a neurologist use to determine how much of Terri's cortex is present?

4 Do Terri's abilities to function fit with severe damage to the cortex?

5 What defines brain death?

6 What type of treatment(s) can be used to help regenerate neurons?

Learning Activities

PowerStudy for Introduction to Psychology 4.5

Try out **PowerStudy's SuperModule** for the Incredible Nervous System! In addition to the quizzes, learning activities, interactive Summary Test, key terms, module outline and abstract, and extended list of correlated websites provided for all modules, the DVD's **SuperModule** for the Incredible Nervous System features:

- Self-paced, fully narrated learning with a multitude of animations.
- Video presenting scans of the nervous system, an exploration of temporal lobe damage, and a demonstration of split-brain research.
- Interactive versions of study resources, including the Summary Test on pages 88–89 and the critical thinking questions for the article on page 90.

Suggested Answers to Critical Thinking

1. The medulla is located at the top of the spinal cord and controls vital reflexes, such as breathing, heart rate, and blood pressure.
2. Terri's body may flinch even though she is unaware of being poked, and she would not feel any pain because her cortex, responsible for experiencing pain, is severely damaged.
3. A neurologist would use MRI (magnetic resonance imaging) because it provides a detailed image of the structure of the brain.
4. Yes. The cortex is responsible for hundreds of "higher-order" functions, such as planning, deciding, reasoning, seeing, speaking, and hearing, none of which Terri is able to do.
5. Brain death can be defined as whole-brain or higher-brain death. Whole-brain death means the cortex and brain stem have shut down, leaving the person unable to move or breathe independently, and there is no brain activity. Higher-brain death means the brain stem still functions, keeping the vital organs working, but the cortex is shut off. Terri's brain stem is functioning, so she is brain-dead only according to the higher-brain death definition.
6. Still experimental, fetal brain tissue transplants (p. 60) show promise in making new connections in the brain, and stem cell transplants (p. 60) are being used to form new neurons.

Artificial Eye: Life-Changing Results

Can Terry see without his eyes?

Terry Byland began having difficulty seeing in dim light, making driving at night a serious problem. When he went to his eye doctor, he was given news no one is ever prepared to hear. The doctor told Terry he had an eye disease that would eventually lead to blindness. His vision worsened gradually over time, leaving him blind just 7 years later at the young age of 45.

After living in total darkness for 11 years, Terry volunteered to have experimental surgery in which a microchip with 16 electrodes was implanted into his eye. By wearing a tiny camera built on a pair of glasses that carries signals to the damaged area of his eye, incredibly, Terry gained vision. He can now see very rough forms of motion, lights, and objects. For example, he now sees light glowing from the chandelier when he flips on the light switch and action figures move across a TV screen. Terry describes how the surgery enabled him to see something even more special—the shadow of his 18-year-old son as he walked by: "It was the first time I had seen him since he was five years old. I don't mind saying, there were a few tears wept that day" (Byland, 2008). Terry couldn't be more pleased with the results of his surgery (adapted from *Science Illustrated,* 2008; USDEOS, 2007).

He can "see" representations of motion, lights, and objects.

Although Terry is officially blind because his eyes are not functioning, he can still "see" rough presentations of motion, lights, and objects. This fact raises a very interesting question: How is it possible to see without using one's eyes? As we answer this question, you'll discover that the eye, ear, nose, tongue, and skin are smaller, more complicated, and better recorders than any of the newest, miniaturized, high-tech video cameras, recorders, or digital disks on the market.

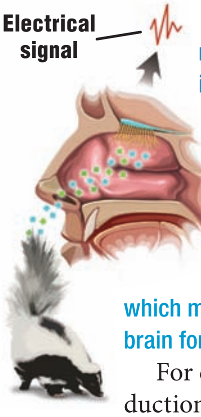
What's Coming

We'll discuss six of the major human senses—vision, hearing, balance (vestibular system), taste, olfaction (smell), and touch. We'll also explain how you see color, why some long-playing rock-and-roll musicians have become partially deaf, why you get motion sickness, and why your sense of taste decreases when you have a cold. Although your sense organs—eye, ear, tongue, nose, and skin—look so very different, they all share the three characteristics defined next.

Three Definitions

Your eyes, ears, nose, skin, and tongue are complex, miniaturized, living sense organs that automatically gather information about your environment. We begin with three definitions that will help you understand sensation.

1 Transduction. The first thing each sense organ must do is to change or transform some physical energy, such as molecules of skunk spray, into electrical signals, a process called transduction.



Transduction **refers to the process in which a sense organ changes, or transforms, physical energy into electrical signals that become neural impulses, which may be sent to the brain for processing.**

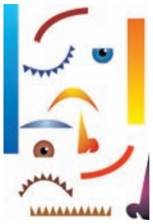
For example, transduction occurs when a skunk's molecules enter your nose, which transforms the molecules into electrical signals, or impulses, that are interpreted by your brain as the very unpleasant odor of a skunk.

2 Adaptation. A short period of time after putting on glasses, jewelry, or clothes, you no longer "feel" them, a process called adaptation.

Adaptation **refers to the decreasing response of the sense organs, the more they are exposed to a continuous level of stimulation.**

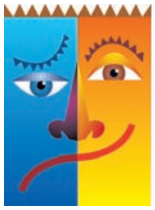
For example, the continuous stimulation of glasses, jewelry, or clothes on your skin results in adaptation so that soon you no longer feel them. Some sense organs adapt very quickly, and some very slowly. However, sense organs do not adapt to intense forms of stimulation, because such stimulation may cause physical damage. Instead, intense stimulation, such as from a very hot shower, may cause pain, which warns us of possible injury.

3 Sensations versus perceptions. Gathering information about the world involves two steps. In the first step, electrical signals reach the brain and are changed into sensations.



Sensations **are relatively meaningless bits of information (left figure) that result when the brain processes electrical signals that come from the sense organs.**

In the second step, the brain quickly changes sensations, which you're not aware of, into perceptions.



Perceptions **are meaningful sensory experiences (right figure) that result after the brain combines hundreds of sensations.**

For example, visual sensations would resemble the top figure, showing meaningless lines, colors, and shapes. Visual perceptions would be like the bottom figure, showing a complete "sad-happy" face.

While all sensations begin with step 1, transduction, sense organs use different mechanisms to do it. We'll start with how the visual system works.

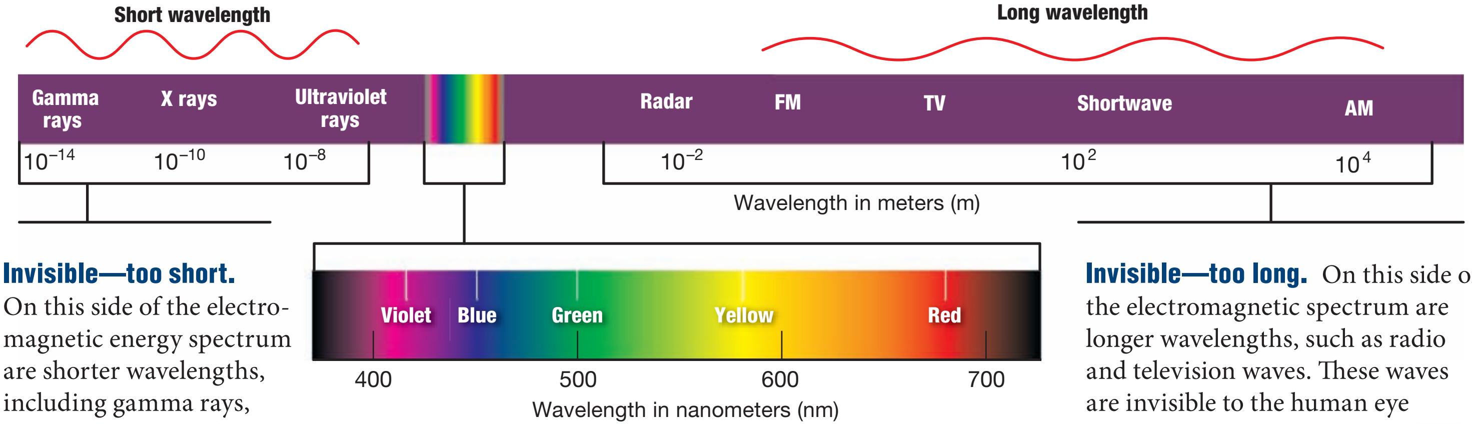
A. Eye: Vision

Stimulus: Light Waves

Why can't you see radio waves?

Each sense organ has a different shape and structure; it can receive only a certain kind of stimulus, or physical energy. For instance, the reason you cannot see radio waves is that their waves are not the right length. Although radio waves, along with light waves from the sun, are all forms of electromagnetic energy, they vary in wavelength. For example, the figure below shows that X rays are very short and AM radio waves are very long. Notice that only a small, specific range of wavelengths that come from a light source, called the visible spectrum, is able to excite receptors in your eyes.



Invisible—too short. On this side of the electromagnetic energy spectrum are shorter wavelengths, including gamma rays, X rays, and ultraviolet rays. These waves are invisible to the human eye because their lengths are too short to stimulate our receptors. However, some birds (such as hummingbirds) and insects can see ultraviolet rays to help them find food.

Visible—just right. Near the middle of the electromagnetic spectrum is a small range of waves that make up the visible spectrum.

The *visible spectrum* is one particular segment of electromagnetic energy that we can see because these waves are the right length to stimulate receptors in the eye.

The reason you can see a giraffe is that its body reflects light waves from the visible spectrum back to your eyes. One function of the eyes is to absorb light waves that are reflected back from all the objects in your environment.

Invisible—too long. On this side of the electromagnetic spectrum are longer wavelengths, such as radio and television waves. These waves are invisible to the human eye because their lengths are too long to stimulate the receptors in the eye. Imagine the awful distraction of seeing radio and television waves all day long!

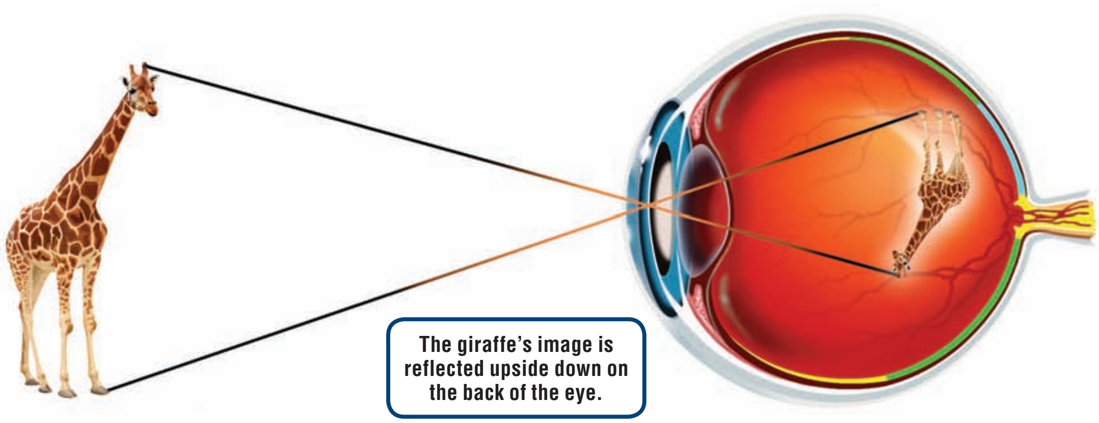
Stimulus. Thus, the most effective stimulus for vision is energy (light waves) from the visible spectrum. However, for you to see anything, reflected light waves must be gathered and changed into electrical signals, and for that process—transduction—we must look inside the eye itself.

Structure and Function

How can you see a giraffe?

For you to see a 16-foot-tall giraffe, your eyes perform two separate processes. First, the eyes gather and focus light waves into a precise area at the back of your eyes. Second, this area absorbs and transforms light waves into impulses, a process known as transduction. We'll follow the path of light waves from the giraffe to the back of your eyes in a series of 7 steps.

1 Image reversed. Notice that, at the back of the eye, the giraffe appears upside down. Even though the giraffe is focused upside down in the eye, somehow the brain turns the giraffe—and all other objects we see—right side up so that we see the world as it really is.



The giraffe's image is reflected upside down on the back of the eye.

2 Light waves. The problem with light waves is that after they strike an object, such as a giraffe, they are reflected back in a broad beam. You cannot see the giraffe unless your eyes change this broad beam of light waves into a narrow, focused one. Your eye has two structures, the cornea and the lens, that bring an image into focus, much as a camera does.

Photo Credit: center left, © Purestock/Getty Images

3 Cornea. The broad beam of light reflected from the giraffe passes first through the cornea.

The ***cornea*** is the rounded, transparent covering over the front of your eye. As the light waves pass through the cornea, its curved surface bends, or focuses, the waves into a narrower beam.

4 Pupil. After passing through the cornea, light waves next go through the pupil.

The ***pupil*** is a round opening at the front of your eye that allows light waves to pass into the eye's interior.

Your pupil grows larger or smaller because of a muscle called the iris.

5 Iris. The opening of the pupil is surrounded by the iris.

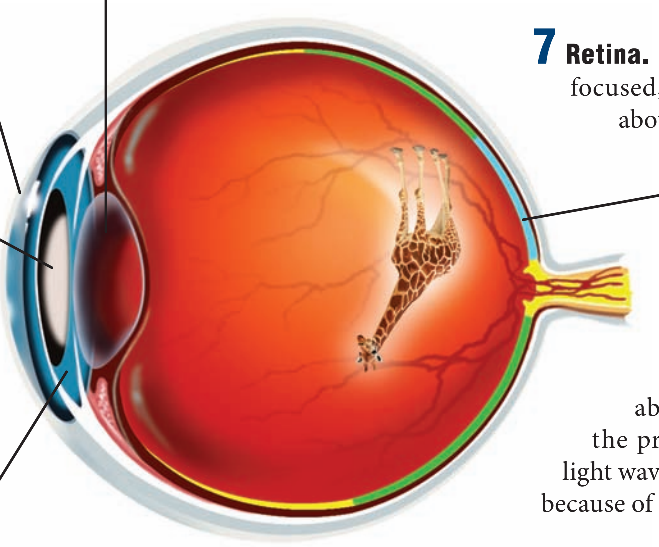
The ***iris*** is a circular muscle that surrounds the pupil and controls the amount of light entering the eye. In dim light, the iris relaxes, allowing more light to enter—the pupil dilates; in bright light, the iris constricts, allowing less light to enter—the pupil constricts. The iris muscle contains the pigment that gives your eye its characteristic color.

If you look in a mirror in bright light, you will see that the iris is constricted and that your pupil—the black dot in the center of your eye—is very small.

6 Lens. After passing through the cornea and pupil, light waves reach the lens.

The ***lens*** is a transparent, oval structure whose curved surface bends and focuses light waves into an even narrower beam. The lens is attached to muscles that adjust the curve of the lens, which, in turn, adjusts the focusing.

For the eye to see distant objects, light waves need less bending (focusing), so muscles automatically stretch the lens so that its surface is less curved. To see near objects, light waves need more focusing, so muscles relax and allow the surface of the lens to become very curved. Making the lens more or less curved causes light waves to be focused into a very narrow beam that must be projected precisely onto an area at the very back of the eye, called the retina.



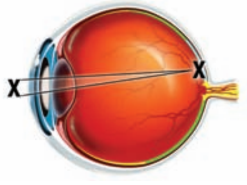
7 Retina. Although light waves have been bent and focused, transduction hasn't yet occurred. That is about to change as light waves reach the retina.

The ***retina,*** located at the very back of the eyeball, is a thin film that contains cells that are extremely sensitive to light. These light-sensitive cells, called photoreceptors, begin the process of transduction by absorbing light waves.

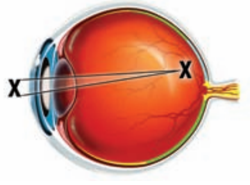
On the following page, we'll describe the two kinds of photoreceptors, how they absorb light waves, and how they carry out the process of transduction. For some people, light waves cannot be focused precisely on the retina because of a problem with the shape of their eyeballs.

Eyeball's Shape and Laser Eye Surgery

Eyeball. Some of us are born with perfectly shaped eyeballs, which contributes to having almost perfect vision. Others, however, are born with eyeballs that are a little too long or too short, resulting in two common visual problems: nearsightedness and farsightedness.



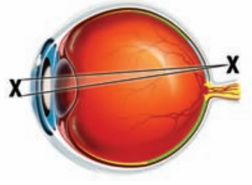
Normal vision. The shape of your eyeball is primarily determined by genetic instructions. If your eyeball is shaped so that objects are perfectly focused on the back of your retina (**black X**), then both the near and distant objects will appear clear and sharp and you will have very good vision (20/20).



Nearsighted. If you inherit an eyeball that is too long, you are likely nearsighted.

Nearsightedness (myopia) results when the eyeball is too long so that objects are focused at a point in front of the retina (**black X**). In this case, near objects are clear, but distant objects appear blurry.

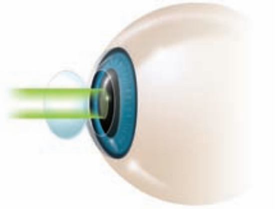
Common treatments involve corrective lenses or eye surgery.



Farsighted. If you inherit an eyeball that is too short, you are likely farsighted.

Farsightedness (hyperopia) occurs when the eyeball is too short so that objects are focused at a point slightly behind the retina (**black X**). In this case, distant objects are clear, but near objects appear blurry.

Common treatments involve corrective lenses or eye surgery.



Eye surgery. Currently, a popular and successful treatment to correct nearsighted vision is called LASIK. In this procedure, the surface of the eye is folded back and a laser is used to reshape the exposed cornea so that light waves are correctly bent and focused on the retina (Gallin, 2008).

Next, we'll examine the retina more closely and see exactly how transduction occurs.

A. Eye: Vision

Retina: Miniature Camera–Computer

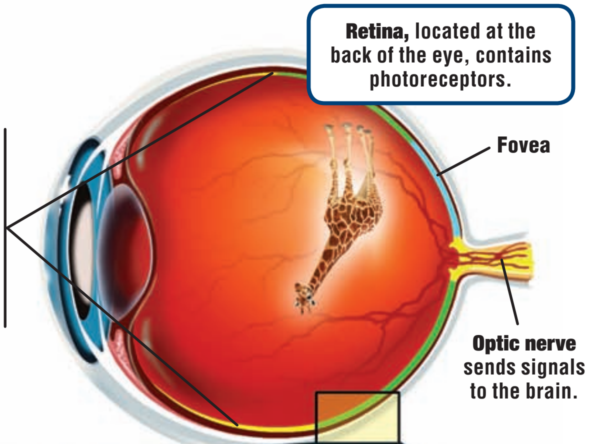
What happens to light waves?

Some miniaturized electronic cameras can record amazingly detailed video pictures. But they are primitive compared to the retina, whose microscopic cells can transform light waves into impulses that carry detailed information to the brain about all kinds of shapes, shadows, sizes, textures, and colors. Think of the retina as a combination of a video camera and a computer whose batteries never run out as it transforms light waves into impulses—the process of transduction. And here's how transduction occurs.

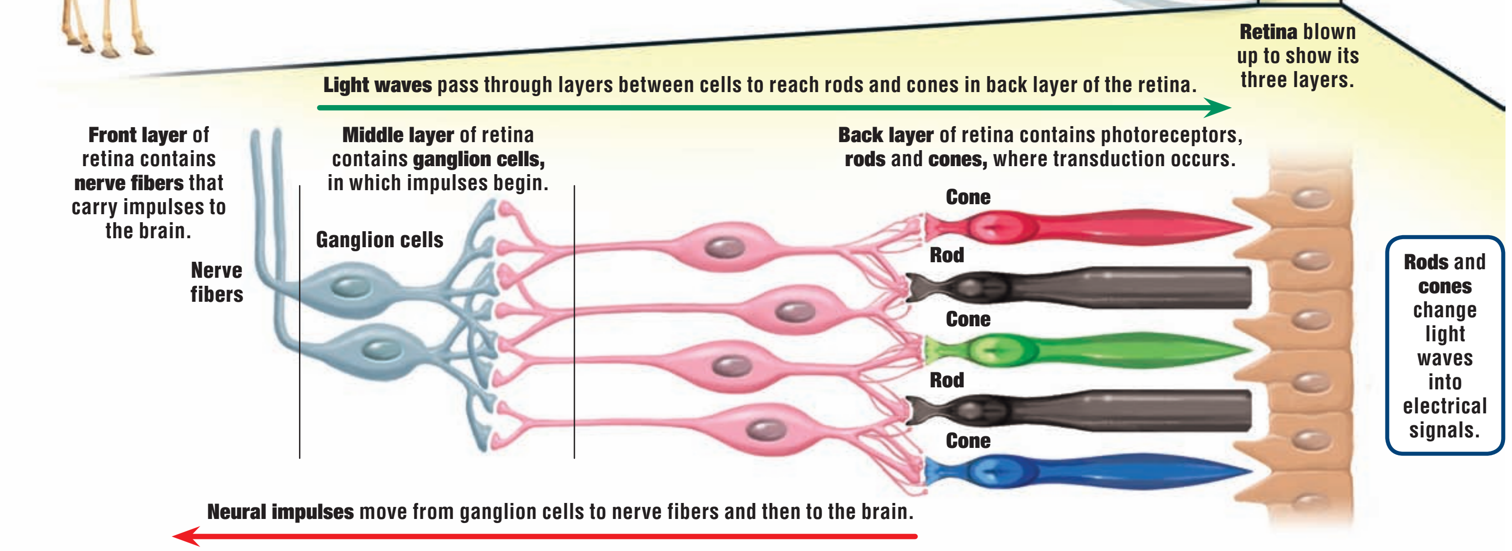
You already know that an object, such as a giraffe, reflects light waves that enter the eye and are bent, focused, and projected precisely on the retina, at the very back of the eyeball.

The ***retina*** has three layers of cells. The back layer contains two kinds of photoreceptors that begin the process of transduction, changing light waves into electrical signals. One kind of photoreceptor with a rodlike shape is called a rod and is located primarily in the periphery of the retina. The other photoreceptor with a conelike shape is called a cone and is located primarily in the center of the retina in an area called the ***fovea*** *(FOH-vee-ah).*

We have enlarged a section of retina to show that it has three layers. We'll explain the function of each layer. Start with #1, located below the figure on the far right, and move left to #3.



Retina, located at the back of the eye, contains photoreceptors.
Fovea
Optic nerve sends signals to the brain.
Retina blown up to show its three layers.



Light waves pass through layers between cells to reach rods and cones in back layer of the retina.
Front layer of retina contains **nerve fibers** that carry impulses to the brain.
Nerve fibers
Middle layer of retina contains **ganglion cells,** in which impulses begin.
Ganglion cells
Back layer of retina contains photoreceptors, **rods** and **cones,** where transduction occurs.
Cone
Rod
Cone
Rod
Cone
Rods and **cones** change light waves into electrical signals.
Neural impulses move from ganglion cells to nerve fibers and then to the brain.

1 Each eye has about 120 million rods, most located in the retina's periphery.

Rods are photoreceptors that contain a single chemical, called rhodopsin *(row-DOP-sin),* which is activated by small amounts of light. Because rods are extremely light sensitive, they allow us to see in dim light, but to see only black, white, and shades of gray.

To see color, we need the cones. Each eye has about 6 million cones, most located in the retina's fovea (Goldstein, 2010).

Cones are photoreceptors that contain three chemicals called opsins *(OP-sins),* which are activated in bright light and allow us to see color. Unlike rods, cones are wired individually to neighboring cells; this one-on-one system of relaying information allows us to see fine details.

Next, we finally get to transduction, which begins in the rods and cones.

2 The process of ***transduction*** begins when chemicals in the rods and cones break down after absorbing light waves. This chemical breakdown generates a tiny electrical force that, if large enough, triggers ***nerve impulses*** in neighboring ***ganglion*** cells; now, transduction is complete.

3 ***Nerve impulses*** generated in ganglion cells exit the back of the eye through the ***optic nerve,*** which carries impulses toward the brain. The point where the optic nerve exits the eye has no receptors and is called the ***blind spot.*** You don't notice the blind spot because your eyes are continually moving.

What's surprising about the eye is that it does not "see" but rather is a sophisticated computer for transduction, for changing light waves into impulses. For you to "see something," impulses must reach the visual areas in the brain, our next stop.

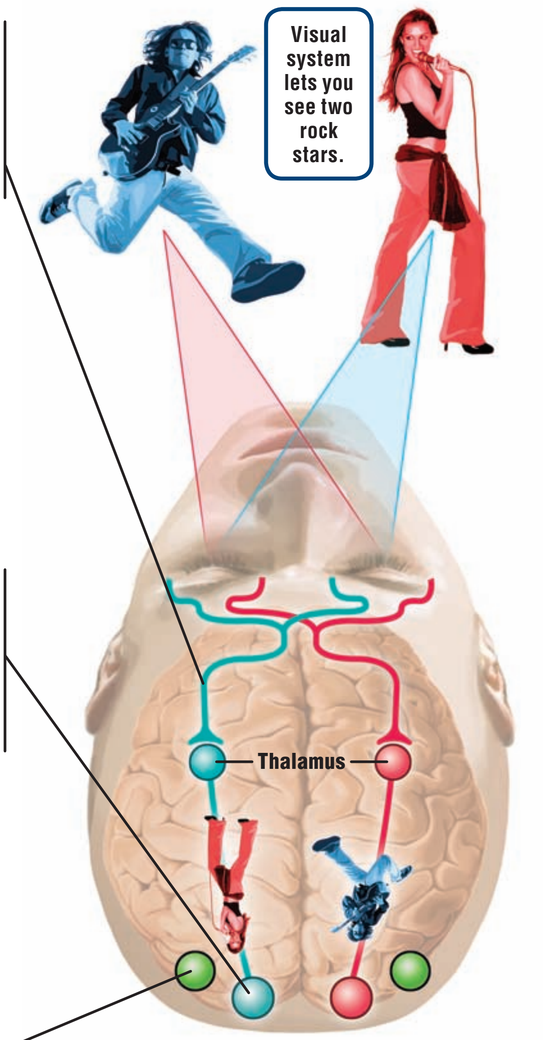
Visual Pathways: Eye to Brain

How do you see rock stars?

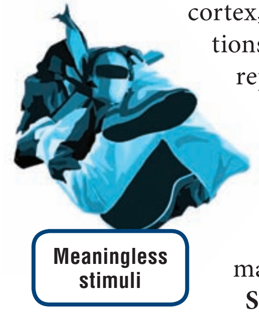
There is a lot of truth to the old saying, "Seeing is believing," but most people don't realize that the "seeing" takes place in the brain, not in the eye. So far, we have traced the paths along which light waves enter the eye, are focused on the retina, are changed into impulses, and leave the eye on the optic nerve. Now we will follow the optic nerve as it reaches its final destination in the occipital lobe, at the back of the brain. There, the occipital lobe changes light waves into colorful rock stars.

1 Optic nerve. Nerve impulses flow through the optic nerve as it exits from the back of the eye. This exit point creates a blind spot that we do not normally see because our eyes are constantly moving and cover any areas that might be in the blind spot.

The optic nerves partially cross over and make a major stop in the ***thalamus,*** which does some initial processing. The thalamus relays the impulses to the back of the occipital lobe in the right and left hemispheres.



2 Primary visual cortex. At the very back of each occipital lobe lies a primary visual cortex, which transforms nerve impulses into simple visual sensations, such as texture, lines, and colors. At this point, you would report seeing only these basic sensations (left figure), not the complete figure of a rock star.



Meaningless stimuli

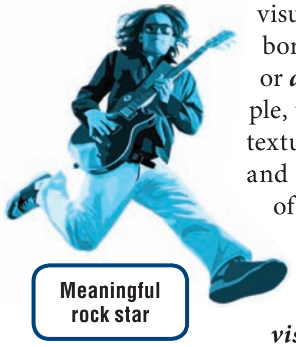
Researchers estimate that about 25% of the entire cortex is devoted to processing visual information, more area than to any other sensory input (Goldstein, 2010). The visual cortex contains many different cells that respond to many different kinds of visual stimulation.

Specialized cells. From the Nobel Prize–winning research of David Hubel and Torsten Wiesel (1979), we know that different cells in the ***primary visual cortex*** respond to specific kinds of visual stimuli. For example, some cortical cells respond to lines of a particular width, others to lines at a particular angle, and still others to lines moving in a particular direction. These specialized cortical cells transform different stimuli into simple visual sensations, such as shadows, lines, textures, or angles.

Blindness. If part of your primary visual cortex were damaged, you would have a blind spot in the visual field, similar to looking through glasses with tiny black spots painted on the lens. Damage to the entire primary visual cortex in both hemispheres would result in almost total blindness; the ability to tell night from day might remain.

However, to make sense of what you see, such as a rock star, nerve impulses must be sent from the primary visual cortex to neighboring visual association areas.

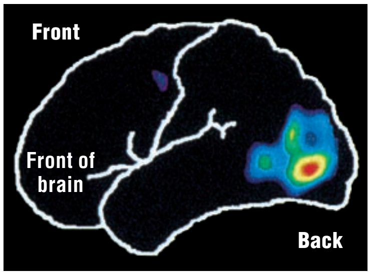
3 Visual association areas. The primary visual cortex sends simple visual sensations (actually, impulses) to neighboring association areas, which add meaning or ***associations*** (Kiernan, 2008). In our example, the association area receives sensations of texture, line, movement, orientation, and color and assembles them into a meaningful image of a complete rock star (left figure). There are visual association areas in each hemisphere. If part of your visual association area were damaged, you would experience ***visual agnosia,*** which is difficulty in assembling simple visual sensations into more complex, meaningful images (Ropper & Samuels, 2009). For instance, a person with visual agnosia could see pieces of things but would have difficulty combining pieces and recognizing them as whole, meaningful objects (see p. 79).



Meaningful rock star

Researchers can use brain scans to show actual neural activity that is occurring in the visual association areas.

4 This brain scan shows that when a subject is silently looking at and reading words, maximum neural activity occurs in the primary visual cortex and nearby visual association areas (red and yellow indicate maximum neural activity; blue and green indicate least). These visual areas are located in the occipital lobe (back of the brain). The visual association areas are involved in many visual activities, such as reading, writing, and perceiving objects, animals, people, and colors (Gaillard et al., 2006; Storbeck et al., 2006).



Next, we'll explain how the visual system transforms light waves into all the colors of the rainbow.

A. Eye: Vision

Color Vision

What is red?

Debra was born with opaque films over her lenses (cataracts) that made her almost totally blind. For her first 28 years, she could tell night from day but see little else. When a newly developed operation restored much of her vision, she cried with delight as she looked around her hospital room and saw things she had only imagined. “Colors were a real surprise to me,” Debra said. “They were so bright. You can’t conceive what colors are until you’ve seen them. I couldn’t imagine what a red apple looked like and now I can hold one and actually see red” (*San Diego Tribune,* April 3, 1984).

Red is actually long light waves.

Like Debra, you might assume that a red apple is really red, but you are about to discover otherwise. Objects, such as a red apple, do not have colors. Instead, objects reflect light waves whose different wavelengths are transformed by your visual system into the experience of seeing colors. So, what is red? The answer is that the color red is actually produced by a certain kind of wavelength.

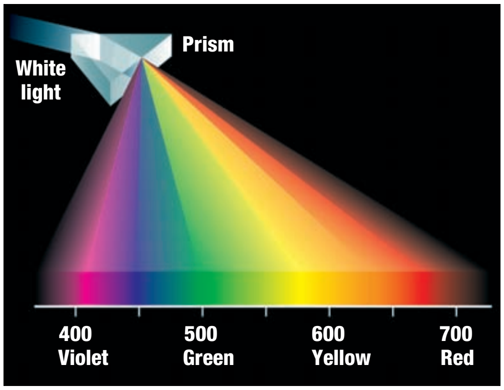
How light waves are turned into millions of colors is a wondrous and interesting process, which begins with a ray of sunlight.

Making Colors from Wavelengths

1. A ray of sunlight is called white light because it contains all the light waves in the visible spectrum, which is what humans can see.

2. As white light passes through a prism, it is separated into light waves that vary in length. Nature creates prisms in the form of raindrops, which separate the passing sunlight into waves of different lengths, creating a spectrum of colors that we call a rainbow.

3. Our visual system transforms light waves of various lengths into millions of different colors. For example, in the figure below, notice that the numbers, which vary from about 400 to 700 (nanometers, or nm), indicate the length of light waves. We see shorter wavelengths as shades of violet, blue, and green, and longer wavelengths as shades of yellow, orange, and red (Silbernagl & Despopoulous, 2008).



You see an apple as red because the apple reflects longer light waves, which your brain interprets as red.

Actually, how our visual system transforms light waves into color is explained by two different theories—the trichromatic and opponent-process theories—which we’ll examine next.

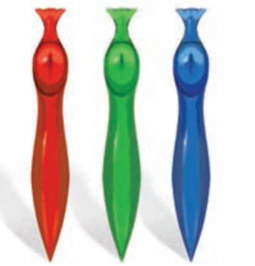
Trichromatic Theory

The explanation of how you see the many colors in the native face (left photo) began over 200 years ago with the early work of a British physicist, Thomas Young. It was his research that laid the basis for a theory of how you see colors, called the trichromatic *(TRI-crow-MAH-tic)* theory of color.

All colors are made from mixing 3 primary colors: red, green, and blue.

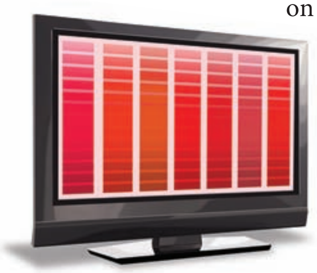
The ***trichromatic theory*** says that there are three different kinds of cones in the retina, and each cone contains one of three different light-sensitive chemicals, called opsins. Each of the three opsins is most responsive to wavelengths that correspond to each of the three primary colors: blue, green, and red. All other colors can be mixed from these three primary colors.

According to the recent version of the trichromatic theory, you see the red around the man’s eyes because this area reflects light waves of a longer wavelength. You see the green in the feathers because they reflect light waves of medium length. You see the blue in the headband because it reflects light waves of shorter length. The different lengths of light waves are absorbed by three different cones whose chemicals (opsins) are most sensitive to one of the three primary colors—red, green, and blue (right figure). Thus, wavelengths of different lengths are changed into one of the three primary colors, which are mixed to produce all colors (Goldstein, 2010).



We have 3 types of cones.

Until recently, color vision was believed to involve only three genes, one each to code the three primary colors of red, green, and blue. Researchers discovered that we had as many as two to nine genes (thus two to nine cones) that code the longer wavelengths involved in seeing red (Neitz & Neitz, 1995). This means that seeing a particular color, such as red, depends on how many color genes you have inherited. For example, which bar on the TV (below) you label as “red” depends on which of the genes (two to nine) you’ve inherited. One person may label deep scarlet as “red” while another sees a pale red. This means that different people may see and label the “same” color, red, very differently (scarlet to pale red), and this difference explains why people may not agree about adjusting the color (red) on their television sets (Lipkin, 1995; Yanoff et al., 2003). Thus, your perception of the color “red” may differ from someone who has different “color genes.”



People do NOT all see the same color of red.

To understand how color coding occurs in the brain, we need to examine the second theory of color vision, the opponent-process theory.

Photo Credit: center, © Digital Stock Corporation

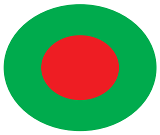
Opponent-Process Theory

If you stare at a red square for about 20 seconds and then immediately look at a white piece of paper, you'll see a green square, which is called an afterimage.

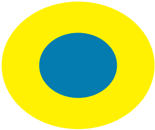
An ***afterimage*** is a visual sensation that continues after the original stimulus is removed.

And if you stare at a blue square, you'll see a yellow afterimage. On the basis of his work with afterimages, physiologist Ewald Hering suggested that the visual system codes color by using two complementary pairs—red-green and blue-yellow. Hering's idea became known as the opponent-process theory.

The ***opponent-process theory*** says that ganglion cells in the retina and cells in the thalamus of the brain respond to two pairs of colors—red-green and blue-yellow. When these cells are excited, they respond to one color of the pair; when inhibited, they respond to the complementary pair.



For example, some ganglion and thalamic cells use a ***red-green*** paired combination: they signal red when excited and green when inhibited.



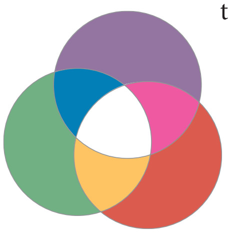
Other ganglion and thalamic cells use a ***yellow-blue*** paired combination: they signal blue when excited and yellow when inhibited.

Thus, different parts of the visual system use different methods to code different colors.

Theories Combined

Because we see colors so automatically and naturally, we don't realize it involves both the opponent-process and trichromatic theories. Here's what happens when we combine the two theories to explain color vision.

First, the trichromatic theory says that there are usually three different kinds of cones (there may be as many as nine) in the retina. Each cone absorbs light waves of different lengths, which correspond to the three primary colors of blue, green, and red. Second, when electrical signals (color information) reach the ganglion cells in the retina and neurons in the thalamus, they use the opponent-process theory, which involves a pair of colors: Activation results in one color of a pair, and inhibition results in the other color. Third, nerve impulses carry this color information to the visual cortex, where other neurons respond and give us the experience of seeing thousands of colors, which can be made by combining the three primary colors of red, green, and blue.



Although most of us have good color vision, some individuals have varying degrees of color blindness.

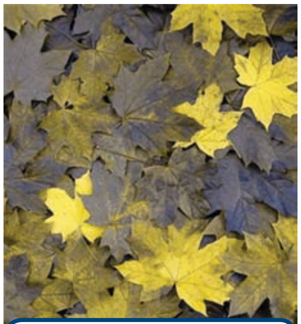
Color Blindness

This is normal color vision.

The vast majority of us have normal color vision. We see the vibrant colors of the leaves on the left—green, red, and yellow. However, about 7% of men and fewer than 1% of women in the United States see these same leaves in shades of blue and yellow (photo below right) because they have inherited the most common form of color blindness (HHMI, 2008).

Color blindness is the inability to distinguish two or more shades in the color spectrum. There are several kinds of color blindness.

Monochromats *(MOHN-oh-crow-mats)* have total color blindness; their worlds look like black-and-white movies. This kind of color blindness is rare and results from individuals having only rods or only one kind of functioning cone (instead of three).



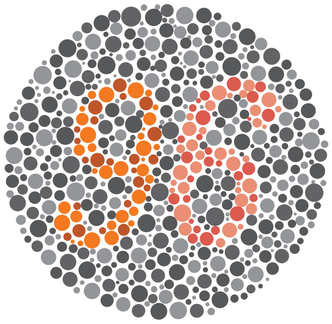
This is red-green color blindness.

Dichromats *(DIE-crow-mats)* usually have trouble distinguishing red from green because they have just two kinds of cones. This is an inherited genetic defect, found mostly in males, that results in seeing mostly shades of blue and yellow (right photo) but differs in severity (Gerl & Morris, 2008).

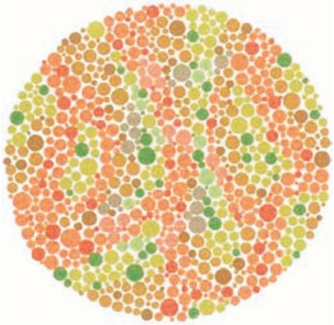
People don't always realize they have color blindness. For example, a little boy came home complaining about being chased by a green dog. The dog really looked green to the little boy; he did not know he had a form of color blindness.

People in some occupations, such as electrical technicians, are screened for color blindness because they must identify differently colored wires.

Below, you see two circles filled with colored dots that are part of a test for color blindness. An individual taking this test is asked to look at each circle and identify what, if any, number is formed by the colored dots.



Individuals with normal vision see the number 96, while people with red-green color deficits find this number difficult or impossible to see.



Those with normal color vision and total color blindness should not be able to read any number. The majority of those with red-green deficiencies should read the number 5.

From our discussion of the eye's structure and function, you can see that the eye is an engineering marvel that makes even the most sophisticated video camera seem like an expensive toy.

Next, we'll examine an equally astonishing sense organ, the ear.

B. Ear: Audition

Stimulus: Sound Waves

What happens when someone yells?

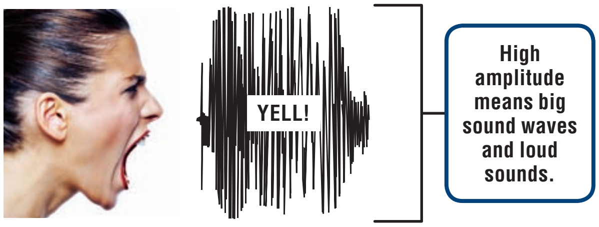
When a cheerleader gives a big yell, she is actually producing the yell by letting out air so that it is alternately compressed and expanded into traveling waves, called sound waves.

Sound waves, which are the stimuli for hearing (audition), resemble ripples of different sizes. Similar to ripples on a pond, sound waves travel through space with varying heights and frequency. Height, which is the distance from the bottom to the top of a sound wave, is called amplitude. Frequency refers to the number of sound waves that occur within 1 second.

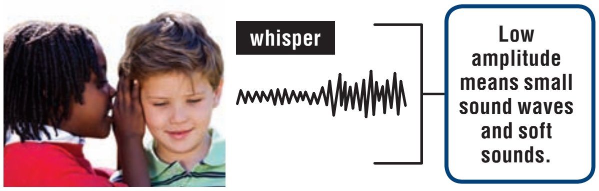
We'll demonstrate the concept of amplitude by comparing sound waves of a cheerleader's yell with a child's whisper.

Amplitude and Loudness

Yell. As a cheerleader yells, she lets out an enormous amount of air that is compressed and expanded into very large traveling waves (shown below). Large sound waves are described as having high amplitude, which the brain interprets as loud sounds.



Whisper. As a child whispers a secret to his friend, he lets out a small amount of air that is compressed and expanded into very small traveling waves. Small sound waves are described as having low amplitude, which the brain interprets as soft sounds.



Relationship: amplitude and loudness. You have no difficulty distinguishing between a cheerleader's yell and a child's whisper because your auditory system automatically uses the amplitude of the sound waves to calculate loudness (Barrett et al., 2009).

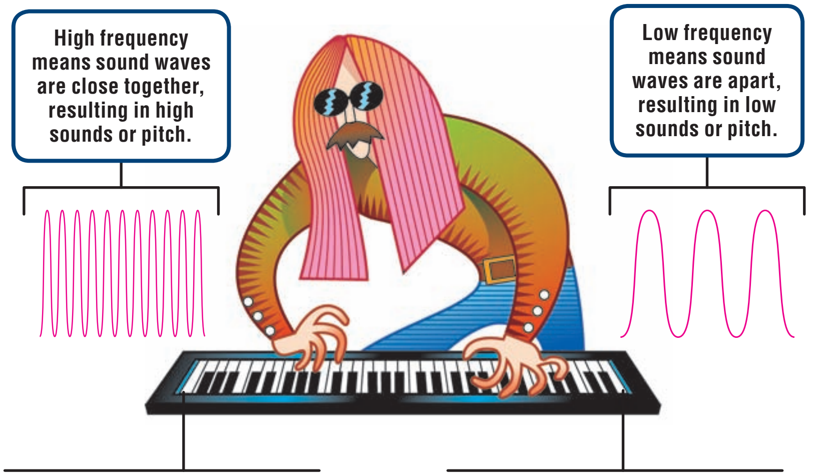
Loudness is your subjective experience of a sound's intensity. The brain calculates loudness from specific physical energy, in this case the amplitude of sound waves.

A whisper, which results in low-amplitude sound waves, is just above our threshold of hearing. The loudest yell on record, which resulted in high-amplitude sound waves, was about as loud as sound heard near speakers at a rock concert.

If the brain uses amplitude to calculate loudness, what does it use to calculate a sound's low or high pitch?

Frequency and Pitch

Screech or boom. As you listen to someone playing a keyboard, you can tell the difference between high and low notes because your brain is continually discriminating between high and low sounds, which is called pitch.



High frequency means sound waves are close together, resulting in high sounds or pitch.
Low frequency means sound waves are apart, resulting in low sounds or pitch.

High note. Striking the top key on a keyboard produces sound waves that travel rapidly and are described as having high frequency. The brain interprets high frequency as high notes or high pitch.

Low note. Striking the bottom key on a keyboard produces sound waves that travel slowly and are described as having low frequency. The brain interprets low frequency as low notes or low pitch.

Relationship: frequency and pitch. When you hear a sound, your auditory system automatically uses frequency to calculate pitch (Barrett et al., 2009).

Pitch is our subjective experience of a sound being high or low, which the brain calculates from specific physical stimuli, in this case the speed or frequency of sound waves. The frequency of sound waves is measured in cycles, which refers to how many sound waves occur within 1 second.

The keyboard's highest key produces sound waves with a high frequency, which results in high sounds or high pitch; the keyboard's lowest key produces sound waves of lower frequency, which results in low sounds or low pitch.

Hearing range. Humans hear sounds within only a certain range of frequencies, and this range decreases with age. For example, infants have the widest range of hearing, from frequencies of 20 to 20,000 cycles per second. For college students, it is 30 to 18,000 cycles per second. With further aging, the hearing range decreases, so that by age 70, many people can't hear sounds above 6,000 cycles per seconds. Many college students are now using an ear-splitting ring tone with a frequency of 17,000 cycles per second so they can hear the ring but their parents and professors cannot (M. Block, 2006; Vitello, 2006).

Next, we'll see how loud a jet plane is compared to a whisper.

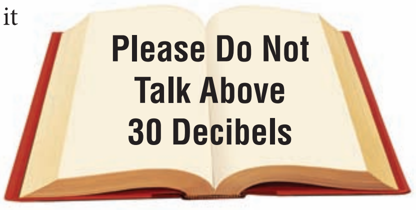
Measuring Sound Waves

How loud is the library?

If the sign on the right were posted in the library, you might not know that it refers to loudness, which is measured in decibels (dB).

A ***decibel*** is a unit to measure loudness, just as an inch is a measure of length. Our threshold for hearing ranges from 0 decibels, which is absolutely no sound, to 140 decibels, which can produce pain and permanent hearing loss.



The following table contains common sounds with their decibel levels. Notice especially those sound levels that can cause permanent hearing loss.

Decibel (dB) level	Sounds and their decibel levels		Exposure time and permanent hearing loss
140	Jet engine, gun muzzle blast, firecracker explosion		Any exposure to sounds this loud is painful and dangerous. That's why aircraft ground personnel must wear ear protectors.
120	Rock concert near speakers, thunderclap, record-setting human yell (115 dB)		Exposure for 15 minutes or less can produce hearing loss. Rock musicians and fans who do not use ear plugs risk hearing loss.
100	Chain saw, jackhammer, baby screaming, inside of racing car		Exposure for 2 hours or more can cause hearing loss. Workers using loud power tools who do not use ear protectors risk hearing loss.
80	Heavy city traffic, alarm clock at 2 feet, subway, MP3 player/iPod		Constant exposure for 8 hours can produce hearing loss. Music lovers should know that stereo headphones can produce sounds from 80 to 115 dB.
60	Conversation, air conditioner at 20 feet		Aging decreases hearing sensitivity, and that's why older adults may ask, "What did you say?" indicating that they may not easily hear normal conversations.
30	Whisper, quiet library, gasoline-only car idling in neutral (45 dB)		Today's cars are engineered for quietness. At idle, many cars are almost as quiet as a library; and at 65 mph (70 dB), they are not much louder than a conversation.
0	Threshold of hearing, hybrid car operating on battery only (3–5 dB)		If you were boating in the middle of a calm lake, you might say, "Now, this is really quiet." In comparison, most of us are accustomed to relatively noisy city environments.

Decibels and Deafness

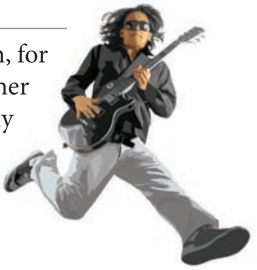
It is well established that continuous exposure to sounds with higher decibel levels (over 85 dB) for certain periods of time can produce permanent hearing loss (B. Healy, 2007). For example, rock musicians, hunters, operators of heavy machinery, airplane workers, and stereo headphone listeners who take no precautions against high decibel levels may suffer permanent hearing loss (Lalwani & Snow, 2006). Most young adults are unaware of the risk of going deaf by listening to loud MP3 players for extended periods of time (Godlasky, 2008).

At the end of this module (p. 115) we'll discuss different causes of deafness and treatment. Now, we'll take you inside the ear and explain how it turns sound waves into wonderful sounds.

B. Ear: Audition

Outer, Middle, and Inner Ear

Is that the Rolling Stones or a barking dog?



Most of us think that we hear with our ears and that's how we tell the difference between, for example, the music of the Rolling Stones and the barking of a dog. But nothing is further from the truth. What really happens is that both music and a dog's barks produce only sound waves, which are just the stimulus for hearing (audition). Your ears receive sound waves, but it is your brain that actually does the hearing, distinguishing the difference between the Stones' song "(I Can't Get No) Satisfaction" and a dog's barks. It's a complicated journey; the first step begins in the outer ear.

1 Outer Ear

The only reason your ear has that peculiar shape and sticks out from the side of your head is to gather in sound waves. Thus, sound waves produced by the Rolling Stones are gathered by your outer ear.

The ***outer ear*** consists of three structures: external ear, auditory canal, and tympanic membrane.

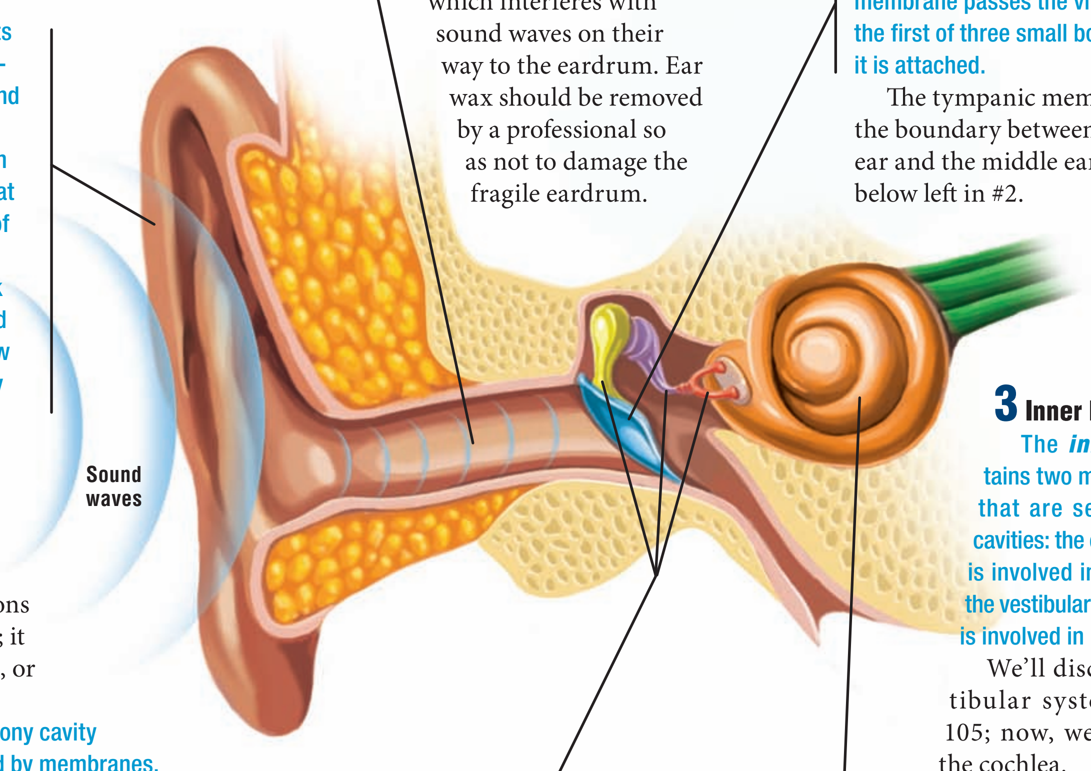
The ***external ear*** is an oval-shaped structure that protrudes from the side of the head. The function of the external ear is to pick up sound waves and send them down a long, narrow tunnel called the auditory canal.

1a The ***auditory canal*** is a long tube that funnels sound waves down its length so that the waves strike a thin, taut membrane—the eardrum, or tympanic membrane.

In some cases, the auditory canal may become clogged with ear wax, which interferes with sound waves on their way to the eardrum. Ear wax should be removed by a professional so as not to damage the fragile eardrum.

1b The ***tympanic*** *(tim-PAN-ick)* ***membrane*** is a taut, thin structure commonly called the eardrum. Sound waves strike the tympanic membrane and cause it to vibrate. The tympanic membrane passes the vibrations on to the first of three small bones to which it is attached.

The tympanic membrane marks the boundary between the outer ear and the middle ear, described below left in #2.



2 Middle Ear

The middle ear functions like a radio's amplifier; it picks up and increases, or amplifies, vibrations.

The ***middle ear*** is a bony cavity that is sealed at each end by membranes. The two membranes are connected by three small bones.

The three tiny bones are collectively called ***ossicles*** *(AW-sick-culls)* and, because of their shapes, are referred to as the hammer, anvil, and stirrup. The first ossicle—hammer—is attached to the back of the tympanic membrane. When the tympanic membrane vibrates, so does the hammer. In turn, the hammer sends the vibrations to the attached anvil, which further sends the vibrations to the attached stirrup. The stirrup makes the connection with the end membrane, the oval window. The three ossicles act like levers that greatly amplify the vibrations, which, in turn, cause the attached oval window to vibrate.

Thus, the function of the middle ear is to pick up vibrations produced by the tympanic membrane, amplify these vibrations, and pass them on to the oval window, which marks the end of the middle ear and beginning of the inner ear.

3 Inner Ear

The ***inner ear*** contains two main structures that are sealed in bony cavities: the cochlea, which is involved in hearing, and the vestibular system, which is involved in balance.

We'll discuss the vestibular system on page 105; now, we'll focus on the cochlea.

The ***cochlea*** *(KOCK-lee-ah),* located in the inner ear, has a bony coiled exterior that resembles a snail's shell. The cochlea contains the receptors for hearing, and its function is transduction—transforming vibrations into nerve impulses that are sent to the brain for processing into auditory information.

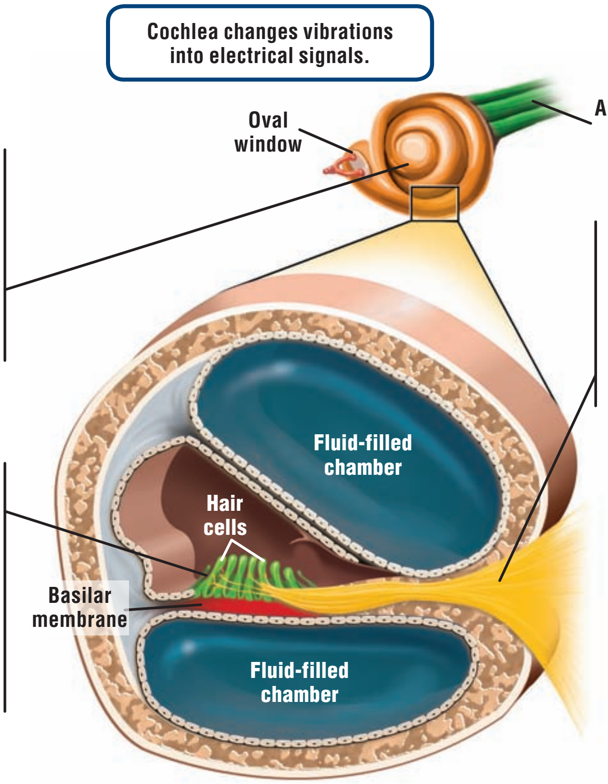
Researchers liken the cochlea to an exquisite miniature box that is made of bone and contains precious jewels, which in this case are miniature cells that are the receptors for hearing.

On the next page, we have enlarged and opened the cochlea so you can see the auditory receptors.

3 Inner Ear *(continued)*

3a If you were to take two drinking straws, hold them side by side, and then wind them around your finger, you would have a huge model of a cochlea. The cochlea consists of two long narrow tubes (straws) separated by membranes (basilar and tectorial) but joined together and rolled up, or coiled. The beginning of the coiled compartments is sealed by a membrane, the oval window. So when the ossicles vibrate the oval window, the oval window vibrates the fluid in the cochlea's tubes, where the auditory receptors are located.

3b The auditory receptors, called ***hair cells,*** are miniature hair-shaped cells that stick up from the cochlea's bottom membrane, called the ***basilar*** *(BAZ-ih-lahr)* ***membrane.*** Vibration of fluid in the cochlear tubes causes movement of the basilar membrane, which literally bends the hair cells. The mechanical bending of the hair cells generates miniature electrical forces that, if large enough, trigger nerve impulses (transduction). Nerve impulses leave the cochlea as explained at right in #3c.



Cross Section of Cochlea

3c The ***auditory nerve*** is a band of fibers that carry nerve impulses (electrical signals) to the auditory cortex of the brain for processing.

Now the cochlea has completed its role of transduction—transforming vibrations into nerve impulses. However, you won't report hearing anything until the impulses reach your brain.

Auditory Brain Areas

How do we tell noise from music?

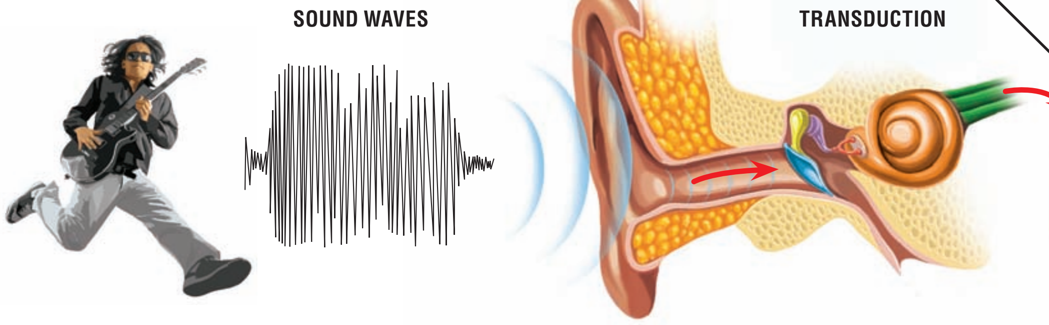
Just as your eye does not see, your ear does not hear. Rather, sense organs, such as the ear, perform only transduction—transform physical energy into nerve impulses. You don't hear or recognize sound as noise, music, or words until nerve impulses are processed by various auditory areas in the temporal lobes of your brain.

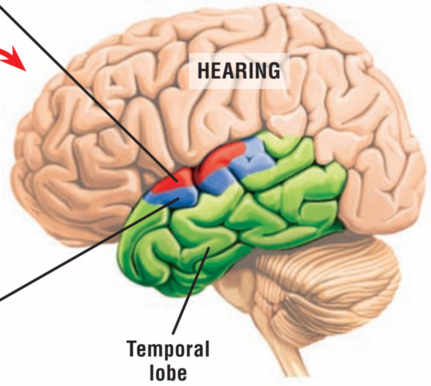
4 Sensations and Perceptions

After nerve impulses reach the brain, a two-step process occurs in which nerve impulses are transformed first into meaningless bits of sounds and then into meaningful sounds. The first step occurs in the primary auditory area, explained in #4a.

4a The ***primary auditory cortex,*** which is located at the top edge of the temporal lobe, transforms nerve impulses (electrical signals) into basic auditory sensations, such as meaningless sounds and tones of various pitches and loudness.

Next, the primary auditory cortex sends impulses (sensations) to the auditory association area, explained in #4b.





4b The ***auditory association area*** receives meaningless auditory sensations in the form of neural impulses from the neighboring primary auditory cortex. The auditory association area combines meaningless auditory sensations into perceptions, which are meaningful melodies, songs, words, or sentences.

It takes only a moment from the time sound waves enter your ear until you say, "That's the Stones' song '(I Can't Get No) Satisfaction.'" But during that amazing moment, sound waves were changed into impulses, impulses into sensations, and finally, sensations into perceptions (Goldstein, 2010).

Now we'll explain how the brain uses nerve impulses to calculate where a sound is coming from, whether it is a high or low sound, and whether it is a loud or soft sound.

B. Ear: Audition

Auditory Cues

Where's the sound coming from?

If someone yelled "Watch out!" you would immediately turn your head toward the source of the sound because your brain automatically calculates the source's location. The brain calculates not only the source of the voice but also whether the voice calling your name is high or low and loud or soft. Thus, sound waves contain an amazing amount of information. We'll begin with how your brain calculates the direction of where a sound is coming from.

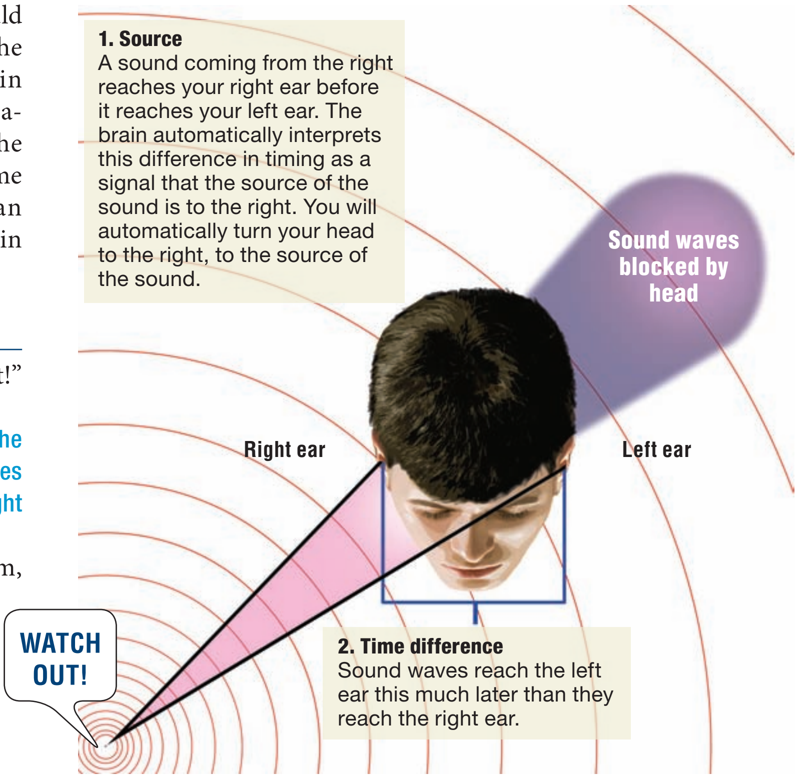
Calculating Direction

You automatically turn toward the source of the yell "Watch out!" because your brain instantly calculates the direction or source.

The brain determines the ***direction of a sound*** by calculating the slight difference in time (see #1 in right figure) that it takes sound waves to reach the two ears, which are about six inches apart (see #2 in right figure) (Goldstein, 2010).

If you have difficulty telling where a sound is coming from, the sound is probably arriving at both ears simultaneously. To locate the direction, you can turn your head from side to side, causing the sound to reach one ear before the other.

The brain uses other cues to calculate a sound's high or low pitch.



1. Source
A sound coming from the right reaches your right ear before it reaches your left ear. The brain automatically interprets this difference in timing as a signal that the source of the sound is to the right. You will automatically turn your head to the right, to the source of the sound.

2. Time difference
Sound waves reach the left ear this much later than they reach the right ear.

Calculating Pitch

Imagine the low, menacing growl of a lion and then the high screech of fingernails on the chalkboard. Your subjective experience of a sound being high or low is referred to as pitch. Exactly how the cochlea codes pitch and the brain interprets the code is rather complicated. We'll focus on two better-known theories of pitch: the frequency and place theories.

The ***frequency theory,*** which applies only to low-pitched sounds, says that the rate at which nerve impulses reach the brain determines how low the pitch of a sound is.

The frequency and place theories explain how we perceive pitch.

For example, the brain interprets a frequency rate of 50 impulses per second as a lower sound than one with a frequency rate of 200 impulses per second. Hearing the low-pitched roar of a lion involves the frequency theory. Hearing higher-pitched sounds, however, such as the screech of fingernails on a chalkboard, involves another theory, the place theory.

The ***place theory*** says that the brain determines medium- to higher-pitched sounds on the basis of the place on the basilar membrane where maximum vibration occurs.

For example, lower-pitched sounds cause maximum vibrations near the beginning of the cochlea's basilar membrane, while higher-pitched sounds cause maximum vibrations near the end of the membrane. Our auditory system combines the frequency and place theories to transform sound waves into perceptions of low- to high-pitched sounds (Goldstein, 2010).

The brain does one more thing: It calculates how loud a sound is.

Calculating Loudness

You can easily tell the difference between a yell and a whisper because your auditory system transforms the intensity of sound waves into the subjective experiences of a soft whisper or a loud yell. This transformation occurs inside the cochlea.

Compared to a yell, a whisper produces low-amplitude sound waves that set off the following chain of events: fewer vibrations of the tympanic membrane, less movement of fluid in the cochlea, less movement of the basilar membrane, fewer bent hair cells, less electrical force, and finally, fewer nerve impulses sent to the brain, which interprets these signals as a soft sound.

The brain calculates ***loudness*** primarily from the frequency or rate of how fast or how slowly nerve impulses arrive from the auditory nerve.

The brain calculates loudness from frequency of nerve impulses.

For example, the brain interprets a slower rate of impulses as a softer tone (whisper) and a faster rate as a louder tone (yell) (Goldstein, 2010).

Earlier, we said that there are two structures in the inner ear, the cochlea and the vestibular system. If you have ever stood on your head, you have firsthand experience with the vestibular system, our next topic.

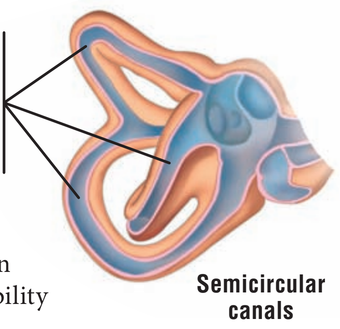
C. Vestibular System: Balance

Position and Balance

What else is in the inner ear?

I guarantee that one question you never ask is "Where is my head?" Even though your head is in a hundred different positions throughout the day, you rarely forget to duck as you enter a car or forget whether you're standing on your feet or your hands. That's because the position of your head is automatically tracked by another sense, called your vestibular system (J. E. Brody, 2008b).

The ***vestibular system,*** which is located above the cochlea in the inner ear, includes three ***semicircular canals,*** resembling bony arches, which are set at different angles (right figure). Each of the semicircular canals is filled with fluid that moves in response to movements of your head. In the canals are sensors (hair cells) that respond to the movement of the fluid. The functions of the vestibular system include sensing the position of the head, keeping the head upright, and maintaining balance.



The vestibular system uses information on the position of your head to indicate whether you're standing on your hands or your feet. A gymnast (left figure) relies heavily on his or her vestibular system to keep balance. Sometimes an inner ear infection affects the vestibular system and results in dizziness, nausea, and the inability to balance.

Vestibular system says you're upside down.

And as you'll see next, the vestibular system is also involved in motion sickness.

Motion Sickness

Why am I getting sick?

One of my (R.P.) terrible childhood memories is sitting in the back seat of a moving car and after 30 minutes of curving roads feeling a cold sweat followed by nausea, dizziness, and an extreme desire to lie down anywhere—stationary. Along with about 25% of the U.S. population, I experienced moderate to severe signs of motion sickness. About 55% of people experience only mild symptoms, while the remaining 20% are lucky and rarely experience any. Researchers think that motion sickness results when information provided by the vestibular system doesn't match information coming from other senses (Ignelzi, 2006b).

Motion sickness results from a mismatch between vestibular and visual systems.

Motion sickness, which consists of feelings of discomfort, nausea, and dizziness in a moving vehicle, is believed to develop when there is a sensory mismatch between the information from the vestibular system—that your head is physically bouncing around—and the information reported by your eyes—that objects in the distance look fairly steady.

Infants rarely have motion sickness, but susceptibility increases from 2 to 12. After 12, susceptibility decreases in men and women. Researchers suspect that genetic and not personality factors determine susceptibility to motion sickness (Ignelzi, 2006b).

A number of drugs reduce symptoms of motion sickness (CDC, 2008a). As an alternative to drugs, military pilots reported a reduction in motion sickness after completing a program that taught them to regulate several physiological responses to decrease their symptoms (Cowings et al., 2005). Other research found that people who used special breathing techniques reported significantly less nausea during an activity designed to induce motion sickness than people who did not learn the breathing techniques (Sang et al., 2003, 2005). Also, the use of ginger or a relief band (a bracelet that emits electronic pulses) may help to reduce motion sickness (CDC, 2008a). The best way to reduce motion sickness may simply be to lie down and close your eyes (*Science Daily,* 2007).

Malfunctioning of the vestibular system can cause terrible symptoms.

Meniere's Disease and Vertigo

Why is the room spinning?

Imagine suddenly having ringing in your ears like Niagara Falls, walking into the bathroom to find the toilet spinning out of range, or vomiting 30 times a day. These are all symptoms of the dreaded Meniere's disease (Miyamoto, 2008).

Meniere's *(main-YERS)* ***disease*** results from a malfunction of the semicircular canals of the vestibular system. Symptoms include attacks of dizziness, nausea, vomiting, spinning, and piercing buzzing sounds.

About 615,000 Americans are diagnosed with Meniere's disease, but it is estimated that over 6 million Americans suffer from the disease, which is thought to be caused by a viral infection of the inner ear (Pray & Pray, 2005). The vestibular system is also involved in vertigo (J. E. Brody, 2008b).

Vertigo, whose symptoms are dizziness and nausea, results from malfunction of the semicircular canals of the vestibular system.

Cheryl experienced a terrible side effect from a medication—damage to her vestibular system. Now she describes her world as made of Jell-O. Cheryl lacks a sense of balance and wobbles with each step; everything she looks at seems to jiggle. She was diagnosed as having vertigo and sought help for her dizziness (J. E. Brody, 2008b).

Meniere's disease and vertigo share some symptoms and have no known cures. There are "dizzy" clinics that use drug and nondrug methods to decrease symptoms that involve malfunctions of the vestibular system.

If you happen to be reading this book in a car or on a plane and feel a little queasy, relax before reading the next section, which is about tasting and smelling food.

D. Chemical Senses

Taste

How does your tongue taste?

You rarely think about the thousands of chemicals you put into your mouth every day, but you do know when something tastes very good or very bad. You also know that if you burn your tongue on hot foods or liquids, your sense of taste can be markedly decreased.

Taste is called a chemical sense because the stimuli are various chemicals. On the surface of the tongue are receptors, called taste buds, for five basic tastes: sweet, salty, sour, bitter, and umami. The function of taste buds is to perform transduction, which means transforming chemical reactions into nerve impulses.

As you imagine biting into and chewing a very bitter slice of lemon, we'll explain how your tongue tastes.

1 Tongue: Five Basic Tastes

You're probably familiar with four basic tastes—*sweet, salty, sour,* and *bitter.* There now appears to be a fifth, called *umami,* a meaty-cheesy taste found in cheese, meat, pizza, and MSG (A. Gilbert, 2008). The right figure shows the areas on the tongue that have the most sensors or taste buds.

The reason many of us have a sweet tooth is that, as newborns, we inherited an innate preference for sweet and salty (Netting, 2001). Like most animals, humans avoid bitter-tasting substances, presumably because many poisonous substances taste bitter (Barinaga, 2000). If you are one of those who like sour lemonade, you know that people can learn to like bitter substances. Tasting begins with what happens in the trenches on the surface of your tongue.

2 Surface of the Tongue

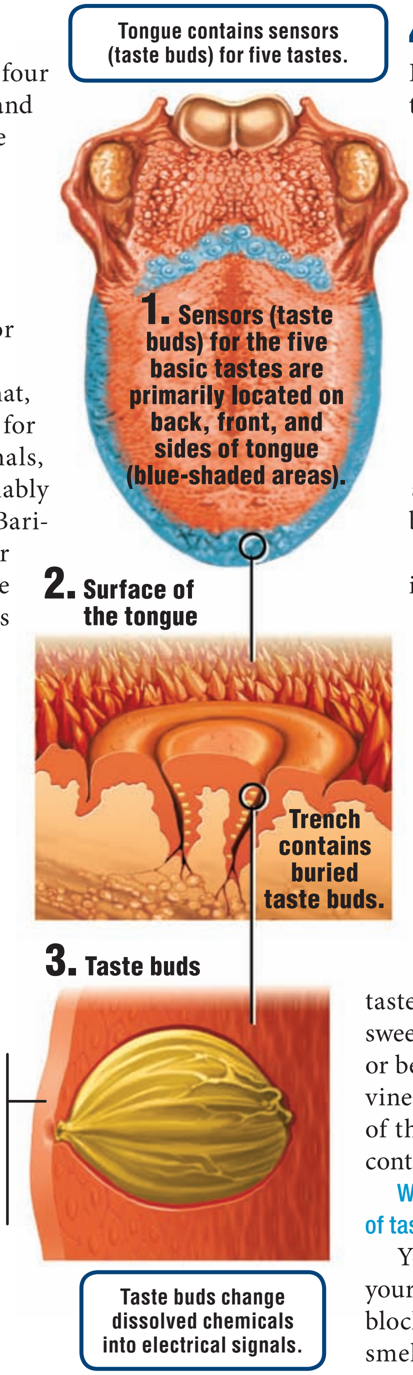
As you chew the lemon, its chemicals, which are the ***stimuli*** for taste, break down into molecules. In turn, these molecules mix with saliva and run down into narrow trenches on the surface of the tongue. Once inside the trenches, the molecules stimulate the taste buds.

3 Taste Buds

Buried in the trenches on the surface of the tongue are many hundreds of bulblike taste buds.

Taste buds, which are shaped like miniature onions, are the receptors for taste. Chemicals dissolved in the saliva activate the taste buds, which produce nerve impulses that eventually reach areas in the brain's parietal lobe. The brain transforms these nerve impulses into sensations of taste.

Taste buds live in a relatively toxic environment and are continuously exposed to heat, cold, spices, bacteria, and saliva. As a result, taste buds wear out and are replaced about every ten days. The human tongue can have as many as 10,000 taste buds and as few as 500; the number remains constant throughout life (Goldstein, 2010).



Tongue contains sensors (taste buds) for five basic tastes.
1. Sensors (taste buds) for the five basic tastes are primarily located on back, front, and sides of tongue (blue-shaded areas).
2. Surface of the tongue
Trench contains buried taste buds.
3. Taste buds
Taste buds change dissolved chemicals into electrical signals.

4 All Tongues Are Not the Same

In rare cases, individuals are born without any taste buds and cannot taste anything because they have a genetically determined disorder (Mass et al., 2005). In contrast, about 35% of women and 15% of men are supertasters, which means they have at least twice as many taste buds as normal, which results in increased sensitivity to sweet, bitter, sour, and salty (Bartoshuk, 2006). For example, supertasters taste sugar to be twice as sweet as most people and get more intense oral burning sensations from the chemical (capsaicin) in chili peppers. Supertasters find grapefruit juice too bitter and don't like broccoli because it also contains a bitter chemical (Bhattacharya, 2003).

Researchers found that being a supertaster is an inherited trait and believe it may have had some evolutionary advantage. For example, supertasters would be better able to identify unsafe foods and toxins, such as whether fruits or berries are poisonous (Bartoshuk, 1997; BBC, 2008b). Today, supertasters may work for food manufacturers and rate the tastes of new food products.

For all of us, our ability to taste is greatly affected by our ability to smell.

5 Flavor: Taste and Smell

If taste receptors are sensitive to only five basic tastes, how can you tell the difference between two sweet tastes, such as a brownie and vanilla ice cream, or between two sour tastes, such as lemon juice and vinegar? The truth is that a considerable percentage of the sensations we attribute to taste are actually contributed by our sense of smell (A. Gilbert, 2008).

We experience ***flavor*** when we combine the sensations of taste and smell.

You have no doubt experienced the limitations of your taste buds' abilities when you had a cold, which blocks the nasal passages and cuts out the sense of smell. Without smell, foods we usually love now taste very bland.

Since our taste of foods is greatly enhanced by the sense of smell, we'll examine smell, or olfaction, next.

Photo Credits: top, © Creatas/SuperStock; center left, © Stockbyte/Getty Images

Smell, or Olfaction

How does your nose smell?

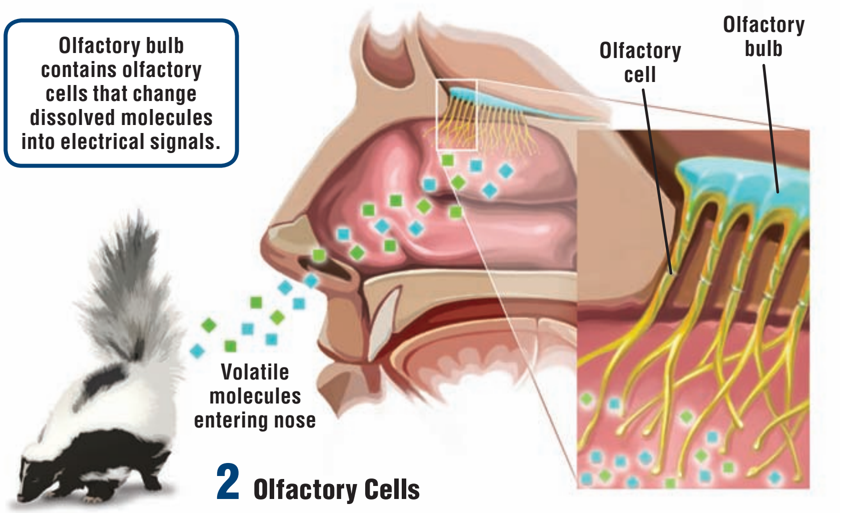
Every year people in the United States spend about $3 billion on perfumes to make themselves smell better (Banay, 2006). You may have been impressed that your tongue has up to 10,000 taste buds, but that number pales in comparison to the nose's millions of receptor cells (Ganong, 2005; Glausiusz, 2008). That's why the sense of smell (olfaction) is 10,000 times more sensitive than taste (Lindstrom, 2005).

Olfaction is called a chemical sense because its stimuli are various chemicals that are carried by the air. The upper part of the nose has a small area that contains receptor cells for olfaction. The function of the olfactory receptors is transduction, to transform chemical reactions into nerve impulses.

We'll explain the steps for olfaction by having you imagine crossing paths with an angry skunk.

1 Stimulus

An angry skunk protects itself by spraying thousands of molecules, which are carried by the air and drawn into your nose as you breathe. The reason you can smell substances such as skunk spray is that these substances are volatile. A volatile substance is one that can release molecules into the air at room temperature. For example, volatile substances include skunk spray, perfumes, and warm brownies, but not glass or steel. We can smell only volatile substances, but first they must reach the olfactory cells in the nose.



Olfactory bulb contains olfactory cells that change dissolved molecules into electrical signals.
Olfactory cell
Olfactory bulb
Volatile molecules entering nose

2 Olfactory Cells

Olfactory cells are the receptors for smell and are located in two 1-inch-square patches of tissue in the uppermost part of the nasal passages. Olfactory cells are covered with mucus, a gluey film into which volatile molecules dissolve and stimulate the underlying olfactory cells. The olfactory cells trigger nerve impulses that travel to the brain, which interprets the impulses as different smells.

As you breathe, a small percentage of the air entering your nose reaches the upper surface of your nasal passages, where the olfactory receptors are located. People can lose their sense of smell if a virus or inflammation destroys the olfactory receptors, or if a blow to the head damages the neural network that carries impulses to the brain. About 5% of all people have no sense of smell, and people lose their ability to smell as they age. For instance, 25% of people older than 60 lose their sense of smell (Raloff, 2007; von Bothmer, 2006). You don't actually smell anything until neural impulses reach your brain.

3 Sensations and Memories

Nerve impulses from the olfactory cells travel first to the olfactory bulb, which is a tiny, grape-shaped area (blue structure in diagram of nose) that lies directly above the olfactory cells at the bottom of the brain. From here, impulses are relayed to the primary olfactory cortex (also called the piriform cortex) located underneath the brain. This cortex transforms nerve impulses into the olfactory sensations of a skunk's spray or a sweet perfume (von Bothmer, 2006).

Although we can identify as many as 10,000 different odors, we soon stop smelling scents we are repeatedly exposed to (deodorants, perfumes) because of decreased responding, called adaptation, in the olfactory cells (Jacob et al., 2006).

Smell, in terms of evolution, is a very primitive sense and has important functions.

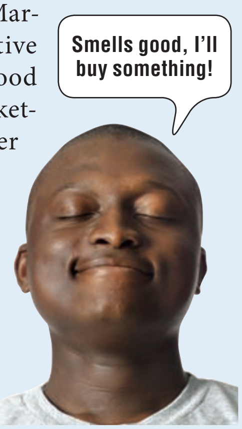
4 Functions of Olfaction

One function of smell is to intensify the taste of food. For example, you could not tell a licorice from an orange jelly bean with your nose held closed. A second function is to warn of potentially dangerous foods; the repulsive odor of spoiled or rotten food does this very effectively. A third function is to elicit strong memories, often associated with emotional feelings; for example, the smell of pumpkin pie may remind you of a family gathering (Ropper & Samuels, 2009). A fourth function may be to aid us in choosing a mate. We know that for many animals smells function to locate mates as well as food and territory. Recent research suggests that females have a distinct ability to smell biological information in sweat or body odor, which may guide them in selecting a mate (Wysocki et al., 2009).

Next, we discuss how marketing companies use smell to improve our mood and encourage us to make purchases.

Can smells increase buying?

For many of us, smelling pies, cakes, or cookies baking in the oven quickly improves our mood, even puts a big smile on our faces. Marketing companies use attractive scents to put us in a good mood and encourage us to make purchases. Scent marketing is clever because smell, more than any other sense, such as sight and sound, is connected to our limbic system (see p. 80), where our motivations and emotions are processed. Consequently, the feelings we get from smells are intense and immediate. This means if businesses use attractive scents, we may make purchases based more on instinct than on rational thought, which of course is exactly what they want us to do (R. Baron, 2008; Herz, 2008).



Smells good, I'll buy something!

Next, we discuss touch and explain what happens when you pet a cat.

D. Control Center: Four Lobes

Definition

What happens when fingers feel fur?

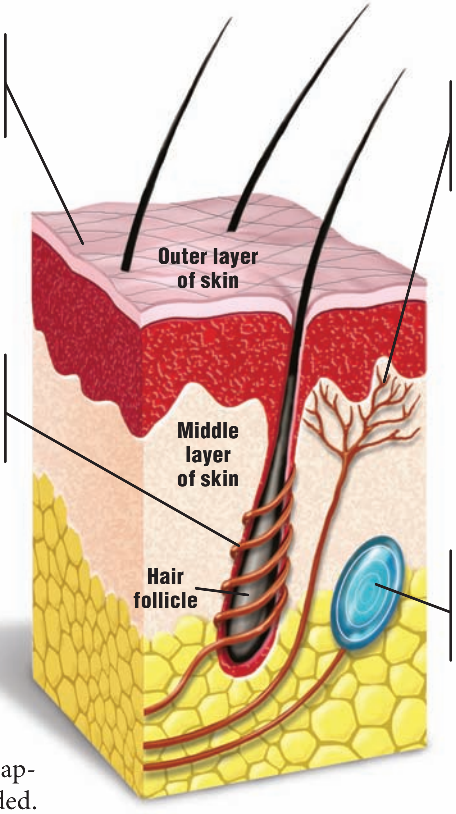
If you were to draw your hand across the surface of a cat, you would have the sensations of touching something soft and furry. These sensations are part of the sense of touch.

The sense of ***touch*** includes pressure, temperature, and pain. Beneath the outer layer of skin are a half-dozen miniature sensors that are receptors for the sense of touch. The function of the touch sensors is to change mechanical pressure or temperature variations into nerve impulses that are sent to the brain for processing.

We'll examine several miniature mechanical sensors and explain how they function.

Receptors in the Skin

If you were to closely examine the surface of your skin, you would see a relatively smooth membrane covered in some places with hair. Some "touch" sensors are wound around hair follicles (the backs of your arms) and are slightly different from sensors in skin without hair (your palms). However, before we discuss several major touch receptors, we need to examine the different layers of the skin.



1 Skin. The skin, which is the body's largest organ, has three layers. The ***outermost layer*** of skin is a thin film of dead cells containing no receptors. Immediately below the dead layer are the first receptors, which look like groups of threadlike extensions. In the ***middle and fatty layers*** of skin are a variety of receptors with different shapes and functions. Some of the major sensors in the middle layer of skin are hair receptors.

2 Hair receptors. In the middle layer are free nerve endings that are wrapped around the base of each hair follicle; these are called ***hair receptors.*** Hair receptors respond or fire with a burst of activity when hairs are first bent. However, if hairs remain bent for a period of time, the receptors cease firing, an example of ***sensory adaptation.*** When you first put on a watch, it bends hairs, causing hair receptors to fire; your brain interprets this firing as pressure on your wrist. If you keep the watch on and it remains in place, keeping the hairs bent, the hair receptors adapt or cease firing, and you no longer feel pressure from your watch, even though it is still there. Your skin contains some receptors that adapt rapidly (hair receptors) and others that adapt slowly. Adaptation prevents your sense of touch from being overloaded.

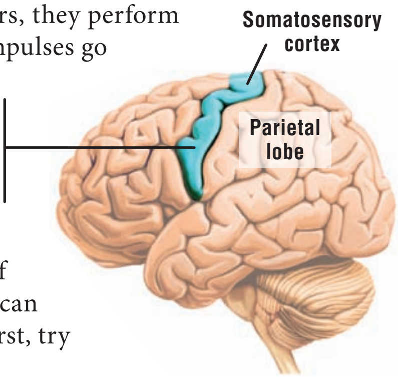
3 Free nerve endings. Near the bottom of the outer layer of skin is a group of threadlike extensions; these are called ***free nerve endings*** because they have nothing protecting or surrounding them. One question about free nerve endings is how the same receptor can transmit information about both temperature and pain. Researchers think that different patterns of neural activity may signal different sensations—for example, slow bursts of firing for temperature and fast bursts for pain (Ferster & Spruston, 1995).

4 Pacinian corpuscle. In the fatty layer of skin is the largest touch sensor, called the ***Pacinian corpuscle*** *(pa-SIN-ee-in CORE-pus-sole).* This receptor, which has distinctive layers like a slice of onion, is highly sensitive to touch, is the only receptor that responds to vibration, and adapts very quickly.

All these receptors send their electrical signals to the brain.

Brain Areas

Did I touch my nose or my toe?



When pressure (touch), temperature, or pain stimulates the skin's receptors, they perform transduction and change these forms of energy into nerve impulses. The impulses go up the spinal cord and eventually reach the brain's somatosensory cortex.

The ***somatosensory cortex,*** which is located in the parietal lobe, transforms nerve impulses into sensations of touch, temperature, and pain. You know which part is being stimulated because, as we explained earlier (p. 77), different parts of the body are represented on different areas of the somatosensory cortex.

Compared with touch and temperature, the sense of pain is different because it has no specific stimulus and can be suppressed by psychological factors. We'll discuss these interesting aspects of pain, along with acupuncture, later in this module.We'll also discuss later how psychological factors can make foods that we think are truly disgusting become delicacies in other parts of the world. But first, try out your memory on the Concept Review.

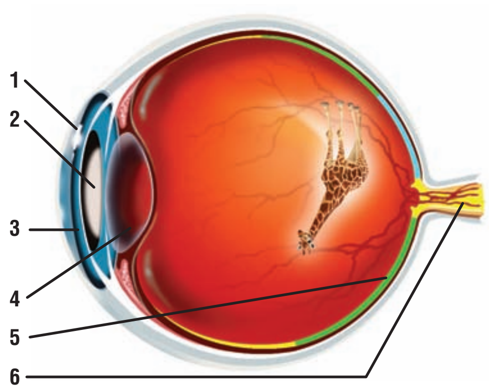
Concept Review

EYE: Numbers on the eye match the numbers of the questions.



1. A transparent, curved structure at the front of the eye, called the ________________, focuses or bends light waves into a more narrow beam.

2. A round opening at the front of the eye that allows varying amounts of light to enter the eye is called the ________________.

3. A circular, pigmented muscle that dilates or constricts, thus increasing or decreasing the size of the pupil, is called the ________________.

4. The function of the transparent, oval structure called the ________________ is to bend light waves into a narrower beam of light and focus the beam precisely on a layer of cells in the very back of the eye.

5. Lining the back of the eye is a filmlike layer called the (a) ________________, which contains several layers of cells. The back layer of cells has two kinds of photoreceptors, called (b) ________________ and (c) ________________.

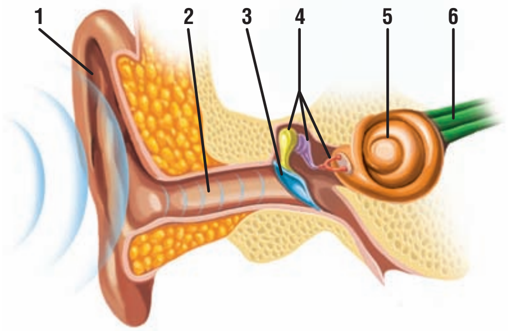
6. This band of nerve fibers, called the (a) ________________, exits from the back of the eye and carries impulses to the brain. The point at which this nerve exits is called the (b) ________________ because it contains no rods or cones.

EAR: Numbers on the ear match the numbers of the questions.

1. The funnel-like structure called the ________________ gathers in sound waves from the environment.

2. The short tunnel called the ________________ carries sound waves that strike a membrane.

3. The thin, taut membrane at the end of the auditory canal, called the ________________, transforms sound waves into vibrations.



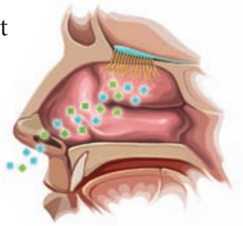
4. The three small bones (hammer, anvil, and stirrup) called the (a) ________________ are part of the middle ear. They transform vibrations of the tympanic membrane into mechanical movements, which in turn vibrate a second membrane, called the (b) ________________.

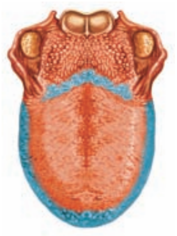
5. The coiled, fluid-filled structure called the (a) ________________ is one part of the inner ear. It contains auditory receptors called (b) ________________ that are attached to the basilar membrane.

6. The band of fibers called the ________________ carries nerve impulses from the cochlea to the brain.

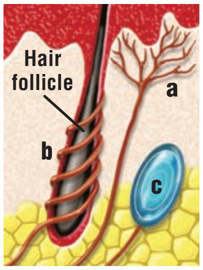
7. The inner ear contains a group of structures shaped like three tiny arches set at different angles. These structures signal body movement and position and are called the ________________ system.

9. Substances give off volatile molecules that are drawn into the nose, dissolve in mucus, and activate the (a) ________________. The function of these cells is to produce (b) ________________ that are sent to the olfactory bulb and brain for processing.





8. Sensors that are located on the surfaces of the tongue respond to five basic tastes, which are (a) ________________, ________________, ________________, ________________, and the newly found taste called ________________. The sensors or receptors for taste are called (b) ________________.



10. There are several kinds of touch receptors: the (a) ________________ is fast adapting; the (b) ________________ is also fast adapting; and the (c) ________________ responds to both touch and vibration.

Answers: *EYE: 1. cornea; 2. pupil; 3. iris; 4. lens; 5. (a) retina, (b) rods, (c) cones; 6. (a) optic nerve, (b) blind spot; EAR: 1. external ear; 2. auditory canal; 3. tympanic membrane (eardrum); 4. (a) ossicles, (b) oval window; 5. (a) cochlea, (b) hair cells; 6. auditory nerve; 7. vestibular; 8. (a) sweet, salty, sour, bitter, umami, (b) taste buds; 9. (a) olfactory cells, (b) nerve impulses; 10. (a) free nerve ending, (b) hair receptor, (c) Pacinian corpuscle*

Psychological Factors

Would you eat a cockroach?

We discussed how senses transform physical energy into impulses, which become sensations and then perceptions. However, your perceptions are usually influenced by psychological factors, such as learning, emotion, and motivation.

If offered a cockroach to eat, most of us would react with great disgust. The facial expression to express disgust (right photo) is similar across cultures.

Disgust is triggered by the presence of a variety of contaminated or offensive things, including foods, body products, and gore. We show disgust, which is a universally recognized facial expression, by closing the eyes, narrowing the nostrils, curling the lips downward, and sometimes sticking out the tongue (above photo).

Tongue contains sensors (taste buds) for five tastes.

Most people are disgusted by cockroaches. But, what if you were offered a glass of juice that just had a sterilized cockroach dipped in it? If the thought "EWWW!" just crossed your mind, you have helped us demonstrate that when something repulsive (cockroach) touches something pleasant (juice), it contaminates or infects the pleasant object, even if it is unchanged (remember, the cockroach is harmless as it had been sterilized). You still feel disgust (Rozin, 2007).

Disgust is considered a basic emotion, and people around the world express disgust in the same way (Rozin et al., 2000). However, cultural factors influence what we perceive to be disgusting.

Cultural Factors

Your particular culture has a strong influence on which foods you learn to perceive as disgusting and which you think are delicious. We'll describe some foods that are considered delicious in some cultures and disgusting in others.

Plump Grubs

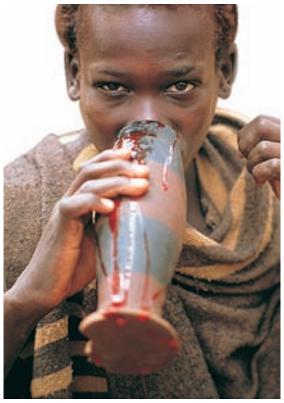
For most U.S. citizens, eating a round, soft, white worm would be totally unthinkable. For the Asmat of New Guinea, however, a favorite delicacy is a plump, white, 2-inch larva—the beetle grub. The natives harvest dozens of the grubs, put them on bamboo slivers, and roast them. A photographer from the United States who did a story on the Asmat tried to eat a roasted grub, but his American tastes would not let him swallow it (Kirk, 1972).

Fish Eyes and Whale Fat

Although some Americans have developed a taste for raw fish (sushi), a common dish in Japan, most would certainly gag at the thought of eating raw fish eyes. Yet for some Inuit (Eskimo) children, raw fish eyes are like candy. Here you see a young girl using the Inuits' all-purpose knife to gouge out the eye of an already-filleted Arctic fish.

Eskimos also hunt a type of whale (the narwhal) that provides much of their protein. They consider the layer of fat under the skin (mukluk) a delicacy, and they eat it raw or dried.

Milk and Blood



Several tribes in East Africa supplement their diet with fresh blood that is sometimes mixed with milk. They obtain the blood by puncturing a cow's jugular vein with a sharp arrow. A cow can be bled many times and suffer no ill effects. The blood-milk drink is a rich source of protein and iron.

Cultural Influences on Disgust

The reaction of U.S. college students to eating white, plump grubs or cold, glassy fish eyes or having a warm drink of blood mixed with milk is almost always disgust. Researchers believe that showing disgust originally evolved to signal rejection of potentially contaminated or dangerous foods. Today, however, because of cultural and psychological influences, we may show disgust for eating a variety of noncontaminated foods (cat, dog, or horse meat) or for certain situations (touching a dead person) (Rozin et al., 2000). The fact that the same things are viewed as all right in one culture but as disgusting in another graphically shows how much cultural values can influence and bias perceptions.

Just as psychological factors are involved in perceiving taste, they are also involved in experiencing pain.

G. Research Focus: Mind over Body?

Definitions

Can sugar pills reduce pain?

One of the truly amazing research findings is how sugar pills or placebos can somehow "trick" us into feeling or getting better. For example, because many of us believe that we will be helped by taking pills, about one-third of the population report feeling much better or having less pain after taking a pill, not knowing that it was only a sugar pill—a placebo.

A ***placebo*** is some intervention, such as taking a pill, receiving an injection, or undergoing an operation, that resembles medical therapy but that, in fact, has no medical effects.

A ***placebo effect*** is a change in the patient's illness (for better or worse) that is due to the patient's beliefs or expectations rather than the medical treatment.

REAL MEDICINE?
SUGAR PILL?

Only a double-blind procedure can tell if a treatment is real or a placebo.

One of the strongest and most studied placebo effects is the ability for placebos to relieve pain (G. A. Hoffman et al., 2005). For example, if people take a pill for headache pain and ***believe*** or ***expect*** that the pill will decrease their pain, about 30 to 60% of people will actually feel less pain after taking a placebo (Talbot, 2000).

Because the placebo effect can occur after taking any pill (injection or medical procedure), researchers needed to find a method that could separate a person's expectations and beliefs from the actual effects of a new drug or medical treatment.

Research Methods

The procedure used to separate a person's expectations (placebo effect) from the effects of a pill or medical treatment is called double-blind.

In a ***double-blind procedure,*** neither the researchers ("blind") nor the subjects ("blind") know who is receiving what treatment. Because neither researchers nor subjects know who is receiving which treatment, the researchers' or subjects' expectations have a chance to equally affect both treatments (drug and placebo).

For example, in a double-blind design, headache sufferers would be told they will be given one of two kinds of pills to decrease pain. Unknown to the subjects ("blind") and the researchers ("blind"), one of the pills is a drug and one is a placebo. If subjects taking the drug report the same decrease in pain as those taking the placebo, researchers conclude the drug is no better than a placebo. If subjects taking the drug report less pain than those taking the placebo, researchers conclude the drug is medically useful because it is better than a placebo.

Over the past 25 years, hundreds of double-blind experiments have found that 30 to 98% of people have reported beneficial effects after taking placebos (Talbot, 2000). For example, 85% of patients reported a reduction in pain from *Herpes simplex* (cold sores and genital sores) after a placebo drug treatment. Also, 98% of patients reported marked or complete relief of pain from ulcers after placebo treatment (Turner et al., 1994). There are hundreds of other examples that are just as incredible!

What follows is a research study that examines whether the cost of a treatment influences its effectiveness—another possible placebo effect. This promises to be interesting . . . let's learn what the researchers found.

Power of Pricing

Is a more expensive pill better?

Is a cheaper pill less effective than a more expensive one? Do we believe that a higher price translates into higher quality, and if we do, can our belief or expectation make the drug more effective? Logic should tell us that the price of a pill does not determine its level of effectiveness.

Researchers examined this fascinating question and their results may surprise you. Researchers asked participants to rate pain caused by electric shocks applied to their wrist, before and after taking a new painkiller. Half of the participants were told the new pill costs 10 cents, and half were told it costs $2.50. In fact, all participants received a placebo. Results showed 85% of those using the expensive pill felt less pain, compared to 61% using the cheaper pill. Thus, the pricier the pill, the higher the expectation of its effectiveness, and the stronger the placebo effect (Ariely, 2008; Waber et al., 2008).

Next we review three major conclusions about placebos.

Conclusion: Mind over Body!

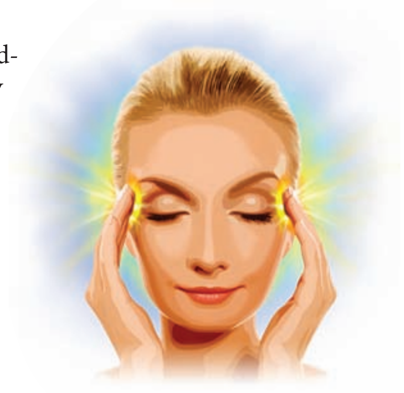
Based on the results of decades of research, three major conclusions about placebos have been reached (Ariely, 2008; Niemi, 2009; Talbot, 2000).

First, potentially powerful placebo effects, such as reducing pain or speeding recovery from medical procedures, have been underestimated.

Second, both medication and fake surgeries can produce significant placebo effects, such as reducing pain, in 30 to 98% of patients.

Third, placebos indicate a powerful mind-over-body interaction, which explains why people may experience health benefits from taking placebos.

Placebos may work by creating positive expectations and beliefs that reduce anxiety and stress. In turn, the reduction of anxiety and stress results in perceiving less pain and improves immune system functioning, so the body makes a quicker recovery (W. A. Brown, 1997). Thus, there is no question our minds have powerful effects on our bodies! In fact, doctors are so aware of the power of placebos that 45% of them have prescribed a placebo to their patients (Sherman & Hickner, 2008).



Placebos work because of the power of our mind.

Next, we'll examine pain in more detail and see how mental factors can affect the perception of pain.

H. Pain

Definition

What causes pain?

All of us can relate to pain because at one time or another we have felt various degrees of pain. ***Pain*** **is an unpleasant sensory and emotional experience that may result from tissue damage, one's thoughts or beliefs, or environmental stressors.**

Pain receptors send nerve impulses to the somatosensory and limbic areas of the brain, where impulses are changed into pain sensations. Pain is essential for survival: It warns us to avoid or escape dangerous situations and makes us take time to recover from injury.

The definition of pain differs from the other senses in three ways. First, pain results from many different stimuli (physical injury, psychological and social stressors), whereas the other senses respond primarily to a single stimulus. Second, pain's intensity depends not only on the physical stimulus but also on social and psychological factors. Third, the treatment of pain depends not only on treating any physical injury but also on reducing emotional distress that may have caused or contributed to the painful sensations (Kerns, 2006, 2007).

Researchers recognize pain is a complex process that may or may not include tissue damage and usually involves social, psychological, and emotional factors, which can cause, increase, or decrease painful sensations (Innes, 2005; Nicholson & Martelli, 2004). Examples of social, psychological, and emotional factors involved in pain perception are religious beliefs and whether the harm was caused intentionally. For instance, practicing Catholics perceive electric shocks as less painful when looking at an image of the Virgin Mary (Wiech et al., 2008). Other research finds that people who believe they are receiving an electric shock from another person on purpose, as opposed to accidentally, rate the same shock as more painful (K. Gray & Wegner, 2008). These studies show that the psychological experiences of pain are different even when the physical sensations are the same!

Research also finds placebo treatments can result in a lower perception of pain. For example, after men had hot metal plates placed on their hands, they were given an injection of either a painkiller or a placebo (they did not know which—double-blind procedure). Brain scans showed that the placebo injections that had reduced pain activated pain-reducing brain circuits similar to the circuits activated by real painkillers (Petrovic et al., 2002; Ploghaus et al., 2003). This and other studies demonstrate how one's beliefs can activate circuits in the brain that, in turn, result in changes in perception (decreased pain) (Erdmann, 2008; Scott et al., 2007).

Other psychological factors, such as changes in attention, can also alter perception of pain and answer an interesting question: Why do headaches come and go, depending on what you are doing?

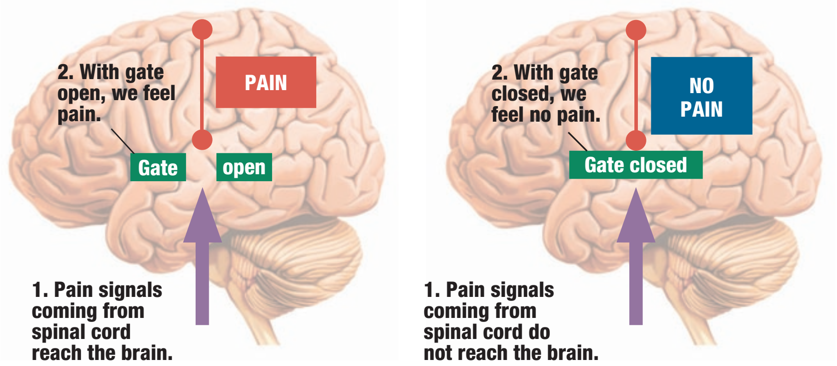
Gate Control Theory

How does the mind stop pain?

Although a headache is painful, the pain may come and go as you shift your attention or become absorbed in some project. This phenomenon is explained by the gate control theory of pain (Melzack & Katz, 2004).

The ***gate control theory*** **of pain says that nonpainful nerve impulses (shifting attention) compete with pain impulses (headache) in trying to reach the brain.**

This competition creates a bottleneck, or neural gate, that limits the number of impulses that can be transmitted. Thus, shifting one's attention or rubbing an injured area may increase the passage of nonpainful impulses and thereby decrease the passage of painful impulses; as a result, the sensation of pain is dulled. The neural gate isn't a physical structure but rather refers to the competition between nonpainful and painful impulses as they try to reach the brain.



2. With gate open, we feel pain.
PAIN
Gate
open
1. Pain signals coming from spinal cord reach the brain.
2. With gate closed, we feel no pain.
NO PAIN
Gate closed
1. Pain signals coming from spinal cord do not reach the brain.

The gate control theory explains how a professional football quarterback was able to play the last six minutes of an important football game with a broken ankle (Associated Press, 2002). The gate control theory says that the football player's intense attentional and emotional involvement in the game caused his brain to send nonpainful impulses that closed neural gates in the spinal cord. The closed neural gates blocked impulses from a painful ankle from reaching his brain and thus prevented feelings of pain (right figure above: NO PAIN). Later, when the game was over, the quarterback's attentional and emotional states calmed down, the neural gates opened, impulses from his broken ankle reached his brain, and he felt lots of pain (left figure above: PAIN). This same process explains why you may not notice the pain from your headache when involved in another activity.

Pain: Physical and Psychological

According to the gate control theory, your perception of pain depends not only on a stressful mental state or physical injury but also on a variety of psychological, emotional, and social factors, which can either decrease or increase your perception of pain (Pincus & Morley, 2001).

Your perception of pain from a serious injury can also be reduced by your brain's ability to secrete its own pain-reducing chemicals, called endorphins.

Photo Credit: Digital Stock Corporation

Endorphins

Does the brain make its own painkillers?

Someone who has experienced a serious injury—in football, for example—will usually report that initially the pain was bearable but with time the pain became much worse. One reason pain seems less intense immediately after injury is that the brain produces endorphins.

***Endorphins** (en-DOOR-fins)* are chemicals produced by the brain and secreted in response to injury or severe physical or psychological stress.

Brain releases endorphins in times of great pain, stress, or fear.

The pain-reducing properties of endorphins are similar to those of morphine, a powerful painkilling drug (Ropper & Samuels, 2009). The brain produces endorphins in situations that evoke great fear, anxiety, stress, or bodily injury, as well as after intense aerobic activity. For example, subjects with severe jaw pain produced increased levels of endorphins after they received a placebo injection, and subjects who reported the greatest pain relief showed the greatest endorphin release (Zubieta et al., 2005). In other research, patients showed increased levels of endorphins after bandages were removed from badly burned areas of their bodies or after nerves of their teeth were touched (Szyfelbein et al., 1985). Overall, there is a strong relationship between an increase in endorphin release and a decrease in pain perception (Zubieta, 2007). These studies indicate that the brain produces endorphins to reduce pain during times of intense physical stress.

Next, we'll look at the connection between dread and your brain's pain center.

Dread

How is dread related to pain?

Dread seems to be connected to the pain centers of the brain. One study placed participants into a brain scanner (fMRI) and offered them the choice of receiving a stronger shock now or a weaker shock in the future. Some participants dreaded the shock so much that they chose to receive the stronger shock instead of waiting to receive a weaker one. Brain imaging of these "extreme-dreaders" showed heightened activity in the brain's pain center. Thus, dread is not simply an emotional response to fear or anxiety; rather, a significant component of dread involves devoting attention to the expected and unpleasant physical threat (in this case shock) (Berns et al., 2006). These results suggest that when it comes to getting root canal surgery or receiving a painful shot, it is not the actual procedure people dread most, but rather the waiting time (Blakeslee, 2006b).

I want my root canal now!

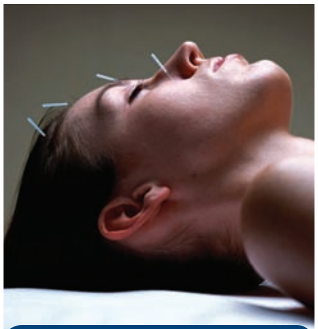
Next, we'll learn how having thin needles inserted into your body can help reduce pain.

Acupuncture

Can an ancient technique reduce pain?

Initially, scientists trained in the rigorous methods of the West (in particular, the United States) expressed doubt about an ancient Chinese pain-reducing procedure, called acupuncture.

Acupuncture is a procedure in which a trained practitioner inserts thin needles into various points on the body's surface and then manually twirls or electrically stimulates the needles.



Acupuncture is effective for nausea, headaches, and some kinds of pain.

After 10–20 minutes of needle stimulation, patients often report a reduction in pain. The mysterious part of this procedure is the points of insertion—such as those shown in the photograph on the right—were mapped thousands of years ago and, as researchers now know, are often far removed from the sites of injury.

Today, modern scientists have explained some of the mystery surrounding acupuncture. First, the points of needle insertion, which seem unrelated to the points of injury, are often close to known pathways that conduct pain. Second, there is some evidence that stimulation of these points causes secretion of endorphins, which we know can reduce pain (Hall, 2008; Kemmer, 2007). For example, if patients are first given a drug that blocks secretion of endorphins, acupuncture does not reduce pain. Third, fMRI brain scans showed that acupuncture decreases neural activity in brain areas involved in pain sensations (Aamodt & Wang, 2008; Ulett, 2003).

Studies on the effectiveness of acupuncture in reducing back pain indicate that almost 50% of patients report long-term improvement (6 months) after acupuncture treatment (Haake et al., 2007). Acupuncture has been shown to relieve some kinds of pain (back and knee pain, dental treatment) and nausea (from chemotherapy or morning sickness), but there is no persuasive evidence that it is effective in other conditions, such as headache or drug addiction (Aamodt & Wang, 2008; Comarow, 2008; Hall, 2008).

One interesting study examined the impact of a placebo treatment (fake acupuncture treatment) by applying equal amounts of heat to people's right and left arms. Researchers then told participants they were being given acupuncture treatment on their right arm, but what participants didn't know is the treatment was a sham. People reported feeling less pain in their right arms than in their left arms even though equally intense heat was applied to both arms (Kong et al., 2006). This study suggests that the power of people's belief in acupuncture is strong enough to change their perception of pain.

Many researchers insist it doesn't matter where needles are placed or that needles are used at all; the only thing that matters, they say, is that a person believes he or she is getting real acupuncture. Furthermore, the stronger their belief, the better the results (Hall, 2008; Madsen et al., 2009; Price et al., 2008).

Next, we turn to a very practical question: Can a sense be replaced if it is damaged? Of the five major senses—vision, audition, taste, olfaction, and touch—damage to vision and audition is especially disastrous to the quality of life. As such, researchers are trying to develop artificial eyes and ears.

I. Application: Artificial Senses

Artificial Visual System

Is an artificial eye possible?

The cause and degree of blindness depend on which part of the visual system is affected. For example, a person would be totally blind if the photoreceptors (rods and cones) in the retina were destroyed (retinitis pigmentosa, an inherited disease) or if the entire retina or optic nerve were damaged. First, we'll look at a microchip that could be implanted into the retina to replace photoreceptors damaged by disease.

Artificial photoreceptors. At the beginning of this module, we told you about Terry, who was completely blind. In Terry's case, he was blind because the photoreceptors (rods and cones) in his retina were damaged by a genetic disease. For individuals like Terry who have problems with their photoreceptors, researchers have developed a microchip the size of a match head that is implanted in the back of the retina. This microchip sends impulses that travel on to the brain for visual processing. Although this microchip does not restore full vision, it allows people who are now totally blind to see rough forms of light, movement, and objects. The illustration to the right shows how this amazing procedure works.

For individuals who are blind because their entire eye or optic nerve is damaged, researchers are developing a complete artificial eye that would send impulses directly to the brain.

Image not available due to copyright restrictions

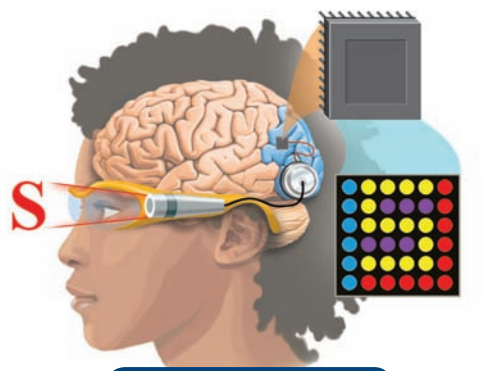
1. Terry scans surroundings with a glasses-mounted camera.

2. Data travel from the glasses through a wire behind his ear to a microcomputer to get processed.

3. Processed data go to a wireless transmitter and then to a receiver implanted behind his ear.

4. Data then go to a microchip implanted in his eye. Normal visual processes occur next. Data are transmitted by the optic nerve to the brain's visual center.

Special glasses and eye implants work together to allow Terry to "see."



Camera sent electrical signals directly to brain.

Brain implant. In an attempt to restore some vision, a blind patient was fitted with a miniature camera that sent electrical signals to 100 electrodes that were implanted directly into the visual cortex, located in the occipital lobe (figure at left). When activated, the electrodes stimulated neurons in the visual cortex and produced 100 tiny spots of light. This patient could see the letter S when some of the 100 electrodes were stimulated (LaFee, 2000). Although the 100 electrodes in this patient's visual cortex provided more visual information than did Terry's 16, neither patient was able to see the outlines of objects or walk around without using a cane.

However, recently, researchers made a significant step forward in developing an artificial visual system.

Artificial visual system lets Jerry "see" a 2-inch-high letter.

Functional vision. The major goal in developing an artificial visual system is to provide enough visual information so a blind person has meaningful visual function, such as reading letters and avoiding objects while walking around a room. Researchers are getting closer to reaching this goal.

Jerry, a 62-year-old man who has been blind since the age of 36, volunteered to have electrodes implanted into his brain's visual cortex (right photo). Jerry wears a pair of glasses that, on one side, holds a tiny camera and, on the other side, an ultrasonic range finder. The range finder analyzes echoes from high-frequency sounds (beyond our range of hearing) that provide information on location, size, and distance of objects. The tiny camera provides visual information that is like looking through a tunnel opening about 2 inches wide and 8 inches high. Both devices send electrical signals to a small computer Jerry wears on his hip. In turn, the computer analyzes and relays electrical information to a panel of electrodes that were implanted into and stimulate the visual area in Jerry's occipital lobe (white cords going into skull) (Dobelle, 2000).

Using this device, Jerry can recognize a 2-inch letter from 5 feet away and avoid large objects as he moves around a room. After receiving upgrades to his device over the years, Jerry can navigate the subway system on his own (J. Anderson, 2005). The development of devices to help provide blind people with functional visual information is advancing. Researchers are now trying to put a tiny camera inside the eye rather than on eyeglasses, which would allow people to scan their environment by simply moving their eyes, rather than moving their heads (Humayun, 2008).

Researchers are also developing an artificial cochlea for the inner ear.

Photo Credit: © AP Images/Stephen Chernin
Figure/Text Credit: (top) Illustration based on K. Daniel Clark from "Newsfronts: Science & Technology," by Dawn Stover, *Popular Science*, August 1997, p. 29. Reprinted by permission.

Kinds of Deafness

What causes deafness?

There are two major kinds of deafness that have different effects, causes, and treatments. The most severe kind of deafness is caused by damage to the inner ear and is called neural deafness. A less severe kind of deafness is caused by problems in the middle ear and is called conduction deafness.

Conduction Deafness

More than 28 million Americans, almost 10% of the population, have hearing loss called conduction deafness (Ruben, 2007).

Conduction deafness **can be caused by wax in the auditory canal, injury to the tympanic membrane, or malfunction of the ossicles. All of these conditions interfere with the transmission of vibrations from the tympanic membrane to the fluid of the cochlea, resulting in degrees of hearing loss.**

Conduction deafness, occurring in 30–40% of adults over 65, can often be treated with a hearing aid, which replaces the function of the middle ear. Hearing aids pick up sound waves, change them to vibrations, and send them through the skull to the inner ear.

Neural Deafness

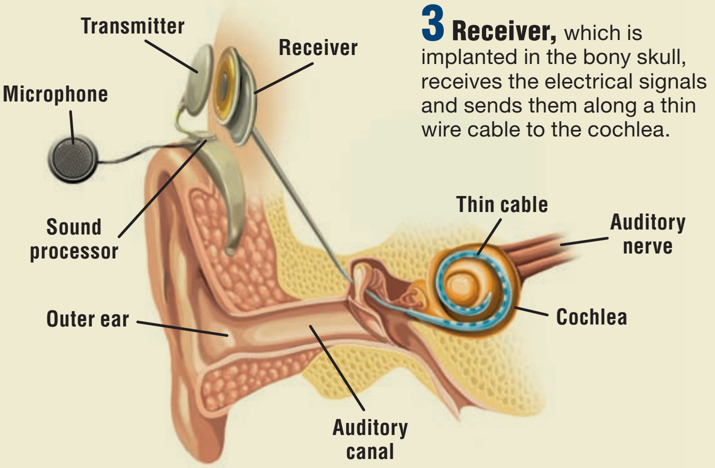
Hellen Keller, who was born deaf and blind, said, "To be deaf is a greater affliction than to be blind." Hellen Keller had neural deafness, which, unlike conduction deafness, is not helped by hearing aids.

Neural deafness **can be caused by damage to the auditory receptors (hair cells), which prevents the production of impulses, or by damage to the auditory nerve, which prevents nerve impulses from reaching the brain.**

Since neither hair cells nor auditory nerve fibers regenerate, neural deafness was generally untreatable until the development of the cochlear implant. Currently, the only approved treatment for certain kinds of neural deafness is the cochlear implant described below.

Cochlear Implants

Cochlear implant: How it works



1 Microphone, which is worn behind the ear, gathers and sends sound waves to a sound processor.

2 Sound processor transforms sound waves into electrical signals, which are sent to a tiny transmitter.

3 Receiver, which is implanted in the bony skull, receives the electrical signals and sends them along a thin wire cable to the cochlea.

4 Thin cable is threaded into a fluid-filled tube of the cochlea until it makes contact with the auditory nerve. When the receiver sends electrical signals through the wire cable, the signals trigger impulses in the auditory nerve.

5 Auditory nerve carries the "manufactured" impulses to the auditory areas in the brain, which interpret and transform impulses into auditory impulses.

Can deaf people hear?

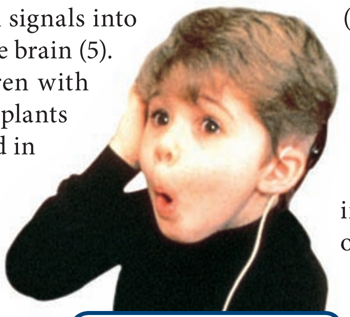
If the auditory nerve is intact, a cochlear implant (figure above) can be used to treat neural deafness that is caused by damage to the ear (Ohl & Scheich, 2007).

The ***cochlear implant*** **is a miniature electronic device that is surgically implanted into the cochlea. The cochlear implant changes sound waves into electrical signals that are fed into the auditory nerve, which carries them to the brain for processing.**

As you proceed step by step through the figure above, notice that the cochlear implant first changes sound waves into electrical signals (1, 2, and 3) and then sends the electrical signals into the auditory nerve (4), which sends impulses to the brain (5).

Worldwide, about 100,000 adults and children with severe neural deafness have received cochlear implants (up from 5,000 in 1990) (Chorost, 2007). The child in the photo at right, deaf from birth, is reacting to hearing his first sounds after receiving a cochlear implant.

Using the newest cochlear implants (cost up to $50,000), adults who had learned to speak before becoming deaf could understand about 80% of sentences without any facial cues and from 90 to 100% of sentences when watching the speaker's face and lips (speech reading). Many could converse on the telephone (B. Stone, 2002; Svirsky et al., 2000).



This child, deaf from birth, reacts after hearing with cochlear implant.

Photo Credit: © James M. Kubus, Greensburg, PA

The results are more complicated for children who did not learn to speak before becoming deaf. Researchers reported that when cochlear implants were put in before age 3½, deaf children had the best neurological development, while implants after age 7 resulted in the poorest auditory development (Seppa, 2005). That's because brains of younger children are more flexible or plastic, which means younger brains are better able to develop neurological responses to auditory information and learn to hear and speak (Rauschecker & Shannon, 2002). For example, Julia received an implant when she was 2½, and at age 9 she speaks and reads above her age level (Reisler, 2002).

Advances in screening for hearing impairments in newborns have made cochlear implants for infants a welcomed new trend. Other recent trends include placing cochlear implants in both ears and implanting in older adults who no longer benefit from hearing aids (Brody, 2008a).

As we end this module, notice that we primarily discussed how senses transform energy into electrical impulses. Next, in Module 6, we'll focus on how "meaningless" sensations turn into meaningful perceptions.

Summary Test

A. Eye: Vision

1. Waves in about the middle of the electromagnetic spectrum are visible because they can be absorbed by the human eye. These waves make up the ________________ and can be absorbed by receptors at the back of the eye.

2. Upon entering the eye, light waves pass first through a curved, thin, transparent structure called the (a) ________________, whose function is to bend or focus light waves into a narrower beam. Next, light waves pass through an opening in the eye called the (b) ________________. Around this opening is a circular, pigmented muscle called the (c) ________________; its function is to dilate or constrict, thus increasing or decreasing the amount of entering light. Finally, light waves pass through a transparent, oval structure called the (d) ________________, whose function is to further focus light waves precisely on the photosensitive back surface of the eye, which is called the (e) ________________.

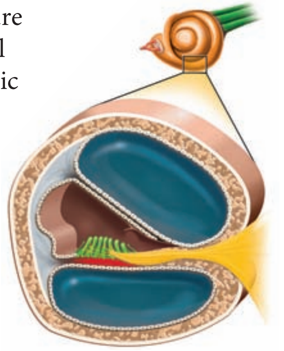
3. The retina has several layers of cells, but only the very back layer contains photoreceptors. The photoreceptors that are used to see in dim light and transmit only black, white, and shades of gray are called (a) ________________. Photoreceptors that are used to see in bright light and transmit colors are called (b) ________________.

4. When rods absorb light waves, a chemical called (a) ________________ breaks down and in turn generates tiny electrical forces that trigger (b) ________________ in neighboring cells. Similarly, when cones absorb light waves, chemicals called (c) ________________ break down and generate tiny electrical forces.

5. Nerve impulses generated in the eye travel along fibers that combine to form the (a) ________________ nerve. This nerve carries nerve impulses to an area in the back of each occipital lobe called the (b) ________________, which transforms impulses into simple visual (c) ________________, such as lines, shadows, colors, and textures. If the primary visual cortex were totally damaged, the person would be essentially blind. Simple, meaningless sensations are transformed into complete, meaningful images when nerve impulses reach an area of the brain known as (d) ________________.

6. We see color because our eyes absorb light waves of different (a) ________________, which are transformed by the visual system into our experience of seeing colors. One theory of color applies to how the cones function; this is the (b) ________________ theory. A second theory of color applies to how the ganglion and thalamic cells function; this is called the (c) ________________ theory of color.

B. Ear: Audition



7. The stimuli for hearing, or audition, are sound waves, which have several physical characteristics. The physical characteristic of amplitude or height of sound waves is transformed into the subjective experience of (a) ________________, which is measured in units called (b) ________________. The frequency of sound waves (cycles per second) is transformed into the subjective experience of (c) ________________, which for humans ranges from about 20 to 20,000 cycles per second.

8. The outer ear is composed of a funnel-like shape, called the external ear, whose function is to gather (a) ________________. These waves travel down a short tunnel called the (b) ________________ and strike a thin, taut membrane called the (c) ________________, whose function is to transform sound waves into (d) ________________.

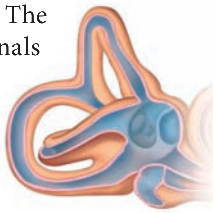
9. The middle ear has three tiny bones (hammer, anvil, and stirrup), which together are called (a) ________________. Vibrations in the tympanic membrane produce mechanical movements in the ossicles, the third of which is attached to another thin membrane, called the (b) ________________, which is made to vibrate.

10. Of several structures in the inner ear, one is a coiled, fluid-filled, tubelike apparatus called the (a) ________________, which contains the auditory receptors, called (b) ________________. Movement of the fluid in the tube causes movement of the basilar membrane, which in turn causes bending of the hair cells, generating a tiny (c) ________________. If this is large enough, it will trigger nerve impulses, which leave the cochlea via the (d) ________________ and travel to the brain.

11. Nerve impulses are transformed into rather simple, meaningless auditory sensations when they reach the (a) ________________, which is located in the temporal lobe. These sensations are transformed into meaningful and complete melodies, songs, words, or sentences by the auditory (b) ________________.

12. To tell the direction of a sound, the brain analyzes the differences in time and intensity between (a) ________________ arriving at the left and right ears. The brain determines degrees of loudness by using the (b) ________________ of the arriving impulses. The discrimination of different tones or pitches is explained by the (c) ________________ and ________________ theories.

C. Vestibular System: Balance



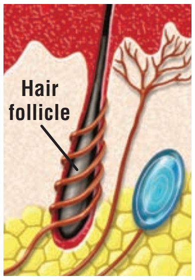
13. Besides the cochlea, the inner ear contains three arch-shaped, fluid-filled structures called ________________. The movement of fluid in these organs provides signals that the brain interprets in terms of the movement and position of the head and body. The vestibular system is also involved in motion sickness, Meniere's disease, and vertigo.

D. Chemical Senses

14. Sensors on the tongue respond to five basic tastes: (a) ________________, ________________, ________________, ________________, and ________________. The receptors for taste, which are called (b) ________________, trigger nerve impulses that travel to the brain, which then transforms them into the sensations of taste.

15. Volatile airborne substances are drawn into the upper part of the nose, where they dissolve in a thin film of mucus. Underneath the mucus are layers of receptors for olfaction (smell), which are called (a) ________________. These receptors trigger impulses that travel to an area underneath the brain called the (b) ________________. This area transforms impulses into hundreds of different odors.

E. Touch

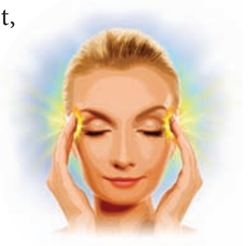


16. The sense of touch actually provides information on three different kinds of stimuli: (a) ________________, ________________, and ________________. The various layers of skin contain different kinds of touch receptors that have different speeds of adaptation. Receptors for the sense of touch trigger nerve impulses that travel to an area in the brain's parietal lobe, called the (b) ________________. This area transforms impulses into sensations of pressure, temperature, and pain. The more sensitive the area of the body is to touch, the larger is its area on the cortex.

F. Cultural Diversity: Disgust

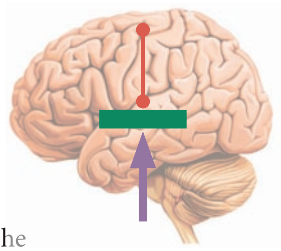
17. A universal facial expression that indicates rejection of food is called (a) ________________. Besides our innate preferences for sweet and salty foods and avoidance of bitter substances, most of our tastes are (b) ________________ and particular to our culture. The fact that foods considered fine in one culture may seem disgusting to people in another culture indicates how much psychological factors influence taste.

G. Research Focus: Mind over Body?



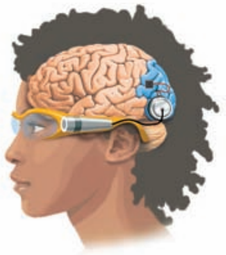
18. In order to control for the placebo effect, researchers use an experimental design in which neither the researchers nor subjects know who is receiving what treatment. This is the ________________ design, which controls for the expectations of both researchers and subjects.

H. Pain



19. After an injury, you feel two different kinds of pain sensations: at first, there is sharp, localized pain, which is followed by a duller, more generalized pain. The receptors for pain are (a) ________________, which send impulses to two areas of the brain, specifically the (b) ________________ and ________________. If you rub an injured area or become totally absorbed in another activity, you may experience a reduction of pain, which is explained by the (c) ________________. Immediately following a serious injury or great physical stress, the brain produces pain-reducing chemicals called (d) ________________.

I. Application: Artificial Senses



20. There are two basic causes of deafness. If the cause is wax in the auditory canal, injury to the tympanic membrane, or malfunction of the ossicles, it is called (a) ________________ deafness. If the cause is damage to hair cells in the cochlea or to the auditory nerve, it is called (b) ________________ deafness. One treatment for neural deafness is to use a (c) ________________, which is more effective if individuals have learned to speak before becoming deaf.

Answers: *1. visible spectrum; 2. (a) cornea, (b) pupil, (c) iris, (d) lens, (e) retina; 3. (a) rods, (b) cones; 4. (a) rhodopsin, (b) impulses, (c) opsins; 5. (a) optic, (b) primary visual cortex, (c) sensations, (d) association areas; 6. (a) lengths, (b) trichromatic, (c) opponent-process; 7. (a) loudness, (b) decibels, (c) pitch; 8. (a) sound waves, (b) auditory canal, (c) eardrum or tympanic membrane, (d) vibrations; 9. (a) ossicles, (b) oval window; 10. (a) cochlea, (b) hair cells, (c) electrical force, (d) auditory nerve; 11. (a) primary auditory cortex, (b) association areas; 12. (a) sound waves, (b) rate, (c) frequency, place; 13. vestibular organs; 14. (a) bitter, sour, salty, sweet, umami, (b) taste buds; 15. (a) olfactory cells, (b) primary olfactory cortex; 16. (a) pressure, temperature, pain, (b) somatosensory cortex; 17. (a) disgust, (b) learned; 18. double-blind; 19. (a) free nerve endings, (b) somatosensory area, limbic system, (c) gate control theory, (d) endorphins; 20. (a) conduction, (b) neural, (c) cochlear implant*

Critical Thinking

What Would It Be Like Never to Feel Pain?

© 2005 Eric Larson/Light of Day, Inc.

At the young age of 5, Ashlyn Blocker has already experienced many serious physical injuries. She's had a massive abrasion to the cornea of her eye, terrible burns, and hundreds of bite marks from fire ants. She's also severely damaged her tongue, cheek, and lips, knocked out most of her front teeth, and crushed her fingers in a door frame. Other children would scream in pain from experiencing any of these injuries, but Ashlyn never yelled, nor did she shed a tear. "I can't feel my boo-boos," she says (Tresniowski et al., 2005). Ashlyn is unique from most other children because she cannot feel pain.

Ashlyn has a rare and incurable genetic disorder called CIPA (congenital insensitivity to pain with anhidrosis). People with CIPA lack pain and temperature sensation, yet have no other sensory deficits. These individuals cannot feel pain and temperature because they lack nerve fibers responsible for carrying the sensation of pain, heat, and cold to the brain. Anhidrosis, or the inability to sweat, can cause life-threatening problems such as developing dangerously high fevers because people aren't able to lower their body temperature by sweating.

Living life without feeling pain is not as wonderful as one might think. Pain serves an important function by telling our brain that something is wrong and something needs to be done to correct it. Imagine having appendicitis and not feeling pain. Appendicitis is especially dangerous for people with CIPA because they wouldn't know a problem existed until after their appendix burst. Also, while most people shift their body weight when feeling pain in their joints, CIPA prevents people from sensing this pain and often results in joint problems. Lack of pain sensitivity can lead to other problems including bone fractures and infections. For example, Ashlyn recently had tonsillitis that went undetected for six months.

Despite the daily challenges Ashlyn faces, she looks like an ordinary girl who enjoys doing the same things others her age do. She likes to swing on the playground and enjoys being tickled and hugged by her parents. Ashlyn is fortunate to have support from her parents and school officials to ensure her safety while allowing her to enjoy her childhood. "There is no reason to think she won't have a normal life," says Dr. Lawrence Shapiro, an internationally recognized child psychologist. Ashlyn's parents describe her as having the "best laugh in the world" and state "she's going to conquer the world" (Tresniowski et al., 2005). (Adapted from Morton, 2004; Tresniowski et al., 2005)

QUESTIONS

1 What type of research method would you use to learn about the life of a person who cannot feel pain?

2 What type of neuron is responsible for people experiencing pain, heat, and cold?

3 What is the name for the optimum state of body arousal Ashlyn cannot achieve as a result of not sweating? Which areas of our brain and body help maintain this optimum level of arousal?

4 How might CIPA affect Ashlyn's ability to learn from her mistakes of injuring herself?

5 How helpful would acupuncture be as a treatment for people with CIPA?

6 Why is it that Ashlyn cannot sense pain or heat, but she can feel her parents tickling and hugging her?

Visit this book's companion website for more resources to help you study, including learning objectives, additional quizzes, flash cards, updated links to useful websites, and a pronunciation glossary.

Study Guide and WebTutor

Work through the corresponding module in your Study Guide for tips on how to study effectively and for help learning the material covered in the book. WebTutor (an online Study Tool accessed through your eResources account) provides an interactive version of the Study Guide.

Suggested Answers to Critical Thinking

1. A case study is an in-depth analysis of the thoughts, feelings, beliefs, or behaviors of one person. There are very few people who cannot feel pain, and so a thorough study of one person would be helpful.
2. Afferent neurons carry information in the form of electrical signals to the spinal cord and brain. Signals for sensing pain, heat, and cold are not being carried to the brain in people with CIPA.
3. The state in which our physiological arousal is kept in balance, an optimum level, is called homeostasis. By not being able to sweat, Ashlyn's body has difficulty maintaining body temperature at an optimum level. The hypothalamus, a part of the limbic system, controls the autonomic nervous system (sympathetic and parasympathetic systems), and they work together to keep the body's level of arousal in balance.
4. Most children learn to avoid engaging in behaviors that result in pain. For example, children quickly learn not to touch a hot flame after burning their hands by doing so. Learning not to engage in repetitive self-injurious behavior is challenging for Ashlyn because she cannot feel pain.
5. Acupuncture is a procedure used to reduce various kinds of pain. People with CIPA do not feel pain, and therefore acupuncture would not be an effective treatment.
6. The same nerve ending responds to pain and temperature, but other nerve endings (such as hair receptors) respond to different types of touch stimulation, such as pressure, making it is possible for Ashlyn to feel her parents tickling and hugging her.

Introduction

Silent Messages

How can I be more confident?

Although it seemed like an ordinary week, Maria and her 7-year-old daughter, Gabrielle, would be involved in three relatively normal events that could change their lives forever.

On Tuesday, Maria's new boss unfairly criticized her work and made her feel insecure and unsure of herself. During her lunch hour, she browsed through a bookstore to find something on building confidence. She was intrigued by an audio CD titled "Improve Self-Esteem." The instructions read, "The listener hears only relaxing music, but the unconscious hears and automatically processes subliminal messages that boost self-esteem. In a few short weeks, the listener is guaranteed to have more confidence and self-esteem. If you're not completely satisfied, return the CD for a full refund." Maria had heard about CDs with subliminal persuasion from a friend who claimed that she used a weight-reduction CD that helped her lose 20 pounds. When Maria asked about the effectiveness of subliminal recordings, the salesperson said that he had a friend who increased his motivation to study by listening to one of these CDs. Maria smiled and said, "Well, it's guaranteed, so what have I got to lose?" She bought the CD, put it in her purse, and as she walked out the door, she was already feeling a little more confident.

IMPROVE
SELF-ESTEEM

Can subliminal messages change a person's behaviors?

Nice Dog, Mean Dog

What's a mean dog?

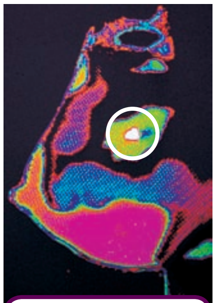
On Saturday afternoon, Maria took her daughter, Gabrielle, to play at the local park, which had slides, swings, ropes, and even a small trampoline. As Gabrielle was walking toward the trampoline, she saw a beautiful white and brown dog sitting by its owner. Gabrielle loved animals, and she ran toward the dog. The dog's owner was deep in conversation and did not notice the cute little girl running toward the beautiful dog. As Gabrielle came closer, she thrust out her hands to pet the dog's smooth black nose. The movement of Gabrielle's hands startled the dog, who reflexively snarled and then snapped at the hands coming at its nose. Gabrielle felt the pain as the dog's teeth nipped two of her fingers, which immediately started to bleed. The owner turned to see what had happened and quickly pulled the dog away as Maria came running. Maria took Gabrielle in her arms, soothed her, and then examined the small cuts on her fingers. Gabrielle looked at her bleeding fingers and then at the big, ugly, white and brown dog that had bit her and said in a tearful voice, "I hate that dog. Bad dog." Seeing her daughter's reaction, Maria began to have doubts about her plans to surprise Gabrielle with a cute little puppy for her birthday.

How does a bad experience create a bad perception?

White Spot

Can the doctor be sure?

On Friday, Maria had to take time from work for her annual physical exam, which included a mammogram. In the past, the doctor had simply said that the results of her mammogram were negative. This time, the doctor brought in her mammogram, which looked like an X ray. He pointed to a small white spot and said in a concerned voice, "I'm afraid that this tiny white dot may be a cancerous tumor." The doctor's words took her breath away. Finally, Maria asked in a terrified whisper, "Are you absolutely sure that spot is cancer?" The doctor paused for a minute, looked again at the mammogram, and said, "I can't be absolutely sure the spot is cancerous until we do a biopsy. All I can say is that there is a good possibility that it is." As Maria scheduled her biopsy, she would never forget seeing that white spot on the mammogram.



Why should two doctors read each mammogram?

Perceiving Things

What are the three questions?

At first glance, these three events—buying a subliminal CD, being bitten by a dog, and seeing a spot on a mammogram—seem to have nothing in common. In fact, these events raise three basic questions about how we perceive things.

Maria's subliminal CD raises the first question: Are there things that we perceive but are not aware of, and can these things influence our behaviors?

Maria's mammogram raises the second question: How large or unusual must things be before our senses can detect them? This is a very important question, since the answer may have serious health consequences (Grady, 2008).

Finally, Gabrielle's painful experience with a dog raises the third question: How much are the things we perceive influenced or biased by our cultural, learning, emotional, and personal experiences (Goldstein, 2010)? These three questions are the key to understanding how we perceive our world.

What's Coming

We'll discuss what perceptual thresholds are, how sensations differ from perceptions, how sensations are combined to form perceptions, how objects can undergo great changes yet appear the same to us, how our senses are fooled by illusions, how cultural experiences change perceptions, whether there is good evidence for ESP (extrasensory perception), and whether the newest kind of perceiving, called virtual reality, can fool our senses into believing we're in a three-dimensional world.

Let's start with the first and most basic perceptual question: At what point do you become aware of seeing, hearing, smelling, tasting, or feeling some stimulus, object, or event?

Photo Credits: top right, © Howard Sochurek/Corbis; bottom left, © image100/SuperStock

A. Perceptual Thresholds

Becoming Aware of a Stimulus

When do you know something is happening?

Imagine suddenly becoming deaf or blind, unable to hear what people are saying or to see where you are going. Only then would you realize that your senses provide a continuous stream of information about your world. Your senses tell you that something is out there, and your perceptions tell you what that something is. However, there are some sounds and objects you may not be aware of because the level of stimulation is too low and does not exceed the threshold of a particular sense.

Threshold **refers to a point above which a stimulus is perceived and below which it is not perceived. The threshold determines when we first become aware of a stimulus.**

IMPROVE
SELF-ESTEEM

Subliminal means that a person has less than a 50% chance of detecting the message.

For example, Maria is not aware of, or does not hear, subliminal messages recorded on the CD because these messages are below her absolute threshold for hearing. To understand how the absolute threshold is determined, imagine that Maria is presented with a series of auditory messages that slowly increase in intensity. Maria is asked to press a button when she first hears a message. You may think that there will be a certain level or absolute value of intensity (loudness) at which Maria will first report hearing a tone. The idea that there is an absolute threshold was proposed by Gustav Fechner (1860), an important historical figure in perceptual research. However, as you'll see, Fechner had difficulty identifying the absolute threshold as he defined it.

1 At first, ***Gustav Fechner*** *(FECK-ner)* defined the absolute threshold as the smallest amount of stimulus energy (such as sound or light) that can be observed or experienced.

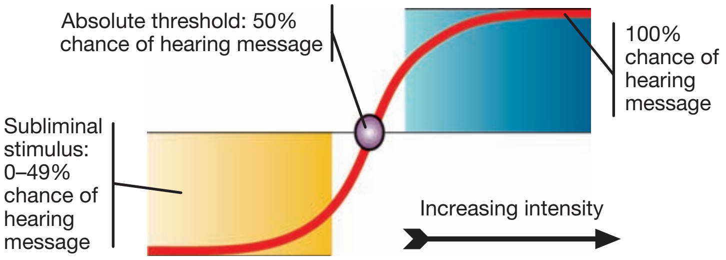
According to Fechner's definition, if Maria's hearing could always be measured under exactly the same conditions, her absolute threshold would always remain the same. Although Fechner tried various methods to identify absolute thresholds, he found that an individual's threshold was not absolute and, in fact, differed depending on the subject's alertness and the test situation. Because of this variability in measurement, researchers had to redefine absolute threshold.

2 The graph below shows how the absolute threshold was redefined.

Absolute threshold **is the intensity level of a stimulus such that a person will have a 50% chance of detecting it.**

According to this updated definition, Maria's absolute threshold is the point on the graph where she has a 50% chance of hearing the message.

Once we have determined Maria's absolute threshold for hearing messages, we can define a subliminal stimulus.

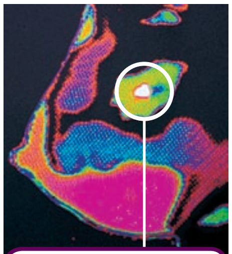


3 The graph above shows that a subliminal stimulus can occur at any point below the absolute threshold (50% chance of hearing).

A ***subliminal stimulus*** **has an intensity that gives a person less than a 50% chance of detecting the stimulus.**

Because subliminal messages can occur in a wide range (0–49%), Maria may or may not report hearing them on the CD. For example, Maria would never report hearing messages of very low intensity (0% level) but may sometimes report hearing messages of higher intensity (49%).

We'll discuss whether subliminal messages can change behaviors or attitudes, such as increasing self-esteem, in the Research Focus (p. 135).



Possible cancerous breast tumor stands out as a white spot.

4 The concept of an absolute threshold has very real consequences in detecting breast cancer.

Each year, about 200,000 women are diagnosed with breast cancer and 40,000 women die of the disease, making it the most frequently occurring cancer in American women and, after lung cancer, the second-leading cancer killer (Grady, 2008). Doctors read 35 million mammograms (X rays of breasts) each year to look for white spots that stand out on a black background; these white spots indicate tumors (photo above) (Grady, 2008). However, some women have so much connective breast tissue, which also appears white, that tiny white tumors go undetected. These women are at an increased risk of having cancer, yet it is 17 times more likely to not be detected using mammograms (Boyd, 2007). This problem, combined with doctors' lack of expertise, results in missing up to 30% of tumors (Pisano et al., 2005).

Accuracy problems. Researchers are constantly looking for ways to lower the threshold for detecting cancerous tumors and thus save patients' lives. The accuracy of identifying cancerous tumors increases when mammograms are read independently by two doctors or when one doctor and a new computer program designed to detect tumors read them (BBC, 2008a; M. Healy, 2000). Recently, digital mammograms, which allow for images to be enhanced or magnified on a computer screen, have been found to be better at detecting cancerous tumors in women who have a lot of connective tissue (Grady, 2008; Kincaid, 2007).

The problem of determining thresholds also applies to the question of how we know a stimulus has changed in intensity. We'll discuss this next.

Photo Credit: © Howard Sochurek/Corbis

Weber's Law

Why is that music still too loud?

Suppose people are playing music too loud and you ask them to turn down the volume. Even after they turn it down, it may still seem just as loud as before. The explanation for this phenomenon can be found in the work of another historical figure in perception, E. H. Weber *(VEY-ber).*

Smallest detectable increase or decrease in sound is a JND.

Weber worked on the problem of how we judge whether a stimulus, such as loud music, has increased or decreased in intensity. This problem involves measuring the difference in thresholds between two stimuli, such as very loud music and not-quite-so-loud music. To solve this problem, Weber (1834) developed the concept of a just noticeable difference.

A ***just noticeable difference,*** or ***JND,*** **refers to the smallest increase or decrease in the intensity of a stimulus that a person is able to detect.**

For example, to measure a just noticeable difference in weight, Weber asked people to compare stimuli of varying intensities and indicate when they could detect a difference between them. He discovered that if he presented two stimuli with very low intensities, such as a 2-ounce weight versus a 3-ounce weight, people could easily detect the difference between them. However, if he presented stimuli with high intensities, such as a 40-pound weight versus a 41-pound weight, people could no longer detect the difference. For higher-intensity stimuli, such as heavy weights, a much larger difference in intensity was required for the difference to be noticed (Kantowitz et al., 2009).

Weber's observations on what it takes to detect just noticeable differences were the basis for what became known as Weber's law.

Weber's law **states that the increase in intensity of a stimulus needed to produce a just noticeable difference grows in proportion to the intensity of the initial stimulus.**

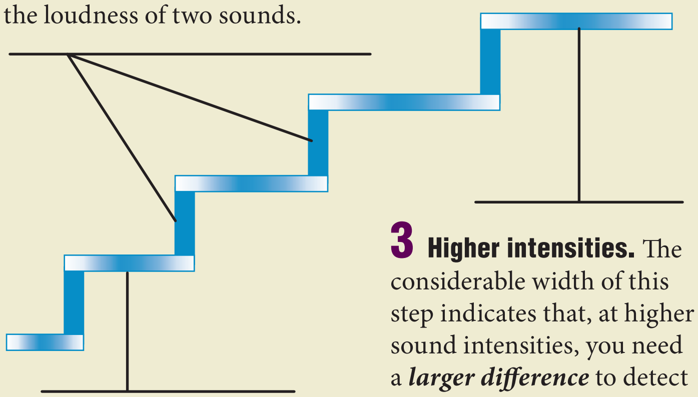
We'll use Weber's law (please read right figure) to explain how if someone is playing the stereo very loud, it must be turned down a great deal, usually more than the person prefers to turn it down, for you to detect a just noticeable decrease in volume.

Weber's Law Explained

Weber's law explains that, at lower intensities, small changes between two stimuli can be detected as just noticeable differences (JNDs); however, at higher intensities, only larger changes between two stimuli can be detected as JNDs.

Stimulus: Lower → Higher

1 JND. The same height of each step illustrates your ability to detect "one sensory unit" of a ***just noticeable difference*** between the loudness of two sounds.



2 Lower intensities. The small width of this step indicates that, at lower intensities, you need only a ***small difference*** in order to detect a just noticeable difference between the loudness of two sounds. This statement follows from Weber's law, which says that only a small difference in intensity is required for you to detect a just noticeable difference when judging stimuli of lower intensity.

3 Higher intensities. The considerable width of this step indicates that, at higher sound intensities, you need a ***larger difference*** to detect a just noticeable difference between the loudness of two sounds. This statement follows from Weber's law, which says that a larger difference in intensity is required for you to detect a just noticeable difference when judging stimuli of higher intensity.

Besides explaining the problem with loud stereos, Weber's law has many practical applications, such as how to detect a difference in the softness of towels.

Just Noticeable Difference (JND) and Soft Towels

Which towel is softer?

Every year, industry and business spend billions of dollars to make sure that consumers can detect just noticeable differences between this year's and last year's cars, shampoos, cereals, and fashions. For example, consumers spend millions of dollars each year on fabric softeners, which are added during washing and are claimed to make clothes feel softer. To test such claims, researchers asked subjects to feel towels washed with and without a fabric softener and rate the softness of the towels on a scale from 1 (hard) to 30 (very soft). Subjects gave an average softness rating of 5 to towels washed repeatedly without softener and an average rating of 18 to towels washed with softener. Researchers concluded that fabric softeners worked, since subjects could easily detect a just noticeable difference in softness (S. I. Ali & Begum, 1994). This is but one practical application of Weber's law and just noticeable difference (JND) in industry.

Judging the softness of towels involves noting JND.

So far, we've focused on how you become aware of and detect stimuli and distinguish between their intensities. Next, we'll discuss one of the most interesting questions in perception: How do you change meaningless bits of sensations into meaningful and complete perceptions?

Photo Credits: left, © Arman Zhenikeyev/Alamy; bottom, © Pat Bruno/Positive Images

B. Sensation Versus Perception

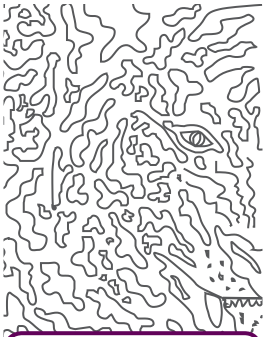
Basic Differences

How can I be successful and happy?

Much of your success in being happy and successful depends on your ability to respond intelligently and adapt appropriately to changes in your environment (NAMHC, 1996). The first step in responding and adapting involves gathering millions of meaningless sensations and changing them into useful perceptions. Because your brain changes sensations into perceptions so quickly, automatically, and with very little awareness, you might assume that what you see (sense) is what you perceive. However, the process of changing sensations into perceptions is influenced by whether you are alert, sleepy, worried, emotional, motivated, or affected by the use of a legal or illegal drug. For example, drinking alcohol causes perceptions in social situations to be less rational and more uninhibited, causing people under its influence to act aggressively, make terrible decisions, create problems, or say really dumb things (R. Goldberg, 2006; Maisto et al., 2008). As you are about to discover, sensing and perceiving are as different as night and day.

For example, quickly glance at the black-and-white figure below on the left and then look away and describe what you saw.

Sensations



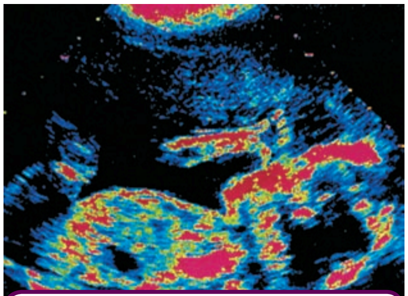
Sensations are MEANINGLESS bits of information.

Initially, the left figure appears to be a bunch of meaningless lines, spaces, and blobs, which, for the sake of simplicity, we'll take the liberty of calling visual sensations. In real life, we rarely if ever experience sensations because, as we'll explain on the next page, they are immediately turned into perceptions.

A *sensation* is our first awareness of some outside stimulus. An outside stimulus activates sensory receptors, which in turn produce electrical signals that are transformed by the brain into meaningless bits of information.

You can approximate how visual sensations may look by placing half of a ping-pong ball over your eye. As you look through this nearly opaque ping-pong ball, you'll see shadows, textures, and dark shapes but nothing meaningful; these are similar to sensations.

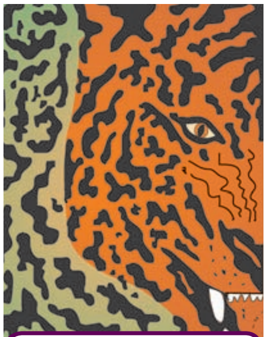
Another example that illustrates the difference between sensations and perceptions is the photo below. Your first impression consists of meaningless shapes, textures, and blotches of color, which we'll again take the liberty of calling visual sensations. However, you can turn these meaningless sensations into a meaningful image—a perception—by using the following clues. This photo is an ultrasound image of a fetus in the womb. The fetus is lying on his back with his rounded tummy on the left and his large head on the right. Above his head is the right arm and hand, and you can even count the five tiny fingers. You can also see that the fetus is sucking on his thumb. Once you know what to look for, you automatically change the random blotches of colors and shapes into the perception of a fetus.



You can turn this sensation into a perception by reading the text (left).

Obviously, it would be impossible to respond, adapt, and survive if you had to rely only on sensations. You can now appreciate the importance of changing sensations into perceptions.

Perceptions



Perceptions are MEANINGFUL patterns, images, or sounds.

As you look at the right stimulus, your brain is processing many thousands of visual sensations involving lines, curves, textures, shadows, and colors. Then, instantaneously, automatically, and without awareness, your brain combines these thousands of sensations into a perception—an orange tiger's face against a green background.

A *perception* is the experience we have after our brain assembles and combines thousands of individual, meaningless sensations into a meaningful pattern or image. However, our perceptions are rarely exact replicas of the original stimuli. Rather, our perceptions are usually changed, biased, colored, or distorted by our unique set of experiences. Thus, perceptions are our personal interpretations of the real world.

If you now look at the black-and-white drawing on the upper left, your brain will automatically combine the formerly meaningless shapes and blobs into a tiger's face. This is an approximate example of how meaningless sensations are automatically combined to form meaningful perceptions.

One important feature of perceptions is that they are rarely exact copies of the real world. For example, people who listen to the same song or music can react very differently (happy, relaxed, agitated, bored). To study how personal preferences for music can bias our perceptions, researchers assigned students who preferred listening to classical music over other types of music to groups that were instructed to sit and relax while listening to either 20 minutes of classical music or 20 minutes of rock music. Researchers used physiological measures to record anxiety levels both before and after subjects listened to music. Findings showed that only those subjects who listened to their favorite kind of music (classical music) had a decrease in anxiety levels (Salamon et al., 2003).

To show that no two individuals perceive the world in exactly the same way, we'll explain how your personal experiences change, bias, and even distort your perceptions.

Photo Credit: bottom, Custom Medical Stock Photo

Changing Sensations into Perceptions

How does a "nice" doggie become a "bad" doggie?

It is most unlikely that you have ever experienced a "pure" sensation because your brain automatically and instantaneously changes sensations into perceptions. Despite what you may think, perceptions do not exactly mirror events, people, situations, and objects in your environment. Rather, perceptions are interpretations, which means that your perceptions are changed or biased by your personal experiences, memories, emotions, and motivations.

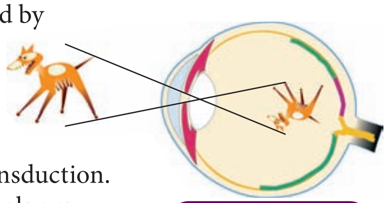
There are five steps in forming perceptions.

For example, at the beginning of this module we told you how 7-year-old Gabrielle's perception of a dog was changed from "nice" to "bad" by her personal experience of being bitten. The next time Gabrielle sees a dog, she won't see just a four-legged creature with ears, nose, and tail; she will see a "bad" four-legged creature. To understand how sensations become perceptions, we have divided the perceptual process into a series of discrete steps that, in real life, are much more complex and interactive.

1 Stimulus. Since normally we experience only perceptions, we are not aware of many preceding steps. The first step begins with some stimulus, which is any change of energy in the environment, such as light waves, sound waves, mechanical pressure, or chemicals. The stimulus activates sense receptors in the eyes, ears, skin, nose, or mouth. In Gabrielle's case, the stimuli are light waves reflecting off the body of a dog.

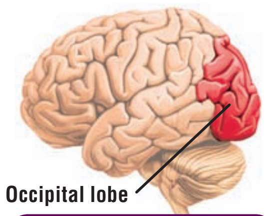
A stimulus (dog) activates receptors in the senses.

2 Transduction. After entering Gabrielle's eyes, light waves are focused on the retina, which contains photoreceptors that are sensitive to light. The light waves are absorbed by photoreceptors, which change physical energy into electrical signals, called transduction. The electrical signals are changed into impulses that travel to the brain. Sense organs do not produce sensations but simply transform energy into electrical signals.



Senses change stimulus into electrical signals.

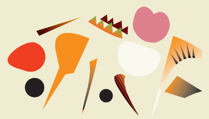
3 Brain: primary areas. Impulses from sense organs first go to different primary areas of the brain. For example, impulses from the ear go to the temporal lobe, from touch to the parietal lobe, and from the eye to areas in the occipital lobe. When impulses reach primary areas in the occipital lobe, they are first changed into sensations. However, Gabrielle would not report seeing sensations.



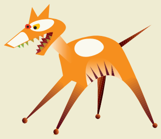
Primary areas of brain change electrical signals into sensations.

4 Brain: association areas. Each sense sends its particular impulses to a different primary area of the brain where impulses are changed into sensations, which are meaningless bits of information, such as shapes, colors, and textures (top right). The "sensation" impulses are then sent to the appropriate association areas in the brain. The association areas change meaningless bits into meaningful images, called perceptions, such as a dog (bottom right).

In Gabrielle's case, impulses from her eyes would be changed into visual sensations by the primary visual area and into perceptions by the visual association areas. However, Gabrielle's perception of a dog would be changed, biased, and even distorted by many psychological, emotional, and cultural factors.



Sensations are meaningless bits of information.



Association areas change sensations into perceptions—dog.

5 Personalized perceptions. Each of us has a unique set of personal experiences, emotions, and memories that are automatically added to our perceptions by other areas of the brain. As a result, our perceptions are not a mirror but a changed, biased, or even distorted copy of the real world (Goldstein, 2010). For example, the visual areas of Gabrielle's brain automatically assemble many thousands of sensations into a meaningful pattern, which in this case is a dog. Now, however, Gabrielle doesn't see just an ordinary white and brown dog because other brain areas add her emotional experience of being bitten. Thus, Gabrielle perceives this white and brown, four-legged creature to be a "bad dog." For this same reason, two people can look at the same dog and have very different perceptions, such as cute dog, great dog, bad dog, smelly dog, or friendly dog. Thus, your perceptions are personalized interpretations rather than true copies of objects, animals, people, and situations in the real world.

The process of assembling and organizing sensations into perceptions was of great interest to early psychologists, who disagreed on how perceptions were formed. As you'll see next, their debate resulted in a very interesting perceptual controversy.

Perceptions do not mirror reality but rather include our biases, emotions, and memories to reflect reality.

C. Rules of Organization

Structuralists Versus Gestalt Psychologists

What was the great debate?

In the early 1900s, two groups of psychologists engaged in a heated debate over how perceptions are formed. One group, called the structuralists, strongly believed that we added together thousands of sensations to form a perception. Another group, called the Gestalt psychologists, just as strongly believed that sensations were not added but rather combined according to a set of innate rules to form a perception (M. A. Peterson et al., 2007). One group won the debate, and you might guess which one before you read further.

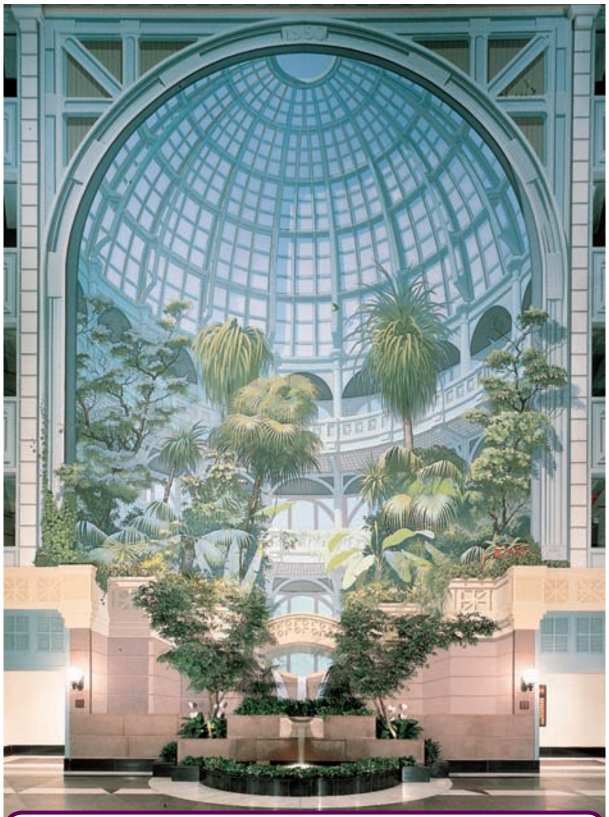
Structuralists

As you look at the scene in the middle of this page, you perceive a fountain at the bottom with shrubs and palm trees on the sides, all topped by a large dome of glass windows. Is it possible that your brain combined many thousands of individual sensations to produce this complex perception? If you answer yes, you agree with the structuralists.

The ***structuralists*** believed that you add together hundreds of basic elements to form complex perceptions. They also believed that you can work backward to break down perceptions into smaller and smaller units, or elements.

Structuralists spent hundreds of hours analyzing how perceptions, such as a falling ball, might be broken down into basic units or elements. They believed that once they understood the process of breaking down perceptions, they would know how basic units are recombined to form perceptions. Thus, structuralists believed that you add together basic units to form perceptions, much as you would add a column of numbers to get a total.

For example, structuralists would say that you add together hundreds of basic units, such as colors, bricks, leaves, branches, tiles, pieces of glass, and bits of steel, to form the perception of the scene above. However, the structuralists' explanation of adding bits to form a perception was hotly denied by Gestalt psychologists.



Do you add together basic elements to form perceptions or does your brain have rules for forming perceptions?

Photo Credit: Painting by Richard Haas, photo © Bill Horsman

Gestalt Psychologists

The Gestalt psychologists said that perceptions were much too complex to be formed by simply adding sensations together; instead, they believed that perceptions were formed according to a set of rules.

Gestalt psychologists believed that our brains follow a set of rules that specify how individual elements are to be organized into a meaningful pattern, or perception.

Unlike structuralists, Gestalt psychologists said that perceptions do not result from adding sensations. Rather, perceptions result from our brain's ability to organize sensations according to a set of rules, much as our brain follows a set of rules for organizing words into meaningful sentences (Donderi, 2006; Quinn et al., 2008).

So how would Gestalt psychologists explain your perception of the scene on the left? They would say that your perception was not formed by simply adding bits of tile, steel, and foliage into a whole image. Rather, your brain automatically used a set of rules to combine these elements to form a unified whole. To emphasize their point, Gestalt psychologists came up with a catchy phrase, "The whole is more than the sum of its parts," to mean that perceptions are not merely combined sensations. The Gestalt psychologists went one step further; they came up with a list of organizational rules.

Evidence for Rules

Who won the debate?

Gestalt psychologists won their debate with the structuralists for two reasons. The first reason comes from our own personal perceptual experiences. For example, as you look again at the beautiful scene above, we must reveal that it is entirely fake. The scene, which looks so realistic and three-dimensional, is actually painted on a flat wall. It seems impossible that we could have such a complex, three-dimensional perceptual experience from simply combining bits and pieces of bricks, branches, leaves, and steel. This fake but truly realistic scene makes the Gestalt motto come to life: "The whole is more than the sum of its parts."

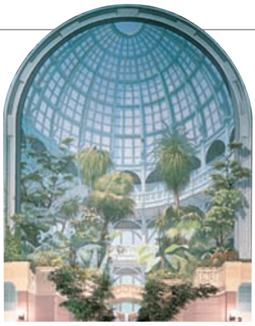
Equally convincing evidence that the whole is greater than the sum of its parts came from a remarkably detailed series of studies in which Gestalt psychologists presented stimuli to subjects and then asked them to describe what they perceived (Rock & Palmer, 1990). On the basis of subjects' reports, researchers discovered that forming perceptions involved more than simply adding and combining individual elements. Modern research has generally supported the early Gestalt conclusion that our brains actually do follow a set of rules for organizing and forming perceptions (Quinn et al., 2008). We'll explain these rules for organizing perceptions next.

Organizational Rules

How many rules are there?

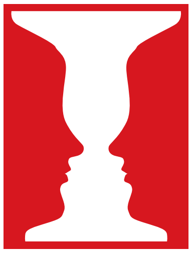
It is very hard to believe that the scene on the preceding page (repeated here on the right) was actually painted on a flat wall. One reason you perceive this scene as complex and 3-dimensional is that the painter followed many of the Gestalt rules of organization (Han & Humphreys, 1999).

Rules of organization, which were identified by Gestalt psychologists, specify how our brains combine and organize individual pieces or elements into a meaningful perception.



As you look at the scene, your brain automatically organizes many hundreds of visual stimuli, including colors, textures, shadows, bricks, steel, glass, leaves, and branches, according to one or more of the six perceptual rules of organization described below. We'll use a relatively simple figure to illustrate each rule.

Figure-Ground

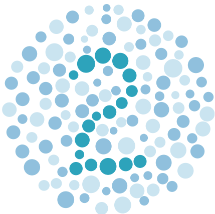


One of the most basic rules in organizing perceptions is picking out the object from its background. As you look at the figure on the left, you will automatically see a white object standing out against a red background, which illustrates the figure-ground principle.

The ***figure-ground rule*** states that, in organizing stimuli, we tend to automatically distinguish between a figure and a ground: The figure, with more detail, stands out against the background, which has less detail.

There is some evidence that our ability to separate figure from ground is an innate response. For example, individuals who were blind from an early age and had their sight restored as adults were able to distinguish between figure and ground with little or no training (Senden, 1960). The figure-ground rule is one of the first rules that our brain uses to organize stimuli into a perception (Vecera, 2002). This particular image is interesting because, as you continue to stare at it, the figure and ground will suddenly reverse and you'll see profiles of two faces. However, in the real world, the images and objects we usually perceive are not reversible because they have more distinct shapes (Humphreys & Muller, 2000).

Similarity



As you look at this figure filled with light and dark blue dots, you see a dark blue numeral 2.

The ***similarity rule*** states that, in organizing stimuli, we group together elements that appear similar.

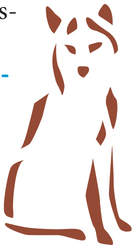
The similarity rule causes us to group the dark blue dots together and prevents us from seeing the figure as a random arrangement of light and dark blue dots.

Closure

Although the lines are incomplete, you can easily perceive this drawing as a cat or dog.

The ***closure rule*** states that, in organizing stimuli, we tend to fill in any missing parts of a figure and see the figure as complete.

For example, the closure rule explains why you can fill in letters missing on a sign or pieces missing in a jigsaw puzzle.

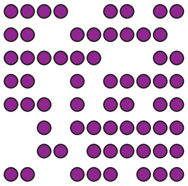


Proximity

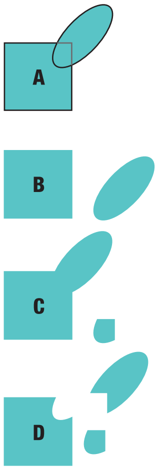
Notice that although there are exactly eight circles in each horizontal line, you perceive each line as formed by a different number of groups of circles.

The ***proximity rule*** states that, in organizing stimuli, we group together objects that are physically close to one another.

You automatically group circles that are close together and thus perceive the first line as composed of three groups (Kubovy & Wagemans, 1995).



Simplicity

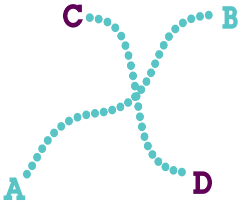


Look at figure A and then decide if it is made up of the pieces shown in figure B, C, or D. Almost everyone sees figure A as made up of the pieces in figure B—an oval with an overlapping square.

The ***simplicity rule*** states that stimuli are organized in the simplest way possible.

For example, almost no one sees figure A as having been formed from the complicated pieces shown in figure C or figure D. This rule says that we tend to perceive complex figures as divided into several simpler figures (Shimaya, 1997).

Continuity



As you scan this figure, keep track of the path that your eyes follow. Most people's eyes will move from left to right in a continuous line, following the path from A to B or from C to D.

The ***continuity rule*** states that, in organizing stimuli, we tend to favor smooth or continuous paths when interpreting a series of points or lines.

For example, the rule of continuity predicts that you do not see a line that begins at A and then turns abruptly to C or to D.

Conclusion. These figures demonstrate the Gestalt rules of organizing stimuli into perceptions. Young children slowly learn these perceptual rules and begin to use them as early as infancy (Quinn et al., 2008). As adults we use these rules to organize thousands of stimuli into perceptions, especially stimuli in print and advertisements. For doctors who read mammograms and other X rays, Gestalt rules such as figure-ground, similarity, and proximity are essential in their daily work (Koontz & Gunderman, 2008).

Next, we examine the question: How can objects change yet appear to remain the same?

Photo Credit: top, Painting by Richard Haas, photo © Bill Horsman

D. Perceptual Constancy

Size, Shape, Brightness, & Color Constancy

Why don't speeding cars shrink?

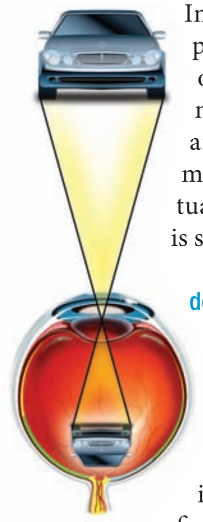
The study of perception is full of interesting puzzles, such as how cars, people, and pets can change their shapes as they move about yet we perceive them as remaining the same size and shape. For example, a car doesn't grow smaller as it speeds away, even though its shape on your retina grows smaller and smaller. A door doesn't become a trapezoid as you walk through it, even though that's what happens to its shape on your retina.

These are examples of how perceptions remain constant, a phenomenon called perceptual constancy.

Perceptual constancy **refers to our tendency to perceive sizes, shapes, brightness, and colors as remaining the same even though their physical characteristics are constantly changing.**

We'll discuss four kinds of perceptual constancy—size, shape, brightness, and color.

Size Constancy

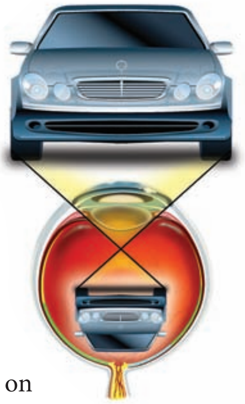


Imagine a world in which you perceived that every car, person, or animal became smaller as it moved away. Fortunately, we are spared from coping with so much stimulus change by perceptual constancy, one type of which is size constancy.

Size constancy **refers to our tendency to perceive objects as remaining the same size even when their images on the retina are continually growing or shrinking.**

As a car drives away, it projects a smaller and smaller image on your retina (left figure). Although the retinal image grows smaller, you do not perceive the car as shrinking because of size constancy. A similar process happens as a car drives toward you.

As the same car drives closer, notice in the figure below how it projects a larger image on your retina. However, because of size constancy, you do not perceive the car as becoming larger.



Size constancy is something you have learned from experience with moving objects. You have learned that objects do not increase or decrease in size as they move about. For example, an individual who was blind since birth and had his vision restored as an adult looked out a fourth-story window and reported seeing tiny creatures moving on the sidewalk. Because he had not learned size constancy, he did not know the tiny creatures were full-size people (Gregory, 1974).

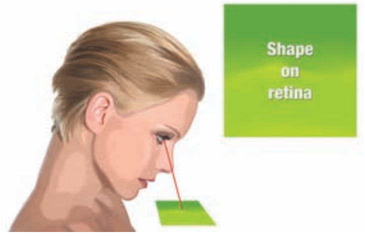
We also perceive shapes as remaining the same.

Shape Constancy

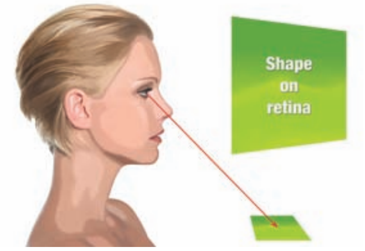
Each time you move a book, its image on your retina changes from a rectangle to a trapezoid. But you see the book's shape as remaining the same because of shape constancy.

Shape constancy **refers to your tendency to perceive an object as retaining its same shape even though when you view it from different angles, its shape is continually changing its image on the retina.**

The figure below shows that when you look down at a rectangular book, it projects a rectangular shape on your retina.



However, if you move the book farther away, it projects trapezoidal shapes on your retina (figure below), but you still perceive the book as rectangular because of shape constancy.



Besides size and shape constancy, there is also brightness and color constancy.

Brightness and Color Constancy

If you look into your dimly lit closet, all the brightly colored clothes will appear dull and grayish. However, because of brightness and color constancy, you still perceive brightness and colors and have no trouble selecting a red shirt.

Brightness constancy **refers to the tendency to perceive brightness as remaining the same in changing illumination.**

Color constancy **refers to the tendency to perceive colors as remaining stable despite differences in lighting.**

For example, if you looked at this young girl's sweater in bright sunlight, it would be a bright yellow.

If you looked at her same yellow sweater in dim light, you would still perceive the color as a shade of yellow, although it is duller. Because of color constancy, colors seem about the same even when lighting conditions change.

However, if the light is very dim, objects will appear mostly gray because you lose color vision in very dim light.

Perceptual constancy is important because it transforms a potentially ever-changing, chaotic world into one with stability and comforting sameness.

Our next perceptual puzzle is how our eyes can see only two-dimensional images but our brain can transform them into a three-dimensional world.

E. Depth Perception

Binocular (Two Eyes) Depth Cues

How can you see in three dimensions?

Normally, movies are shown in only two dimensions: height and width. But if you have ever seen a movie in 3-D (using special glasses to see three dimensions: height, width, and depth), you know the thrill of watching objects or animals leap off the screen so realistically that you duck or turn your head. You may not have realized that your eyes automatically give you a free, no-glasses, 3-D view of the world. And the amazing part of seeing in 3-D is that everything projected on the retina is in only two dimensions, height and width, which means that your brain combines a number of different cues to add a third dimension—depth (J. M. Harris & Dean, 2003).

Seeing in 3-D means seeing length, width, and DEPTH.

Depth perception **refers to the ability of your eye and brain to add a third dimension, depth, to all visual perceptions, even though images projected on the retina are in only two dimensions, height and width.**

The object on the left has been given a three-dimensional look by making it seem to have depth. It is impossible for most sighted people to imagine a world without depth, since they rely on depth perception to move and locate objects in space. The cues for depth perception are divided into two major classes: binocular and monocular.

Binocular depth cues **depend on the movement of both eyes (*bi* means "two"; *ocular* means "eye").**

We'll start with two binocular cues: convergence and retinal disparity.

Convergence

When you have an eye exam, the doctor usually asks you to follow the end of her finger as she holds it a few feet away and then slowly moves it closer until it touches your nose. This is a test for convergence.

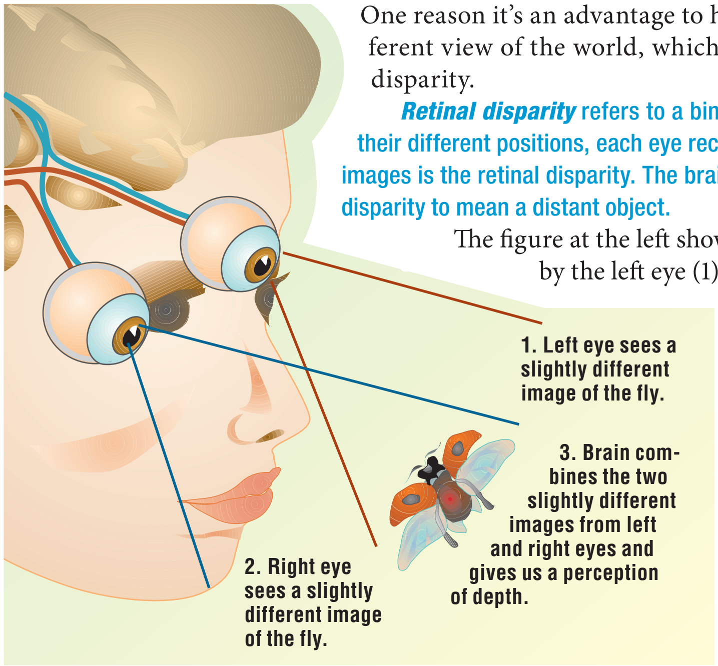
Convergence **refers to a binocular cue for depth perception based on signals sent from muscles that turn the eyes. To focus on near or approaching objects, these muscles turn the eyes inward, toward the nose. The brain uses the signals sent by these muscles to determine the distance of the object.**

The woman in the photo at the right is demonstrating the ultimate in convergence as she looks at the bubble. You can experience convergence by holding a finger in front of your nose and slowly bringing it closer to your nose. Your finger appears to move closer to your nose because the muscles that are turning the eyes inward produce signals corresponding to convergence. The more your eyes turn inward or converge, the nearer the object appears in space. The woman in the photo sees the bubble because of convergent clues from her turned-in eyes.

During convergence the eyes turn inward to see objects up close.

The second binocular cue comes from having an eye on each side of your face.

Retinal Disparity



1. Left eye sees a slightly different image of the fly.
3. Brain combines the two slightly different images from left and right eyes and gives us a perception of depth.
2. Right eye sees a slightly different image of the fly.

One reason it's an advantage to have an eye on each side of your face is that each eye has a slightly different view of the world, which provides another binocular cue for depth perception called retinal disparity.

Retinal disparity **refers to a binocular depth cue that depends on the distance between the eyes. Because of their different positions, each eye receives a slightly different image. The difference between the right and left eyes' images is the retinal disparity. The brain interprets a large retinal disparity to mean a close object and a small retinal disparity to mean a distant object.**

The figure at the left shows how retinal disparity occurs: The difference between the image seen by the left eye (1) and the one seen by the right eye (2) results in retinal disparity (3).

Another example of retinal disparity occurs when viewers wear special glasses to watch a 3-D movie, which has width, height, and depth. Standard 3-D glasses use a red and a green lens, which is a technique to allow the right and left eyes to perceive slightly different views of the same scene. As a result, the brain receives two slightly different images. As the brain automatically combines the slightly different images, we get the feeling of depth—for example, seeing a mad dog jump out of the movie screen into the audience (followed by much screaming).

Individuals who have only one eye still have depth perception because there are a number of one-eyed, or monocular, cues for depth perception, which we'll explain next.

Photo Credit: center, © RubberBall/SuperStock

E. Depth Perception

Monocular (One Eye) Depth Cues

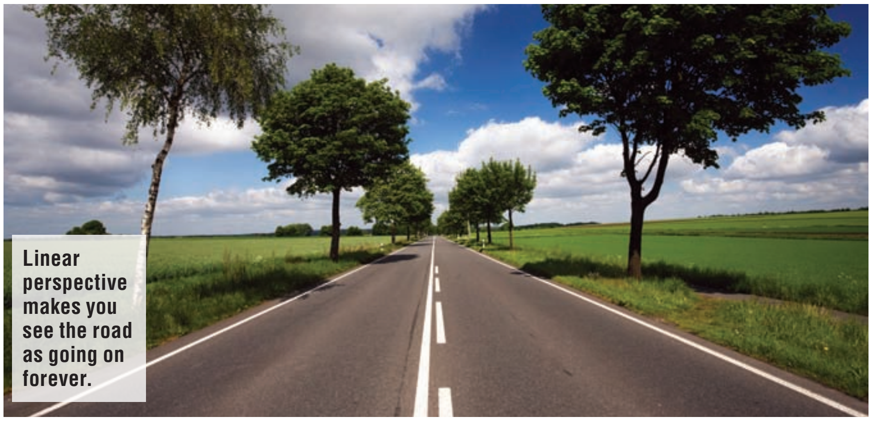
Could a Cyclops land an airplane?

I could land an airplane with one eye!

A mythical creature called the Cyclops had only one eye in the middle of his forehead. Although a Cyclops would lack depth perception cues associated with retinal disparity, he would have depth perception cues associated with having one eye, or being monocular (*mon* means "one"). This means that a Cyclops or an individual with only one good eye could land an airplane because of monocular depth cues.

Monocular depth cues are produced by signals from a single eye. Monocular cues most commonly arise from the way objects are arranged in the environment.

We'll show you seven of the most common monocular cues for perceiving depth.

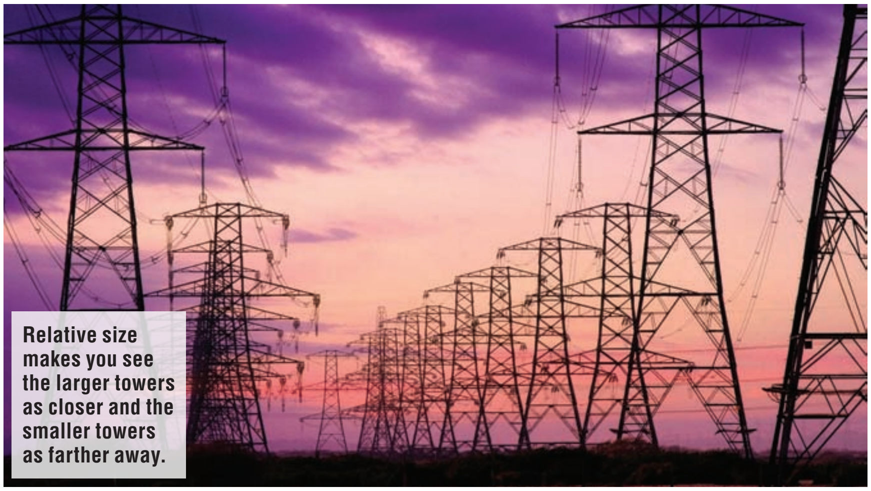


Linear perspective makes you see the road as going on forever.

1 Linear Perspective

As you look down a long stretch of road, the parallel lines formed by the sides of the road appear to come together, or converge, at a distant point. This convergence is a monocular cue for distance and is called linear perspective.

Linear perspective is a monocular depth cue that results as parallel lines come together, or converge, in the distance.

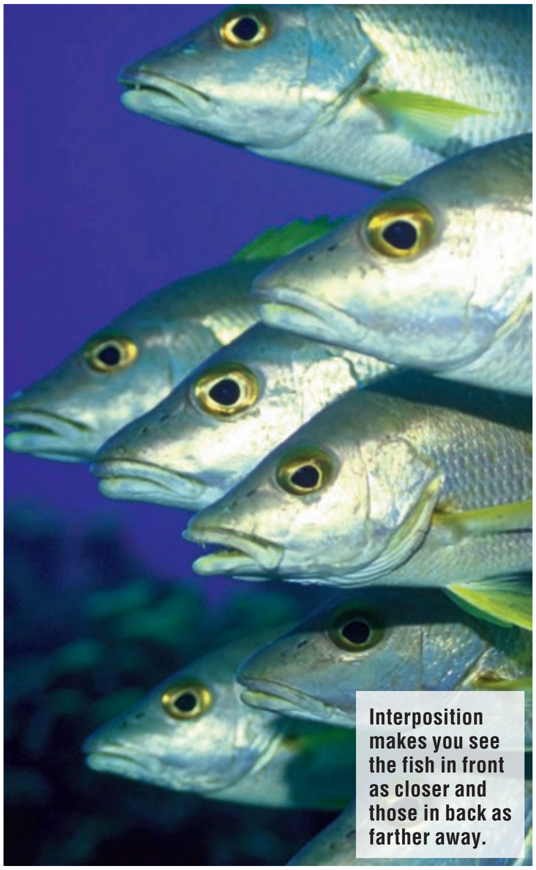


Relative size makes you see the larger towers as closer and the smaller towers as farther away.

2 Relative Size

You expect the electric towers in the photo above to be the same size. However, since the electric towers in the front appear larger, you perceive them as closer, while the electric towers in the back appear smaller and thus farther away. The relative size of objects is a monocular cue for distance.

Relative size is a monocular cue for depth that results when we expect two objects to be the same size and they are not. In that case, the larger of the two objects will appear closer and the smaller will appear farther away.



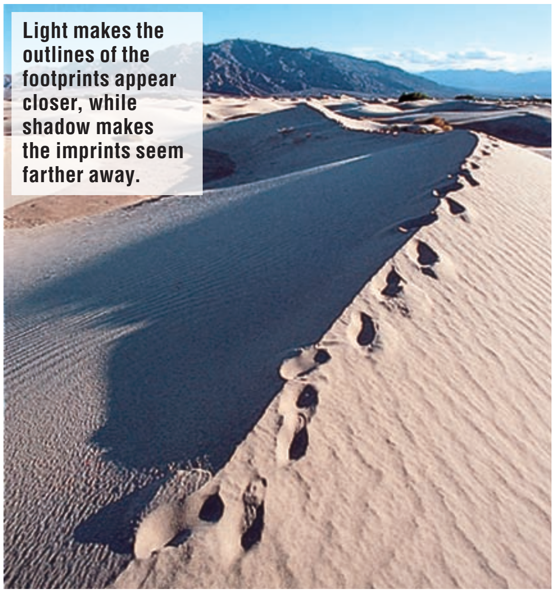
Interposition makes you see the fish in front as closer and those in back as farther away.

3 Interposition

As you look at the school of fish in the photo above, you can easily perceive which fish are in front and which are in back, even though all the fish are about the same size. You can identify and point out which fish are closest to you and which are farthest away by using the monocular depth cue of overlap, which is called interposition.

Interposition is a monocular cue for depth perception that comes into play when objects overlap. The overlapping object appears closer, and the object that is overlapped appears farther away.

Photo Credits: top left, © Walter Bibikow/Getty Images; right, © Digital Stock Corporation; bottom left, © Digital Vision/Alamy

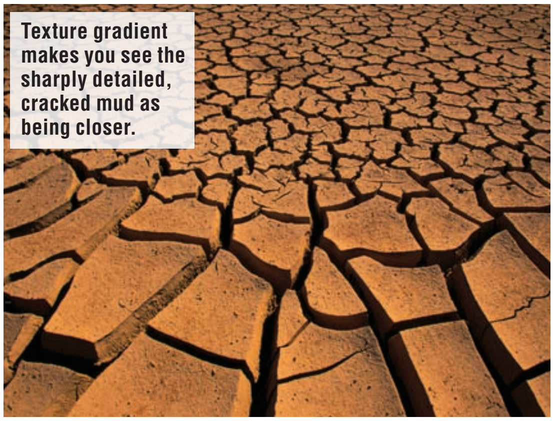


Light makes the outlines of the footprints appear closer, while shadow makes the imprints seem farther away.

4 Light and Shadow

Notice how the brightly lit edges of the footprints appear closer, while the shadowy imprint in the sand appears to recede. Also, the sunny side of the sand dune seems closer, while the back side in shadows appears farther away. The monocular depth cues shown here involve the interplay of light and shadows.

Light and shadow make up monocular cues for depth perception: Brightly lit objects appear closer, while objects in shadows appear farther away.



Texture gradient makes you see the sharply detailed, cracked mud as being closer.

5 Texture Gradient

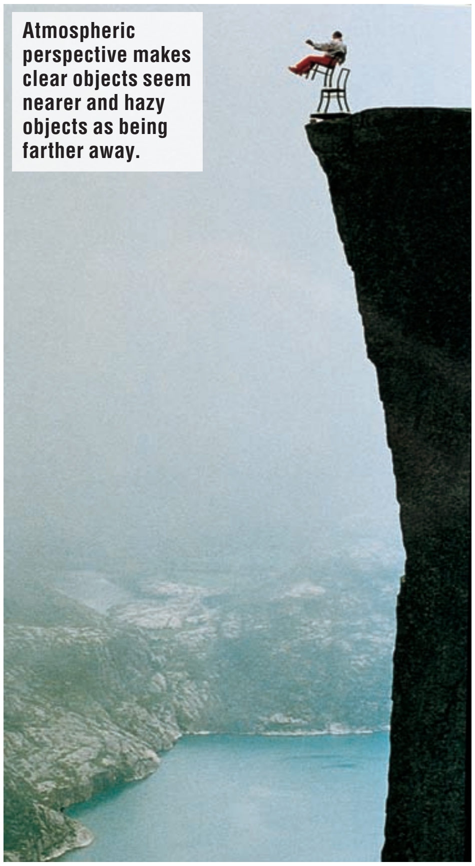
You can't help but notice how the wide, detailed surface cracks in the mud seem closer, while the less detailed and narrower cracks appear farther away. These sharp changes in surface details are monocular depth cues created by texture gradients.

Texture gradient is a monocular depth cue in which areas with sharp, detailed texture are interpreted as being closer and those with less sharpness and poorer detail are perceived as more distant.

6 Atmospheric Perspective

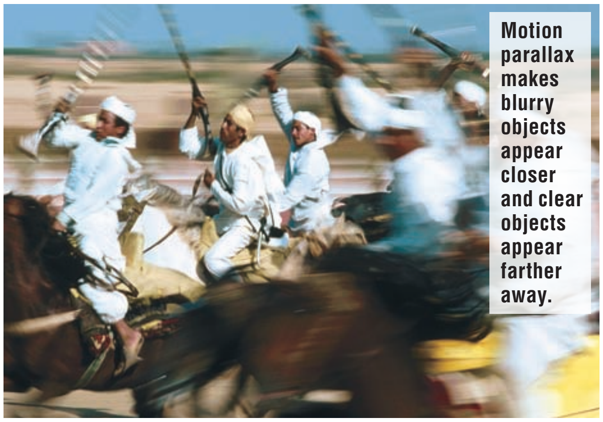
One of the depth cues you may have overlooked is created by changes in the atmosphere. For example, both the man sitting on the chair and the edge of the cliff appear much closer than the fog-shrouded hills and landscape in the background. These monocular depth cues are created by changes in the atmosphere.

Atmospheric perspective is a monocular depth cue that is created by the presence of dust, smog, clouds, or water vapor. We perceive clearer objects as being nearer, and we perceive hazy or cloudy objects as being farther away.



Atmospheric perspective makes clear objects seem nearer and hazy objects as being farther away.

7 Motion Parallax



Motion parallax makes blurry objects appear closer and clear objects appear farther away.

In this photo, you can easily tell which riders seem closer to you and which appear farther away. That's because you perceive fast-moving or blurry objects (horsemen on the right) as being closer to you and slower-moving or clearer objects (horsemen on the left) as being farther away. These monocular depth cues come from the way you perceive motion.

Motion parallax is a monocular depth cue based on the speed of moving objects. We perceive objects that appear to be moving at high speed as closer to us than those moving more slowly or appearing stationary.

We have just discussed seven monocular cues involved in perceiving depth and distance accurately. Because they are monocular cues—needing only one eye—it means that people with only one eye have depth perception good enough to land a plane, drive a car, or play various sports such as baseball and tennis. If you wish to try some of these monocular cues, just hold your hand over one eye and see if you can avoid objects as you walk around a room.

We turn next to occasions where our perceptual system is fooled, and we see things that are not there. Welcome to the world of illusions.

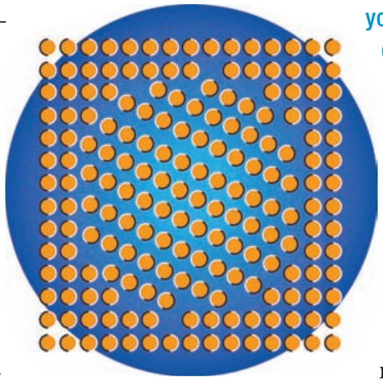
F. Illusions

Strange Perceptions

What is an illusion?

There are two reasons that much of the time your perceptions of cars, people, food, trees, animals, furniture, and professors are reasonably accurate reflections but, because of emotional, motivational, and cultural influences, never exact copies of reality.

First, we inherit similar sensory systems whose information is processed and interpreted by similar areas of the brain (Franz et al., 2000). However, damage to sensory areas of the brain can result in very distorted perceptions, such as the neglect syndrome (p. 79), in which people do not perceive one side of their body or one side of their environment. The second reason our perceptions are reasonably accurate is that we learn from common experience about the sizes, shapes, and colors of objects. But we've already discussed how perceptions can be biased or distorted by previous emotional and learning experiences, such as perceiving dogs differently after being bitten by one. Now we come to another way that perceptions can be distorted: by changing the actual perceptual cues so you perceive something unlikely, which is called an illusion.



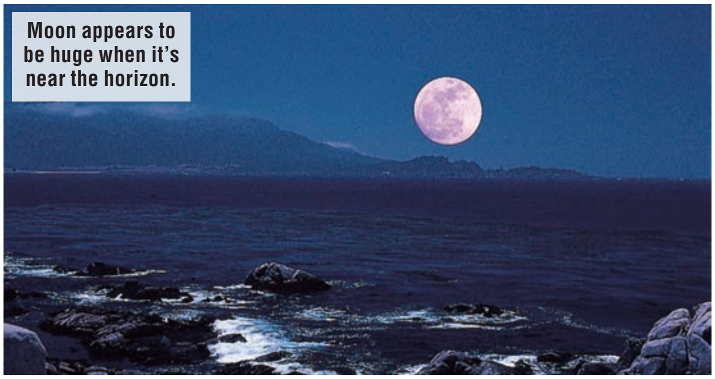
Eyes see circles moving in this illustration, even when movement doesn't really exist!

An ***illusion*** is a perceptual experience in which you perceive an image as being so strangely distorted that, in reality, it cannot and does not exist. An illusion is created by manipulating the perceptual cues so that your brain can no longer correctly interpret space, size, and depth cues.

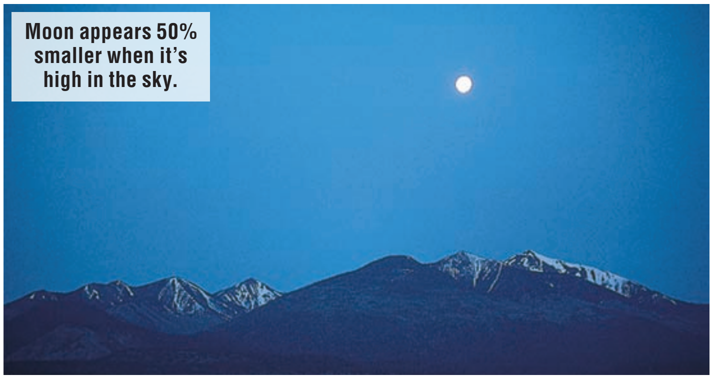
For example, if you look at the illustration to the left, you'll notice the orange circles are moving right before your eyes! You have to admit this is a fun and impressive illusion. But how can the circles appear to be moving when it's actually a still illustration? In this case, we do not know for sure. The illustration somehow activates motion-detecting neurons in the visual pathway. Patterns in illustrations like this one fool the visual system into seeing motion when it doesn't really exist (Ramachandran & Rogers-Ramachandran, 2007). The motor perception area of the brain actually shows heightened activity as people move their eyes while looking at these types of illusions (Kuriki et al., 2008). (If you cannot see the circles move, please don't worry; some people with otherwise normal vision cannot see movement in this illustration.)

One of the oldest illusions that you have often experienced is the moon illusion, which also has proven very difficult to explain (H. E. Ross & Plug, 2002).

Moon Illusion



Moon appears to be huge when it's near the horizon.



Moon appears 50% smaller when it's high in the sky.

The moon illusion has intrigued people for centuries because it is so impressive. The left photo shows that when a full moon is near the horizon, it appears (or gives the illusion of being) as much as 50% larger than when it is high in the sky (right photo). Here's the interesting part: You perceive this 50% increase in size even though the size of both moons on your retinas is exactly the same.

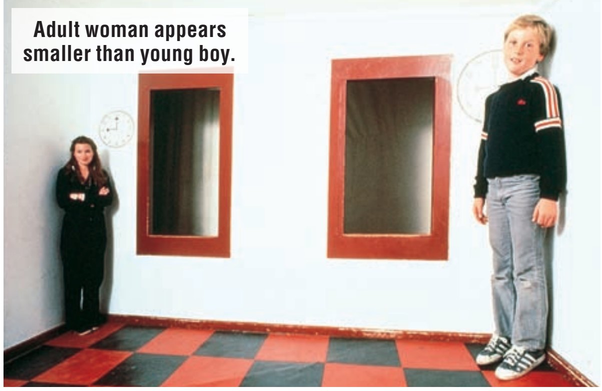
For over 50 years, researchers have proposed different theories for the moon illusion. Currently, no single theory can explain the moon illusion completely and it is believed that several factors contribute to it. The most important factor has to do with how the view of the landscape surrounding the moon influences our depth perception (H. E. Ross & Plug, 2002).

When we view the moon on the horizon, we see it in relation to the landscape (trees, mountains, buildings), which consists of depth information. In contrast, because we view the elevated moon through empty space, there are no cues to indicate distance. Thus, our brains perceive the moon on the horizon to be farther away than the elevated moon. Consequently, since the size of both moons on our retinas is exactly the same and the moon on the horizon is perceived as being farther away, our brain compensates to correct this inconsistency by inflating our perception of the size of the moon on the horizon. Consistent with this theory, researchers found that subjects estimated the horizon moon to be much farther away and interpreted its size as being larger. Likewise, subjects estimated the elevated moon to be closer and perceived it as being smaller (L. Kaufman, 2000).

Besides naturally occurring illusions, there are others that humans have created. One of the most interesting illusions comes from looking inside the Ames room.

Photo Credits: left, © Robert P. Comport/Animals Animals/Earth Sciences; right, © John Elk/Stock, Boston

Ames Room

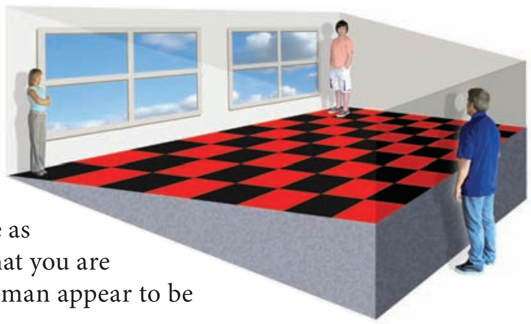


Adult woman appears smaller than young boy.

In the Ames room (left photo), you perceive the boy on the right to be twice as tall as the woman on the left. In fact, the boy is smaller than the woman but appears larger because of the design of the Ames room.

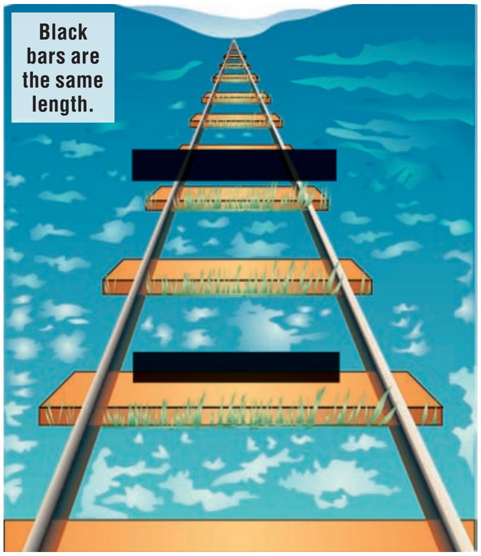
The ***Ames room,*** named after its designer, shows that our perception of size can be distorted by changing depth cues.

The reason the boy appears to be twice as tall as the woman is that the room has a peculiar shape and you are looking in from a fixed peephole. To see how the Ames room changes your depth cues, look at the diagram of the Ames room in the drawing below right. If you view the Ames room from the fixed peephole, the room appears rectangular and matches your previous experience with rooms, which are usually rectangular. However, as the right figure shows, the Ames room is actually shaped in an odd way: The left corner is twice as far away from the peephole as the right corner. This means that the woman is actually twice as far away from you as the boy. However, the Ames room's odd shape makes you think that you are seeing the two people from the same distance, and this (illusion) makes the farther woman appear to be shorter than the boy (Goldstein, 2010).



The next two illusions either change your perceptual cues or rely too much on your previous perceptual experiences.

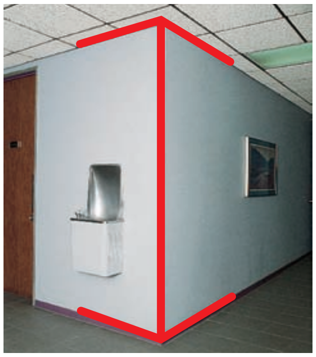
Ponzo Illusion



Black bars are the same length.

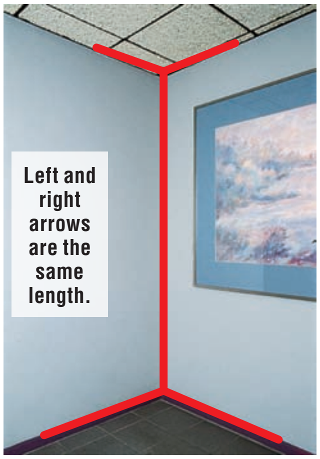
In the figure above, the top black bar appears to be much longer than the bottom black bar. However, if you measure these two bars, you will discover that they are exactly the same size. This is the ***Ponzo illusion.*** I clearly remember measuring the first time I saw this picture because I couldn't believe the bars were the same size. You perceive the top bar as being farther away, and you have learned from experience that if two objects appear to be the same size but one is farther away, the more distant object must be larger; thus, the top bar appears longer.

Müller-Lyer Illusion



The figures at the left and right illustrate the ***Müller-Lyer illusion.*** Notice that the left arrow appears noticeably shorter than the right arrow. However, if you measure them, you'll prove that the arrows are of equal length.

One explanation for this illusion is that you are relying on size cues learned from your previous experience with corners of rooms. You have learned that if a corner of a room extends outward, it is closer; this experience distorts your perception so that the left arrow appears to be shorter. In contrast, you have learned that if a corner of a room recedes inward, it is farther away, and this experience makes you perceive the right arrow as longer (Goldstein, 2010). Illusions are fun, but what have we learned?



Left and right arrows are the same length.

Learning from Illusions

Most of the time, you perceive the world with reasonable accuracy by using a set of proven perceptual cues for size, shape, and depth. However, illusions teach us that when proven perceptual cues are changed or manipulated, our reliable perceptual processes can be deceived, and we see something unreal or an illusion. Illusions also teach us that perception is a very active process, in which we continually rely on and apply previous experiences with objects when we perceive new situations. For example, you'll discover later (p. 140) how the entertainment industry changes the perceptual rule of closure to create movies, whose motion is a brilliant illusion. After the Concept Review, we'll discuss a form of perception that the U.S. Congress almost outlawed.

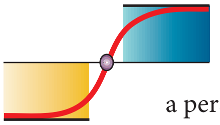
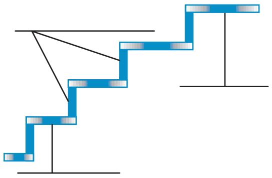
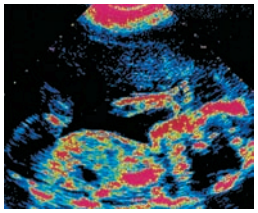
Concept Review



1. This figure illustrates the concept of the __________, which is defined as the intensity level of a stimulus such that a person will have a 50% chance of detecting it.

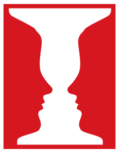


2. The smallest increase or decrease in the intensity of a stimulus that a person can detect is called a (a) __________. The increase in intensity of a stimulus needed to produce a just noticeable difference grows in proportion to the intensity of the initial stimulus; this is called (b) __________ law.

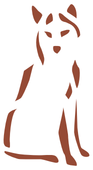


3. Our first awareness of sensory information, in the form of meaningless bits of information, is called a (a) __________. When many bits of sensory information have been assembled into a meaningful image, it is called a (b) __________, which can be biased or distorted by our unique set of experiences.

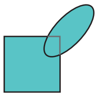
4. Early psychologists discovered a set of rules or principles that our brains use to automatically group or arrange stimuli into perceptual experiences. These early researchers, who were called __________ psychologists, disagreed with other early psychologists, who were called structuralists.



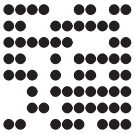
5. You automatically separate an image into a more dominant, detailed figure and a less detailed background according to the __________ rule.



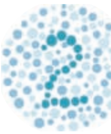
6. You fill in missing parts to form a complete image as a result of the __________ rule.



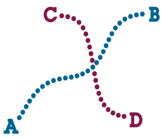
7. You see this image as formed by an oval and an overlying square because of the __________ rule.



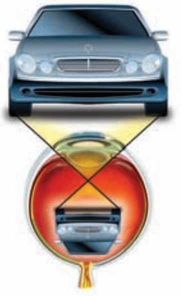
8. You divide each line of this figure into separate groups of objects according to the __________ rule.



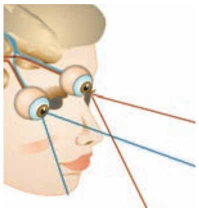
9. In this figure, you see a blue numeral 2 instead of light and dark blue circles because of the __________ rule.



10. In this figure, you see a continuous line from A to B, rather than a line from A to C, following the __________ rule.

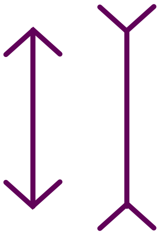


11. Although physical qualities of stimuli may change, you may perceive them as remaining the same because of (a) __________. For example, as a car drives away from you, its image on your retina becomes smaller but you know that the car does not shrink in size because of (b) __________ constancy. When you close a door, its shape on your retina changes from a rectangle to a trapezoid, but you perceive the door as remaining the same because of (c) __________ constancy. If you had a bright red car, it would appear red in bright light and still appear to be red in dimmer light because of (d) __________ constancy.



12. Cues for depth perception that depend on both eyes are called (a) __________ cues. Cues for depth perception that depend on a single eye are called (b) __________ cues. The binocular cue that occurs when your eyes move inward to track a fly landing on your nose is called (c) __________. The binocular cue that occurs when each eye receives a slightly different image is called (d) __________.

13. Monocular cues for depth perception include: cues from overlapping objects, called (a) __________; cues from two parallel lines converging, called (b) __________; cues from larger and smaller images, called (c) __________; cues from the presence of dust and smog, called (d) __________; and cues from nearer and farther objects moving at different speeds, called (e) __________.



14. If perceptual cues are so changed that our brains can no longer interpret them correctly, we perceive a distorted image of reality, called an (a) __________. Such a distorted perception illustrates that perception is an active process and that we rely on previous (b) __________ when perceiving new situations.

__Answers:__ 1. absolute threshold; 2. (a) just noticeable difference, (b) Weber's; 3. (a) sensation, (b) perception; 4. Gestalt; 5. figure-ground; 6. closure; 7. simplicity; 8. proximity; 9. similarity; 10. continuity; 11. (a) perceptual constancy, (b) size, (c) shape, (d) color; 12. (a) binocular, (b) monocular, (c) convergence, (d) retinal disparity; 13. (a) interposition, (b) linear perspective, (c) relative size, (d) atmospheric perspective, (e) motion parallax; 14. (a) illusion, (b) experiences

G. Research Focus: Influencing Perception

Can "Unsensed Messages" Change Behavior?

Why did people buy more popcorn?

Eat popcorn!

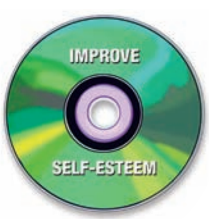
Sometimes research questions come from unusual places—in this case, a movie theater. In the late 1950s, moviegoers were reported to have bought 50% more popcorn and 18% more Coca-Cola when the words "Eat popcorn" and "Drink Coca-Cola" were projected subliminally (1/3,000 of a second) during the regular movie (J. V. McConnell et al., 1958). Researchers recently found the first physiological evidence that subliminal images attract the brain's attention on a subconscious level. People's brains responded to subliminal images even when they were not conscious of having seen them (Bahrami et al., 2007). As impressive as these results sound, the study did not examine whether subliminal images could influence thought or behavior. Even so, many advertisers now claim that subliminal messages can change specific behaviors.

Changing Specific Behaviors

At the beginning of this module, we told you about Maria, who, like millions of other Americans, bought an audio CD because it claimed to contain subliminal persuasion that would effortlessly change her behavior.

A ***subliminal message*** is a brief auditory or visual message that is presented below the absolute threshold, which means that there is less than a 50% chance that the message will be perceived.

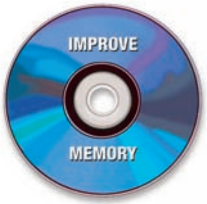
To answer the research question, Can subliminal messages change specific behaviors?, researchers conducted a well-designed experiment that used a double-blind procedure.



Labels did not match subliminal messages.

Method. For several weeks, subjects listened to two different recordings titled either "Improve Self-Esteem" or "Improve Memory." Then they rated any improvement in these behaviors.

Double-blind procedure. Researchers had to control for any possible placebo effects, such as subjects showing improvement because they believed they were hearing powerful subliminal messages. Therefore, subjects were not told which subliminal messages the recordings contained. For example, some recordings labeled "Improve Memory" contained subliminal messages for improving memory, while others contained subliminal messages for improving self-esteem. Thus, because of the double-blind procedure, subjects were unaware of the fact that some recordings' subliminal messages did not match the recordings' labels.



But, subjects believed what the labels said.

Results. About 50% of subjects reported improvements in either self-esteem or memory. However, subjects reported improvements in behavior based on what the ***recordings' labels promised*** rather than on what the subliminal messages were. For example, a subject who listened to a recording labeled "Improve Self-Esteem" reported improvements in self-esteem even though the recording contained subliminal messages for improving memory. These results suggest a self-fulfilling prophecy at work.

Self-fulfilling prophecies involve having strong beliefs about changing some behavior and then acting, unknowingly, to change that behavior.

Researchers concluded that subliminal messages in self-help recordings did not affect the behavior they were designed to change. Instead, any changes in behavior resulted from listeners' beliefs that the recordings would be effective (Epley et al., 1999). Most research, in fact, suggests that subliminal messages cannot change our behaviors in any significant way (Dijksterhuis et al., 2007; Greenwald et al., 2002).

There is evidence, however, that unconscious attitudes can unknowingly or subliminally influence perception.

Influencing Perceptions

Is it possible to have biased attitudes and be unaware of having them? If so, can these unknown or unconscious attitudes influence our perceptions? These questions are similar to those Mahzarin Banaji, a researcher at Harvard, has been asking for many years now. In one very interesting study, she wanted to determine whether people's expectations could unknowingly influence their perceptions (Vedantam, 2005).

Method. Fifty business executives viewed a black-and-white video clip of a basketball game in which the players were making quick passes and rapidly changing positions. The executives were asked to count the number of passes made during the video clip. When the video clip ended, executives excitedly shouted out answers. However, Banaji was not interested in their answers and instead asked whether anyone had seen anything unusual. The video watched by the executives did in fact show something unusual; about halfway through the video, a woman with an open white umbrella slowly walked through the screen from one end to the other. How many of the executives do you think noticed something so obvious?

Results. It turns out that none of the fifty executives noticed the woman with the white umbrella. Banaji played the video clip for the executives again and this time told them not to pay attention to the basketball passes. When the woman appeared, the executives could not believe they had not noticed something so obvious and worried that hidden biases could influence them in other ways.

These results indicate that people's expectations can unknowingly or subliminally influence their perceptions. Other research has also shown that subtle cues often influence people without their awareness. Several studies focused on racial biases found that even when people genuinely deny having racial biases, results reveal that they hold biased racial attitudes without their awareness. Thus, people's unconscious attitudes can unknowingly influence their behaviors and potentially influence the way people make important decisions, such as those made in the hiring process or in court trials or even in critical medical situations (S. Carpenter, 2008; Lehrman, 2006; Vedantam, 2005).

Next, you'll see how cultural values and experiences can also unknowingly change what you perceive.

H. Cultural Diversity: Influence on Perceptions

What Do Cultural Influences Do?

If you visit ethnic sections of large U.S. cities, such as Chinatown or Little Italy, or visit foreign countries, you become aware of cultural differences and influences. For example, this photo shows two Japanese women in traditional robes and setting, which symbolize the different cultural influences of Japan compared to Western countries.

Cultural influences are persuasive pressures that encourage members of a particular society or ethnic group to conform to shared behaviors, values, and beliefs.

What if you were raised in a different culture?

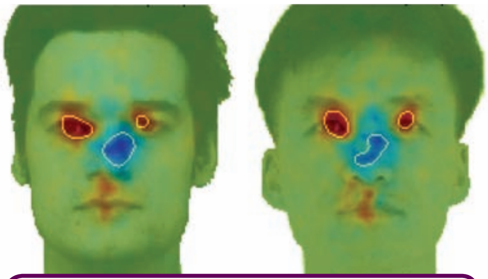
No one doubts that cultural influences affect the way people eat, dress, talk, and socialize. But you are less likely to notice how cultural influences also affect how you perceive things in your own environment.

For example, cultural anthropologists, who study behaviors in natural settings in other cultures, have reported intriguing examples of how cultural experiences influence perceptual processes. We'll begin with a remarkable finding about the role of cultural influences in how people recognize faces.

Perception of Faces

It is generally believed that basic visual processes, such as recognizing faces, are common to all people, regardless of their culture. People all around the world are able to quickly recognize whether a face is familiar or not, but new research shows that people's culture influences the process they use to recognize faces.

Researchers recorded eye movements of Western Caucasians (English, French, German) and East Asians (Chinese, Japanese) while they looked at Western Caucasian and East Asian faces. The results showed that the eye movements of Western Caucasians followed a triangular pattern, focusing on the eyes and mouth (see red areas in right photos), whereas East Asians looked at only the central region of faces, focusing mostly on the nose (see blue areas in left photos). The results were the same whether the faces they looked at were of Western Caucasian or East Asian males (Blais et al., 2008).



Western Caucasians focused mostly on the eyes and mouth (red areas), whereas East Asians focused mostly on the nose (blue areas).

One possible explanation for the cultural differences in how people perceive faces has to do with the value placed on eye contact. Eye contact is important in Western culture but inappropriate and even improper in many Asian cultures. It is possible that Asians are taught to recognize faces without looking into others' eyes (Blais et al., 2008).

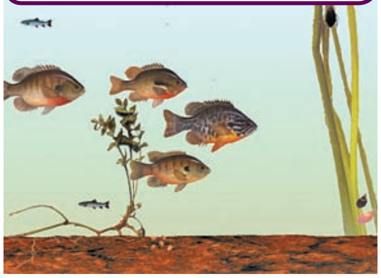
How we describe images is another example of how culture influences what we perceive.

Perception of Images

Please look at the photo below for a few seconds and then close your eyes and describe what you saw. Richard Nisbett (2000) and colleagues found that what you see or think about depends, to a large extent, on your culture.

For example, after looking at the underwater scene, Americans tended to begin their descriptions by focusing on the largest fish and making statements like "There was what looked like a trout swimming to the left." Americans are more likely to zero in on the biggest fish, the brightest object, the fish moving the fastest.

Look at the photo briefly and then close your eyes and describe it.



Compared to Americans, Japanese subjects were much more likely to begin by setting the scene, saying, for example, "The bottom was rocky." On average, Japanese subjects made 70% more statements about how the background looked than Americans did and twice as many statements about the relationships between the fish and the backgrounds. For instance, Japanese subjects were more likely to say, "The big fish swam past the gray seaweed."

Generally, Americans analyze objects separately, which is called analytical thinking—seeing a forest and focusing more on separate trees. In comparison, Easterners tend to think more about the relationship between objects and backgrounds, which is called holistic thinking—seeing a forest and thinking about how trees combine to make up a forest (Chua et al., 2005).

These differences in thinking and perceiving (analytical versus holistic) have been thought to primarily come from differences in culture, including social and religious practices, languages, and even geography (Nisbett, 2007; Nisbett & Miyamoto, 2005). Research has even shown that an individual's cultural background influences brain activity during simple tasks. For instance, one study involved two tasks assigned to East Asians and Americans. In one task, people estimated the length of a line—an easier task for Americans. In another, they estimated the line's length relative to the size of a square—an easier task for East Asians. Even though no difference in performance was found between the two groups, the level of brain activity differed, suggesting varying amounts of effort. Brain activity was greater for the tasks each group found to be more difficult (Hedden et al., 2008).

Thus, cultural differences in people's perceptions are based not only on differences in thinking and perceiving, but also on actual differences found in the brain.

Cultures also influence how we see cartoons.

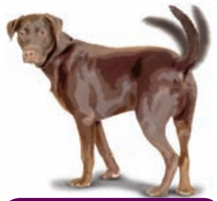
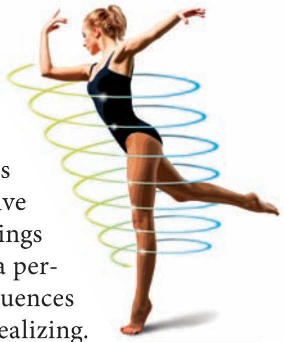
Perception of Motion



What is the dog's tail doing?

For just a moment, look at the picture of the dog (below) and notice what its tail is doing. Then look at the female figure (right) and describe what the figure is doing. Most people in Western cultures immediately perceive what is happening: the dog is wagging its tail, and the figure is spinning. Because of our Western cultural experience with pictures, we have learned to recognize that certain kinds of repeated images (the dog's tail) and certain lines and circles (the dancing figure) indicate movement. We have learned and become so accustomed to seeing these kinds of pictures indicate motion that the tail and the dancer really do seem to be in motion.

However, people from non-Western cultures, who have no experience with these pictures, do not perceive the dog's tail or the figure as moving. Non-Westerners see only an unusual dog that has three tails and a strange figure that is surrounded by circles; they do not perceive any indication of movement in these drawings (S. Friedman & Stevenson, 1980). This is a perfect example of how Western cultural influences shape our perceptions, often without our realizing.

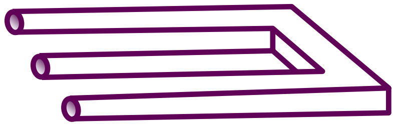


What is this dancer doing?

If part of your cultural experience involves seeing 3-dimensional objects in books, you won't be able to draw the next figure.

Perception of 3 Dimensions

Can you draw this impossible figure?



Earlier in this module, we talked about illusions. The above figure is an example of an illusion. You will find that if you look at the right end of this tuning fork, it appears to have two prongs. But if you look at the left end, it appears to have three prongs. You're looking at a figure that most of us cannot draw because it seems impossible.

An *impossible figure* is a perceptual experience in which a drawing seems to defy basic geometric laws.

As you look at it, it changes almost magically back and forth from a two-pronged to a three-pronged tuning fork. The illusion is that the middle fork is unreal because it seems to come out of nowhere.

When people from industrialized nations try to draw this figure from memory, they almost surely fail. What is interesting is that Africans who have no formal education do not see any illusion but perceive only a two-dimensional pattern of flat lines, which they find easy to draw from memory. In contrast, people with formal education, who have spent years looking at three-dimensional representations in books, perceive this object as having three dimensions, a pattern that is almost impossible to draw (Coren & Ward, 1993).

Perception of Beauty

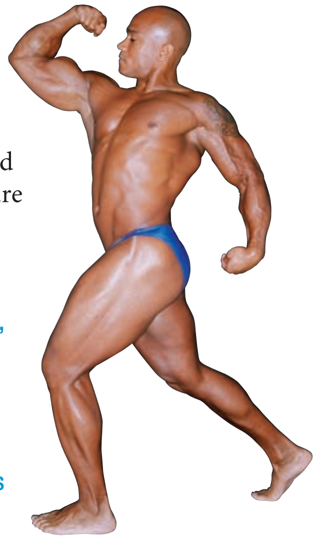
Do you think this woman is attractive?

In the past, when Burmese girls were about 5 years old, they put a brass coil one-third-inch wide around their necks. As they grew older, girls added more brass coils until they had from 19 to 25 wrapped around their necks, sometimes weighing over 10 pounds. The appearance of long necks, caused by the brass coils, was perceived as being very attractive by Burmese people, who live in southeast Asia. This custom eventually declined as neck coils were no longer considered beautiful, just cruel and uncomfortable. Recently, however, the custom has been revived because now tourists come and pay about $6 to see and take photos of women with brass neck coils (Moe & Son, 2005).

This example illustrates how cultural values influence our perceptions of personal beauty.

Perceptual Sets

Do you think this muscular body is beautiful?



From our previous cultural experiences with images and objects, we develop certain expectations about how things should be; these expectations are called perceptual sets.

Perceptual sets are learned expectations that are based on our personal, social, or cultural experiences. These expectations automatically add information, meaning, or feelings to our perceptions and thus change or bias our perceptions.

For example, as you look at this bodybuilder, you automatically add personal feelings, such as like/dislike and approve/disapprove, as well as impressions of physical characteristics: height, about 6 feet, and weight, about 225 pounds. Because of your perceptual set for bodybuilders, you expect them to be large, and so you will be surprised to learn that this bodybuilder is only 5 feet 2 inches tall and weighs 182 pounds. One function of perceptual sets is to automatically fill in information or add feelings that can greatly modify our perceptions.

These examples show that we rarely perceive the world exactly as it is. Rather, our perceptions can be changed, biased, or distorted by experiences, such as cultural influences and perceptual sets.

Next, we'll discuss a controversial kind of perception that goes by the initials ESP.

I. ESP: Extrasensory Perception

Definition and Controversy

What are psychic powers?

No one doubts your ability to receive information through one or more of your major senses—seeing, hearing, tasting, smelling, and touching—because this ability has been repeatedly demonstrated and reliably measured. In comparison, most research psychologists do not believe you can receive information outside normal sensory channels, which is called extrasensory perception, because this phenomenon has been neither repeatedly demonstrated nor reliably measured (D. J. Bem & Honorton, 1994).

Extrasensory perception (ESP) is a group of psychic experiences that involve perceiving or sending information (images) outside normal sensory processes or channels.

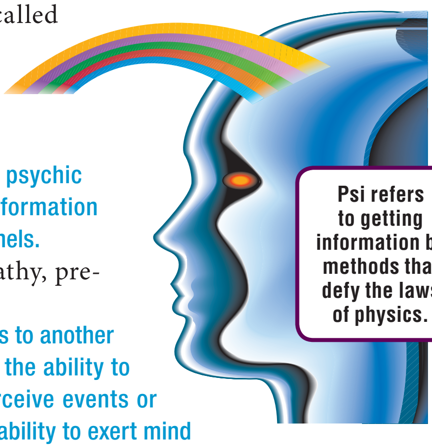
ESP includes four general abilities—telepathy, precognition, clairvoyance, and psychokinesis.

Telepathy is the ability to transfer one's thoughts to another or to read the thoughts of others. ***Precognition*** is the ability to foretell events. ***Clairvoyance*** is the ability to perceive events or objects that are out of sight. ***Psychokinesis*** is the ability to exert mind over matter—for example, by moving objects without touching them.

Together, these extrasensory perceptions are called psi phenomena.

The term ***psi*** refers to the processing of information or transfer of energy by methods that have no known physical or biological mechanisms and that seem to stretch the laws of physics.

According to the Gallup polls, 41% of adult Americans believe in ESP, 31% believe in communication between minds without the use of regular senses, 21% believe they can communicate mentally with someone who has died, and as many as 55% believe in psychics (D. W. Moore, 2005). In fact, only 7–10% of Americans do not believe in any of these extrasensory perceptions (Begley, 2007c, 2008c). The reason so many Americans but so few research psychologists believe in ESP is that researchers demand hard, scientific evidence rather than evidence from testimonials (p. 30), which are based on personal beliefs or experiences and have a high potential for error and bias. There are many examples of testimonials that, when evaluated with scientifically designed experiments, were found to be unproven. Questioning testimonial evidence applies especially to ESP, which is outside normal senses, defies physical and biological explanations, and stretches the laws of physics (P. Kurtz, 1995; Nisbet, 1998).



Psi refers to getting information by methods that defy the laws of physics.

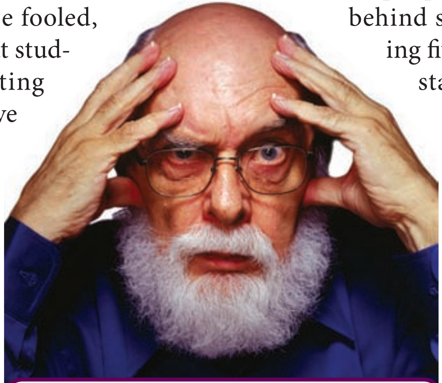
Researchers have been studying the brain to better understand ESP. In one study, two groups of people, believers and nonbelievers in ESP, were shown rapidly displayed images of real faces and scrambled faces as well as real words and nonwords (Begley, 2007c). Their task was to identify real faces and words. Nonbelievers identified more real faces as scrambled faces and more real words as nonwords than believers in ESP. Even more fascinating is that when these nonbelievers in ESP were given a drug that increases levels of the neurotransmitter dopamine, they identified more faces and words as real, even those that weren't. It turns out that having more of a neurotransmitter found in all of our brains may make us more likely to believe in the supernatural!

Another reason researchers demand reliable and repeatable evidence to prove the existence of ESP is that some demonstrations of psi phenomena have involved trickery or questionable methodology. For example, one well-known researcher has used trickery and magic to duplicate many of the better-known demonstrations of ESP, such as mentally bending spoons, moving objects, and reading messages in sealed envelopes. This researcher's name is the Amazing Randi.

Trickery and Magic

Could you spot a trick?

According to James Randi, known as the Amazing Randi (below photo), and others acquainted with magic, much of what passes for extrasensory perception is actually done through trickery (Randi, 2005, 2009; Ybarra, 1991). For example, to show how easily people may be fooled, Randi sent two young magicians to a lab that studied psychic phenomena. Instead of admitting they were magicians, the pair claimed to have psychic powers and to perform psychic feats, such as mentally bending keys and making images on film. After 120 hours of testing, the lab's researchers, who had carefully conducted and supervised the ESP demonstrations, concluded that the two did indeed have genuine psychic abilities. The lab's researchers were not expecting trickery, had not taken steps to prevent it, and were thus totally fooled into believing they were witnessing ESP.



The Amazing Randi, professional magician, shows people how ESP is done through trickery.

Many years ago, a television show under the supervision of James Randi offered $100,000 to anyone who could demonstrate psychic powers. Twelve people claimed to have psychic powers, such as identifying through interviews the astrological signs under which people were born, seeing the auras of people standing behind screens, and correctly reading Zener cards (showing five symbols: square, circle, wavy lines, plus sign, and star). Of the 12 people who claimed psychic powers, none scored above chance on any of these tasks (Steiner, 1989). Although people may claim psychic powers, most cannot demonstrate such powers under controlled conditions, which eliminate trickery, magic, and educated guessing. On the next page, we'll learn how one popular TV psychic responded to being asked to take James Randi's test to prove she had psychic powers.

To eliminate any trickery, claims of psychic abilities must withstand the scrutiny of scientific investigation. Let's see how a controlled ESP experiment is designed and conducted.

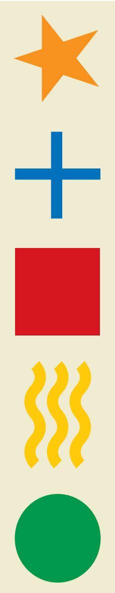
Photo Credit: bottom, © Jeffery Allan Salter/Corbis

ESP Experiment

How do researchers study psychic abilities?

One of the more common demonstrations of psychic ability is to use Zener cards, which show five symbols—circle, waves, square, plus sign, and star (on right). A researcher holds up the back of one card and asks the subject to guess the symbol on the front. If there were 100 trials, the subject could identify 20 symbols correctly simply by guessing (chance level). However, if a subject identifies 25 symbols correctly, which is above chance level, does that mean the subject has psychic powers? This is a simplified example of a very complicated statistical question: How can we determine whether a person has psychic powers or is just guessing correctly? Therefore, to solve one major problem in psi research—how to eliminate guesswork and trickery—researchers use a state-of-the-art method called the Ganzfeld procedure.

The *Ganzfeld procedure* is a controlled method for eliminating trickery, error, and bias while testing telepathic communication between a sender—the person who sends the message—and a receiver—the person who receives the message.



Symbols used to study ESP

Ganzfeld procedure involves mentally sending this picture to a person in another room.

In the Ganzfeld procedure, the receiver is placed in a reclining chair in an acoustically isolated room. Translucent ping-pong ball halves are taped over the eyes, and headphones are placed over the ears. The sender, who is isolated in a separate soundproof room, concentrates for about 30 minutes on a target, which is a randomly selected visual stimulus, such as a photo or art print (right figure). At the end of this period, the receiver is shown four different stimuli and asked which one most closely matches what the receiver was imagining. Because there are four stimuli, the receiver will guess the target correctly 25% of the time. Thus, if the receiver correctly identifies the target more than 25% of the time, it is above chance level and indicates something else is occurring, perhaps extrasensory perception (D. J. Bem & Honorton, 1994).

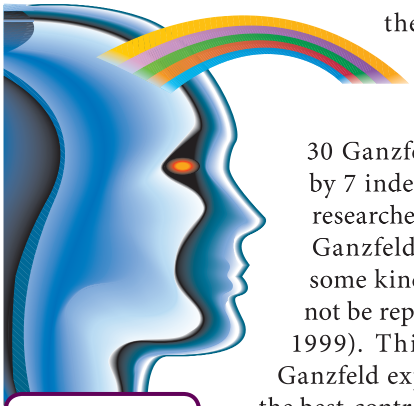
We have described the Ganzfeld procedure in detail to illustrate the precautions and scientific methodology that researchers must use to rule out the potential for trickery, error, and bias. The next question is perhaps the most interesting of all: What have researchers learned from recent Ganzfeld experiments?

Status of ESP and TV Psychics

What is the scientific status of ESP?

The history of psychic research is filled with controversy, especially about replication, which is the ability of other researchers to do similar experiments and obtain similar results. For example, Daryl Bem and Charles Honorton (1994), two respected researchers, reported that the Ganzfeld procedure (described above) provided evidence for mental telepathy; that is, one person mentally transferred information to a person in another room. The biggest question about Bem and Honorton's controversial mental telepathy results was whether their findings could be repeated or replicated by other researchers.

Importance of replication. Science has a powerful weapon for evaluating research findings, called ***replication,*** that simply says: If other scientists cannot repeat the results, the results probably occurred by chance. More recently, researchers evaluated the results of 30 Ganzfeld experiments conducted by 7 independent researchers. These researchers reported that the original Ganzfeld finding, which supported some kind of mental telepathy, could not be replicated (Milton & Wiseman, 1999). This failure to replicate the Ganzfeld experiments, which represent the best-controlled studies on ESP to date, means that there is currently little or no reliable scientific evidence to support the existence of ESP or psi phenomena (Milton & Wiseman, 2001). One of the biggest problems with ESP is that those who claim to have it are rarely subjected to scientific study. Such is the case with so-called psychic hotlines.



The best-known mental telepathy results could not be replicated.

Television psychics. There is no test or training for becoming a psychic, so anyone can claim to be one. Many alleged TV psychics were recruited through want ads and paid $15 to $20 an hour to answer questions from strangers (Nisbet, 1998). TV psychics have been so popular that at one time they took in $100 million a year.

TV psychic Sylvia Browne refuses to take a controlled test to prove her psychic powers.

Sylvia Browne is a well-known TV psychic who has become a multimillionaire by writing books, providing psychic readings in person (cost $700) and over the phone (cost $200), and making regular appearances on *The Montel Williams Show,* where she gives advice and claims to connect viewers with their loved ones who have died. Sylvia Browne has been repeatedly asked by the Amazing Randi to take his controlled test to prove she has psychic powers. Despite agreeing on national TV that she would do so, now years later she has yet to take the test (R. Friedman, 2006; Randi, 2008). There is no scientific evidence that self-proclaimed psychics are better at knowing or predicting the future than would occur by chance (Sheaffer, 1997).

Next, we'll discuss several other forms of perceptions that fool our senses into believing that fixed things are moving.

Photo Credit: top right, © Corel Gallery

J. Application: Creating Perceptions

Can we create new perceptions?

Painted 20,000 years ago

About 20,000 years ago, early humans *(Homo sapiens)* created some of the earliest images by using earth pigments to paint prancing horses on the sides of their caves (right photo) (S. Fritz, 1995). About 3,000 years ago, Egyptians created some of the most impressive images with their enormous and long-lasting pyramids. Today, computer researchers are using virtual reality techniques to develop new images and perceptions that can put you in the middle of a mind-blowing three-dimensional world. We'll begin our look at how perceptions are created with an old perceptual device that is used in modern billboards.

Creating Movement

The father of the flashing lights used in today's billboards, movie marquees, and traffic arrows was a distinguished Gestalt psychologist named Max Wertheimer. In the early 1900s, Wertheimer spent a considerable amount of time in a darkened room, where he experimented with flashing first one light and then a second light that was positioned some distance away. He discovered that if the time between flashing one light and then the other was adjusted just right, the two flashes were actually perceived as a moving spot of light rather than as two separate flashes. He called this illusion phi movement.

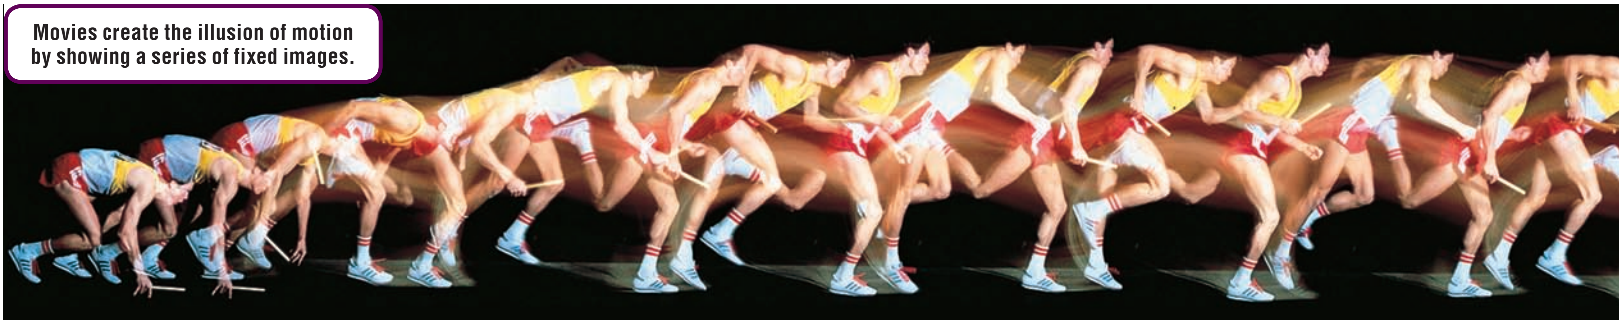
Neon billboards use flashing lights to create the illusion of movement.

Phi movement **refers to the illusion that lights that are actually stationary seem to be moving. This illusory movement, which today is called apparent motion, is created by flashing closely positioned stationary lights at regular intervals.**

Each time you pass a traffic arrow composed of flashing lights or perceive a moving string of lights used in an advertising sign, you are seeing a practical application of Wertheimer's phi movement. This phi movement was one of the first examples of how ordinary visual stimuli could be adjusted to create an illusion.

Another example of creating wonderful moving illusions with stationary visual stimuli came from the remarkable genius of Thomas Edison, who invented motion pictures in 1893.

Creating Movies



Movies create the illusion of motion by showing a series of fixed images.

If you attend a track meet and watch a 100-meter race and then, minutes later, watch a videotaped replay of the same race, you perceive motion produced in two very different ways. One kind of motion is real, while the other is an illusion.

Real motion **refers to your perception of any stimulus or object that actually moves in space.**

As you watch a live 100-meter race, you are perceiving real motion. However, when you watch a replay of that same race, you are seeing apparent motion.

Apparent motion **refers to an illusion that a stimulus or object is moving in space when, in fact, the stimulus or object is stationary. The illusion of apparent motion is created by rapidly showing a series of stationary images, each of which has a slightly different position or posture than the one before.**

The principle for creating apparent motion is deceptively simple and can be easily discovered by examining the positions of the runner's body in each frame of the time-lapse photo shown above. Beginning on the left side of the photo, notice that each frame shows only a slight change in the position of the runner's body. However, if these frames were presented rapidly—for example, at the movie standard of 24 frames per second—you would perceive the illusion of an athlete running down the track.

In a series of ingenious experiments, researchers discovered that several complex mechanisms built into our visual system detect cues that produce the illusion of motion (Ramachandran & Anstis, 1986). One such cue is the closure principle, which means that our brains fill in the motion expected to occur between images that vary only slightly in position and are presented in rapid sequence. Without apparent motion, there would be no movies, television, or flip books.

Currently, researchers have developed a procedure that creates a three-dimensional perceptual experience of walking through a house, dissecting a frog, or doing complicated human surgery. This is the brave new world of virtual reality.

Photo Credits: top right, © Gianni Dagli Orti/Corbis; center, © PhotoDisc, Inc.; bottom, © Globus Brothers

Creating Virtual Reality

What is a surgical robot?

The invention of the movie camera was revolutionary because it created a new perceptual experience: the illusion that still pictures moved. Currently, another perceptual revolution is under way, and it's called virtual reality.

Virtual reality refers to a perceptual experience of being inside an object, moving through an environment, or carrying out some action that is created or simulated by computer.

Remote and robotic surgery. In a medical application of virtual reality, surgeons can now practice their skills with surgical simulators on virtual cadavers. Research shows that the use of virtual reality significantly improves surgeons' skills, reduces their error rates, and brings reduced pain and quicker recovery for patients (Dellorto, 2008; *Science Daily,* 2008). Virtual reality is also being used on real patients. For example, a surgeon can insert and maneuver a tiny camera and surgical tools in patients through pencil-thin incisions. The surgeon operates by maneuvering robotic arms (photo below), which are steadier and more precise than human arms. Robotic surgery has already been performed more than 70,000 times in many procedures, including the removal of prostate cancers and brain tumors, as well as heart surgery, middle-ear surgery, and pediatric surgeries (Berlinger, 2006; Dellorto, 2008; J. Fox, 2005; "Medical robot," 2002). Another truly amazing advance in surgical technology is the ability for a surgeon to perform remote surgery using a robot (Berlinger, 2006). For instance, one surgeon in New York robotically removed a gallbladder from a patient in France with no complications!

Doctors use virtual reality to guide a robot to perform operations.

Psychotherapy. In a psychological application of virtual reality, clients with such fears as spiders, flying, or heights are exposed to the feared stimuli in a three-dimensional environment where everything appears very real.

Therapists use virtual reality to treat phobias (fear of spiders).

In this photo, a client is being treated for fear of spiders. She wears a plastic helmet that contains a computer monitor that puts her inside a virtual reality kitchen in which she sees, touches, and kills spiders. For example, Joanne Cartwright suffered a debilitating fear of spiders. "I washed my truck every night before I went to work in case there were webs," she said. "I put all my clothes in plastic bags and taped duct tape around my doors so spiders couldn't get in. I thought I was going to have a mental breakdown" (Robbins, 2000, p. D6). After receiving 12 virtual reality sessions to decrease her fear, Joanne said, "I'm amazed because I am doing all this stuff I could never do—camping, hunting and hiking" (Carlin, 2000). Psychotherapists report success in using virtual reality therapy to treat a wide variety of phobias, posttraumatic stress disorder (PTSD) (see p. 491), and drug addictions (Bergfield, 2006; Mozes, 2008; Rizzo, 2006; Z. Rosenthal, 2007).

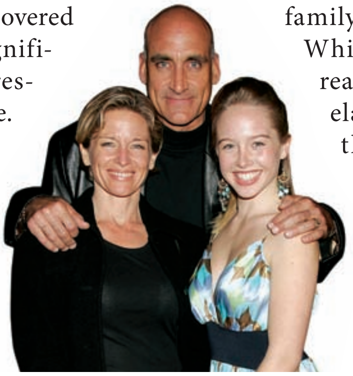
The next topic focuses on how much your first impressions of other people depend on your perceptions of their physical appearances.

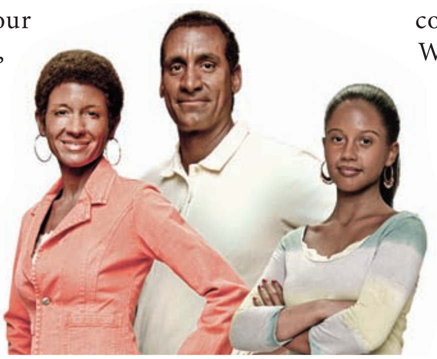
Creating First Impressions

What's your impression of the White and Black family pictures?

Social psychologists have discovered that facial features have a significant effect on our first impressions and perceptions of people. For example, we tend to perceive an attractive person as being interesting, sociable, intelligent, outgoing, and kind (Lemley, 2000). Similarly, first impressions are also influenced by racial stereotypes, both positive and negative, based on physical features such as skin color and hairstyle. Hollywood hair stylists know very well that the kind, amount, color, and style of actors' hair can radically change their appearance and our impressions of them. Besides hair color and style, skin color has a considerable impact on first perceptions and impressions.

To illustrate how skin color can greatly change your perceptions of people, please look at the two photos on the right and think about your first impressions of each person. Did you notice anything peculiar about the two pictures? You'll likely be surprised to learn the two pictures show the same people. Both pictures are of the Wurgel family (mom, dad, and daughter), all of whom are White. The Wurgel family participated in a TV reality series called *Black.White.* and underwent elaborate makeup transformations to change their racial complexions (Associated Press, 2006b; Gliatto, 2006; Patterson, 2006). The real pictures of the Wurgel family are on the top, and their transformation pictures are on the bottom!





Now that you have seen the dramatic effect race can have on our impressions of others, you can judge for yourself how skin color influences your perceptions of others. We'll discuss how we perceive people and form impressions in Module 25.

The factors involved in forming first impressions as well as in creating moving lights, movies, and virtual reality illustrate an important underlying principle of perception: Our perceptions, which may be changed or biased by personal experiences, are interpretations rather than exact copies of reality.

Summary Test

A. Perceptual Thresholds

1. We discussed three basic questions that psychologists ask about perception. Our first question—At what point are we aware of a stimulus?— can be answered by measuring the threshold of a stimulus, which is a point above which a stimulus is perceived and below which it is not. The intensity level at which a person has a 50% chance of perceiving the stimulus is called the ______________.

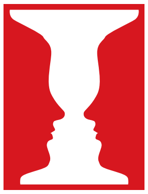
2. Our second question—At what point do we know a stimulus intensity has increased or decreased?—can be answered by measuring the smallest increase or decrease in the intensity of a stimulus that a person can detect; this is called a (a) ______________. It has been found that the increase in stimulus intensity needed to produce a just noticeable difference increases in proportion to the intensity of the initial stimulus; this is called (b) ______________ law.

B. Sensation Versus Perception

3. Our third question—How are meaningless sensations combined into meaningful perceptions?—can be answered by analyzing our own perceptual experiences. Our first awareness of some outside stimulus is called a (a) ______________. This awareness results when some change in energy activates sensory receptors, which produce signals that, in turn, are transformed by the brain into meaningless sensory experiences. When many individual sensations are assembled into a meaningful experience, image, or pattern, it is called a (b) ______________. The latter is not an exact replica of the real world but rather a copy that has been changed, biased, or distorted by our unique set of (c) ______________. Our brain transforms sensations into perceptions instantaneously, automatically, and without our awareness.

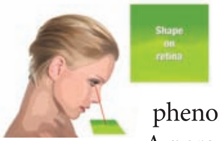
4. The (a) ______________ argued that we can explain how perceptions are formed by dividing perceptions into smaller and smaller elements. They believed that we combine basic elements to form a perception. In contrast, the (b) ______________ psychologists replied that the formation of perceptions cannot be understood by simply breaking perceptions down into individual components and then studying how we reassemble them. They argued that "the whole is more than the sum of its parts," by which they meant that perceptions are more than a combination of individual elements. The Gestalt psychologists believed that the brain has rules for assembling perceptions, which they called principles of (c) ______________.

C. Rules of Organization



5. Many of the rules of perceptual organization involve ways of grouping or arranging stimuli. According to one of these rules, the first thing we do is automatically separate an image into two parts: the more detailed feature of an image becomes the (a) ______________ and the less detailed aspects become the (b) ______________. According to the (c) ______________ rule, stimuli tend to be organized in the most basic, elementary way. According to the (d) ______________ rule, stimuli that appear the same tend to be grouped together. According to the (e) ______________ rule, stimuli that are near one another tend to be grouped together. According to the (f) ______________ rule, stimuli that are arranged in a smooth line or curve tend to be perceived as forming a continuous path. According to the (g) ______________ rule, we tend to fill in the missing parts of a figure and perceive it as complete.

D. Perceptual Constancy



6. Although the size, shape, brightness, and color of objects are constantly changing, we tend to see them as remaining the same, a phenomenon that is called (a) ______________. A person walking away does not appear to grow smaller, even though the image on the retina is decreasing in size, because of (b) ______________ constancy. Even though the image of a door that is opened and closed changes on the retina from a rectangle to a trapezoid, we see it as retaining its rectangular outline because of (c) ______________ constancy. Even though the color and brightness inside a car are altered when we drive from bright into dim light, we tend to see little change because of (d) ______________ and ______________ constancy.

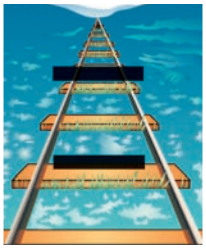
E. Depth Perception

7. The visual system transforms the two-dimensional image (height and width) of stimuli projected onto the retina into a three-dimensional experience by adding depth. Cues for depth that are dependent on both eyes are called (a) ______________; cues for depth that are dependent on only a single eye are called (b) ______________. The binocular cue for depth that arises when muscles turn your eyes inward is called (c) ______________. The binocular cue for depth that arises because the two eyes send slightly different images to the brain is called (d) ______________.

Photo Credits: top left, © Arman Zhenikeyev/Alamy; bottom, © Walter Bibikow/Getty Images

8. There are a number of monocular cues for depth. When an object appears closer because it overlaps another, the cue is called (a) ______________. When parallel lines seem to stretch to a point at the horizon and create a sense of distance, the cue is called (b) ______________. When two figures are expected to be the same size but one is larger and thus appears closer, the cue is called (c) ______________. If dust or smog makes objects appear hazy and thus farther away, the cue is called (d) ______________. As texture changes from sharp and detailed to dull and monotonous, it creates the impression of distance; this cue is called (e) ______________. The play of light and shadow gives objects a three-dimensional look, a cue that is called (f) ______________. As you ride in a car, the impression that near objects are speeding by and far objects are barely moving is called (g) ______________.

F. Illusions



9. For much of the time, our perceptions are relatively accurate reflections of the world (except for anything added by our attentional, motivational, or emotional filters). However, if perceptual cues that we have learned to use and rely on are greatly changed, the result is a distorted image, called an ______________. Although illusions are extreme examples, they illustrate that perception is an active, ongoing process in which we use past experiences to interpret current sensory experiences.

G. Research Focus: Influencing Perception

IMPROVE
SELF-ESTEEM

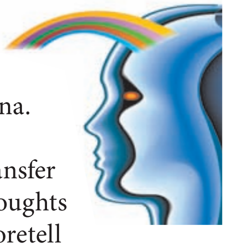
10. Brief auditory or visual messages that are presented below the absolute threshold, which means that their chance of being heard or seen is less than 50%, are called (a) ______________. Researchers have concluded that any behavioral changes attributed to subliminal messages actually result because listeners' strong belief that a behavior will change leads them to act, unknowingly, to change that behavior; this is called a (b) ______________.

H. Cultural Diversity: Influence on Perceptions

11. Experiences that are typical of a society and shared by its members are called ______________ influences. These influences have significant effects on the perception of images, constancy, depth, and motion.

12. Because of cultural influences, Americans tend to engage more in (a) ______________ thinking, while Easterners (Japanese) engage more in (b) ______________ thinking.

I. ESP: Extrasensory Perception



13. The perception and transmission of thoughts or images by other than normal sensory channels are referred to as psychic experiences or (a) ______________ phenomena. ESP, which stands for (b) ______________, includes four psychic abilities. The ability to transfer one's thoughts to another or read another's thoughts is called (c) ______________. The ability to foretell events is called (d) ______________. The ability to perceive events or objects that are out of sight is called (e) ______________. The ability to move objects without touching them is called (f) ______________. Two reasons many researchers are skeptical of psychic abilities are that some supposedly psychic phenomena were actually accomplished with (g) ______________ and some previous studies that supported ESP had questionable (h) ______________. Although some studies supported the occurrence of psi phenomena, recent studies showed that the experiments that supported psi phenomena could not be (i) ______________.

J. Application: Creating Perceptions

14. When you view objects moving in space, it is called (a) ______________ motion. When you view images of stationary objects that are presented in a rapid sequence, it is called (b) ______________ motion, which is the basic principle used to create movies. The illusion that stationary lights are moving can be traced to the work of Max Wertheimer, who called this phenomenon (c) ______________ movement. A perceptual experience that is created by allowing the viewer to enter and participate in computer-generated images is called (d) ______________; it breaks down some of the traditional boundaries between reality and fantasy. Virtual reality has been applied to treat excessive fear of spiders, flying, or heights, which are called (e) ______________.

Answers: *1. absolute threshold; 2. (a) just noticeable difference, (b) Weber's; 3. (a) sensation, (b) perception, (c) experiences; 4. (a) structuralists, (b) Gestalt, (c) perceptual organization; 5. (a) figure, (b) ground, (c) simplicity, (d) similarity, (e) proximity, (f) continuity, (g) closure; 6. (a) perceptual constancy, (b) size, (c) shape, (d) color, brightness; 7. (a) binocular, (b) monocular, (c) convergence, (d) retinal disparity; 8. (a) interposition, (b) linear perspective, (c) relative size, (d) atmospheric perspective, (e) texture gradient, (f) light and shadow, (g) motion parallax; 9. illusion; 10. (a) subliminal messages, (b) self-fulfilling prophecy; 11. cultural; 12. (a) analytical, (b) holistic; 13. (a) psi, (b) extrasensory perception, (c) telepathy, (d) precognition, (e) clairvoyance, (f) psychokinesis, (g) trickery, (h) methodology, (i) replicated; 14. (a) real, (b) apparent, (c) phi, (d) virtual reality, (e) phobias*

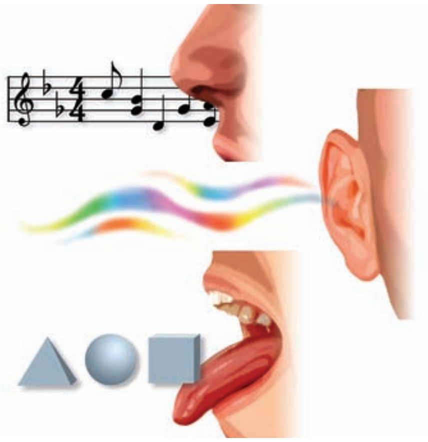
Critical Thinking

Taste Shapes? Hear Colors? Smell Sounds?

When Carol Crane hears the sound of guitars, she feels as if someone is blowing on her ankles. Hearing the piano gives her a tapping sensation on her chest. Hearing jazz music makes her feel as if heavy, sharp raindrops are falling all over her body! When Carol looks at the number 4, she sees red, and when she looks at the letter b, she sees blue. Carol is unique from most other people because of the complex way she experiences many sensations.



Carol has an uncommon condition called synesthesia, which means when one of her senses gets stimulated, another sense automatically, involuntarily gets stimulated too. Perceiving colors with letters and numbers is the most common form of synesthesia. Less common types include experiencing sounds with smells and shapes with flavors. Sometimes, the associations are reasonable or logical, such as the smell of lemons leading people to see yellow. But, other times, the associations are surprising, such as the smell of lavender leading people to see green and to feel stickiness.

Many people with synesthesia enjoy their special abilities; however, there is a real downside for others. Some people experience unpleasant associations, such as the awful taste of earwax when hearing certain words. As you can imagine, this can make reading very unpleasant! As a result of having multiple senses stimulated, people can experience distractions at work, while reading or studying, or while driving and looking at road signs. These unique experiences can be frustrating because they are frequent and automatic, making them very difficult to prevent or stop.

Researchers have been studying people with synesthesia and have learned some fascinating things. In people with synesthesia, the signals that come from sensory organs, such as the eyes and ears, travel to places in the brain they shouldn't necessarily be going to, which leads to the signals being interpreted as multiple sensations. For example, when people experience color sensations when hearing words, hearing words activates areas of the brain responsible for both hearing and vision.

Other biological research suggests that synesthesia runs in families; however, its genetics are not well understood. Researchers recently made a significant stride in understanding the genetic involvement of synesthesia. They identified specific chromosomal regions associated with auditory-visual synesthesia, which is when people see colors in response to sounds. Still, the genetic basis for synesthesia is complex and understanding how it develops requires much further study. Researchers are hopeful that understanding the genetic involvement in synesthesia will also help them better understand how the brain is organized and how different areas are connected, ultimately leading to a better understanding of human perception. (Adapted from Asher et al., 2009; Callejas, 2008; Cytowic, 1999; Hitti, 2006b; Hubbard & Ramachandran, 2005; Lemley, 1999; Nunn et al., 2002; Rouw & Scholte, 2007; Steven et al., 2006; Weir, 2009)

QUESTIONS

1 If researchers wanted to better understand how Carol's brain processes sensory experiences, which type(s) of brain scan should they use?

2 Is synesthesia a type of illusion?

3 Does having synesthesia help improve your memory?

4 Which part of the neuron is responsible for taking signals that come from sensory organs to multiple areas of the brain?

5 Which brain areas are responsible for hearing words and seeing colors?

6 Which modern approach to psychology is used to study the genetic involvement of synesthesia?

Learning Activities

PowerStudy for Introduction to Psychology 4.5

Try out **PowerStudy's SuperModule** for Perception! In addition to the quizzes, learning activities, interactive Summary Test, key terms, module outline and abstract, and extended list of correlated websites provided for all modules, the DVD's **SuperModule** for Perception features:

- Self-paced, fully narrated learning with a multitude of animations.
- Video about motion parallax, the Ames room, and virtual reality therapy.
- Interactive versions of study resources, including the Summary Test on pages 142–143 and the critical thinking questions for the article on page 144.

CengageNOW!

Study Guide and WebTutor

Work through the corresponding module in your Study Guide for tips on how to study effectively and for help learning the material covered in the book. WebTutor (an online Study Tool accessed through your eResources account) provides an interactive version of the Study Guide.

Suggested Answers to Critical Thinking

1. The two types of brain scans that measure activity of neurons during sensory experiences are the fMRI (functional magnetic resonance imaging) and PET (positron emission tomography) (pp. 70–71).
2. No. An illusion is a perceptual experience in which you perceive an image as being so strangely distorted that, in reality, it cannot and does not exist. Synesthesia involves not only having visual sensations but also experiencing two different sensations triggered by the stimulation of one sense.
3. The more associations we make with information we are trying to store in our memory, the more likely we are to remember it well. People with synesthesia activate multiple areas of their brain when experiencing sensory information. This leads to making more associations with these experiences and likely improves their ability to recall information later.
4. The dendrites receive the electrical signals from the sensory organ and later send the information through the axons to reach the specific area of the brain to experience a particular sensation. In cases of synesthesia, the axons likely take signals to two areas of the brain, one where it is supposed to go and another it shouldn't be sending information to. This process may explain why these people experience multiple simultaneous sensations after only one sense is stimulated.
5. The temporal lobe is involved with hearing, and the occipital lobe is involved with vision. More specifically, the auditory association area within the temporal lobe transforms basic sensory information, such as sounds, into recognizable auditory information, such as words (p. 78). Also, the primary visual cortex within the occipital lobe receives electrical signals and transforms these signals into colors (p. 79).
6. The biological approach (p. 6) examines how our genes interact with our environment to influence many abilities, including the processing of sensory information.

Living in a Cave

Would you answer this ad?

The advertisement read: "We are looking for a hardy subject to live alone in an underground cave for four months. We'll provide board, room, and a monthly allowance. It will be necessary to take daily physiological measurements, measure brain waves, and collect blood samples."

Twenty people answered this ad, but researchers selected Stefania because she seemed to have the inner strength, motivation, and stamina to complete the entire four months. On the chosen day, Stefania crawled 30 feet underground with her favorite books into a 20-by-12-foot Plexiglas module, which had been sealed off from sunlight, radio, television, and other time cues.

During her first month underground, Stefania's concentration seemed to come and go. She appeared depressed, and she snapped at researchers when they asked her to do routine measurements. She had strange dreams—for example, that her computer monitor had turned into a TV that was talking to her. After several months, however, she became more comfortable with her underground isolation. She followed a regular routine of taking her body temperature, heart rate, and blood pressure and typing the results into a computer monitor, her only link with the outside world.

Without clocks, radio, television, or the sun, Stefania found it difficult to keep track of time, which seemed to have slowed down. When told she could leave her underground cave (photo below) because her 130 days were up, she felt certain she had been underground only about 60 days. Her time underground, which was a women's record (the men's record is 210 days), allowed researchers to closely monitor her sleeping and waking behaviors in the absence of all light and time cues (adapted from *Newsweek,* June 5, 1989).

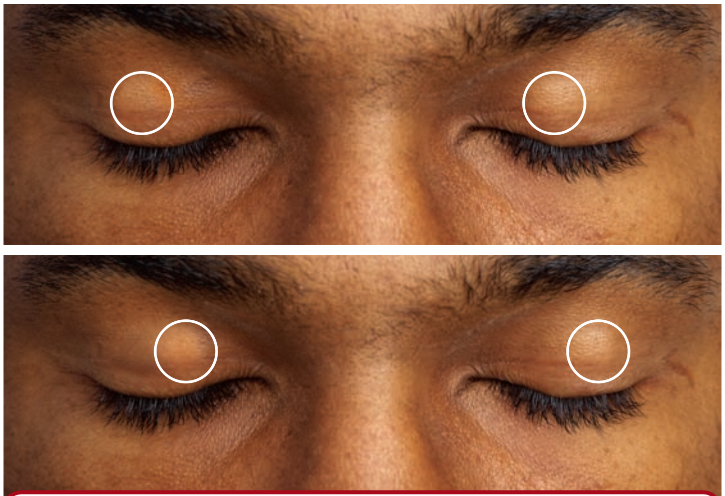
Stefania leaves an underground cave in which she had lived for 130 days without any time cues (clocks, sunshine, radio, TV).

Asking Stefania to live in a cave for many months was not a publicity stunt but a way to answer questions about how long a day is and how much one sleeps when there are no light cues. To answer these questions, researchers used a case study approach, which meant studying Stefania's behaviors and physiological responses in great detail and depth and doing so in a reasonably naturalistic setting. Researchers discovered that the preferred length of a day is not 24 hours and that during a particular kind of sleep Stefania's eyes moved back and forth as if she were watching a ping-pong game. The significance of these eye movements emphasizes the fact that some major discoveries in science occur quite by accident.

Chance Discovery

Why are your eyes moving?

In the early days of sleep research, psychologists were observing changes in sleeping subjects and noticed that during a certain stage of sleep a person's eyes suddenly began to move rapidly back and forth. This back-and-forth eye movement can actually be seen under the eyelids in the photos below. Even more interesting, when subjects were awakened during rapid eye movement, they usually reported that they had been dreaming. This chance observation of rapid eye movement and its high association, or correlation, with dreaming gave researchers a reliable method to identify and study dreaming in the laboratory (Dement & Kleitman, 1957).



During one kind of sleep (REM—rapid eye movement sleep), the eyes dart back and forth beneath the eye lids.

These examples show how researchers study waking, sleeping, and dreaming in different settings, including underground caves and sleep laboratories, and also how they were helped along by a chance discovery.

What's Coming

We'll discuss the preferred length of a day, how you know when to sleep and wake up, what happens to your body and brain during sleep, how much sleep you need, why you sleep, and common sleep problems and their treatments. We'll also discuss the one question students always ask: What do dreams mean? All these areas fit neatly under a much broader phenomenon that we call awareness, or consciousness, and that is where we'll begin.

Photo Credits: left, © Murrae Haynes; right, © Stockbyte/Getty Images

A. Continuum of Consciousness

Different States

Are you conscious now?

One curious and amazing feature of consciousness is that, at some point, the person is actually observing himself or herself (Rochat, 2003). For example, how do you know that at this very moment you are conscious?

Consciousness refers to different levels of awareness of one's thoughts and feelings. It may include creating images in one's mind, following one's thought processes, or having unique emotional experiences.

One way you know that you are conscious is that you are aware of your own thoughts and existence (Pinker, 2000). You may think that when awake you are conscious and when asleep you are unconscious, but there is actually a continuum of consciousness.

The ***continuum of consciousness*** refers to a wide range of experiences, from being acutely aware and alert to being totally unaware and unresponsive.

We'll summarize some of the experiences that make up the continuum of consciousness.

Controlled Processes

A problem with cell phones is we have the ability to focus all of our attention on only one thing, which is an example of controlled processes.

Controlled processes are activities that require full awareness, alertness, and concentration to reach some goal. The focused attention required in carrying out controlled processes usually interferes with the execution of other ongoing activities.

Talking on a cell phone while driving is a controlled process.

A controlled process such as talking on a cell phone while driving involves focusing most of your attention on talking and little on driving. There's less problem if the driving is easy, but if you need to take quick action, your driving will likely suffer because your attention is primarily focused on your phone conversation (P. J. Cooper et al., 2003). In fact, listening to a conversation while driving increases brain activity in language areas and decreases brain activity in spatial areas involved in driving (Just, 2008). People who use cell phones while driving have 4 times the risk of having an accident (Kirtland, 2009). The use of a cell phone is the most common distraction while driving (NHTSA, 2008). For these reasons, handheld cell phones are banned in six states (O'Donnell, 2009).

Automatic Processes

Eating while reading is an automatic process.

Since this man's attention is focused primarily on reading an important report, he is almost automatically eating the apple; this is an example of an automatic process.

Automatic processes are activities that require little awareness, take minimal attention, and do not interfere with other ongoing activities.

Examples of automatic processes include eating while reading or watching television and driving a car along a familiar route while listening to the radio or thinking of something else.

Although we seem to concentrate less during automatic processes, at some level we are conscious of what is occurring. For instance, as we drive on automatic pilot, we avoid neighboring cars and can usually take quick evasive action during emergencies.

Daydreaming

Many of us engage in a pleasurable form of consciousness called daydreaming.

Daydreaming is an activity that requires a low level of awareness, often occurs during automatic processes, and involves fantasizing or dreaming while awake.

We may begin daydreaming in a relatively conscious state and then drift into a state between sleep and wakefulness. Usually we daydream in situations that require little attention or during repetitious or boring activities.

Men's and women's daydreams are similar.

Most daydreams are rather ordinary, such as thinking about getting one's hair cut, planning where to eat, or fantasizing about a date. These kinds of daydreams serve to remind us of important things in our future. Although you might guess otherwise, men's and women's daydreams are remarkably similar in frequency, vividness, and realism (Klinger, 1987).

Altered States

Over 3,000 years ago, Egyptians brewed alcohol to reach altered states of consciousness (Samuel, 1996).

Altered states of consciousness result from using any number of procedures—such as meditation, psychoactive drugs, hypnosis, or sleep deprivation—to produce an awareness that differs from normal consciousness.

Meditation is an altered state.

For example, this woman is using meditation to focus her attention on a single image or thought, free her mind from external restraints, and enter an altered state of consciousness.

In an interesting series of studies on himself, neuropsychologist John Lilly (1972) repeatedly took LSD (when it was legal) and reported that it caused unusual, bizarre, and sometimes frightening altered states of consciousness. For example, he described leaving his body, seeing it from above, and being afraid he would not be able to return safely to it.

The chief characteristic of altered states, whichever way they are produced, is that we perceive our internal and external environments or worlds in ways different from normal perception.

Sleep and Dreams

We enter an altered state of consciousness every night when we go to sleep.

Sleep **consists of five different stages that involve different levels of awareness, consciousness, and responsiveness, as well as different levels of physiological arousal. The deepest state of sleep borders on unconsciousness.**

Because of our decreased awareness, 8 hours of sleep may seem like one continuous state. However, it is actually composed of different states of body arousal and consciousness (Lee-Chiong, 2008). One interesting sleep state involves dreaming.

Dreaming **is a unique state of consciousness in which we are asleep but experience a variety of astonishing visual, auditory, and tactile images, often connected in strange ways and often in color. People blind from birth have only auditory or tactile dreams.**

Newborns sleep about 17 hours a day.

During the initial stage of sleep, we are often aware of stimuli in our environment. However, as we pass into the deepest stage of sleep, we may sleeptalk or sleepwalk and children may experience frightening night terrors but have no awareness or memory of them.

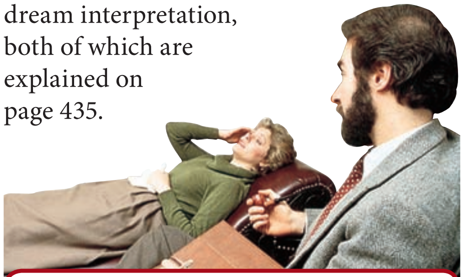
Most of this module focuses on waking, sleeping, and dreaming.

Unconscious and Implicit Memory

We told you that one of Sigmund Freud's revolutionary ideas was his concept of the unconscious (see pp. 9, 434–437).

According to Freud's theory, when we are faced with very threatening wishes or desires, especially if they are sexual or aggressive, we automatically defend our self-esteem by placing these psychologically threatening thoughts into a mental place of which we are not aware, called the ***unconscious.*** **We cannot voluntarily recall unconscious thoughts or images.**

Freud believed that we can become aware of our unconscious thoughts only through a process of free association or dream interpretation, both of which are explained on page 435.



Freud's idea of the unconscious is different from implicit memory.

Somewhat related to Freud's theory of the unconscious is a new concept developed by cognitive neuroscientists called implicit or nondeclarative memory (Frensch & Runger, 2003).

Implicit **or** ***nondeclarative memory*** **means learning without awareness, such as occurs in emotional situations or in acquiring habits. We are unaware of such learning, which can influence our conscious feelings, thoughts, and behaviors.**

For example, you cannot describe the complex motor movements your feet make as they walk down stairs because such motor memories are stored in implicit memory, which you are unaware of and cannot voluntarily recall. Implicit memory explains why people cannot recall and are unaware of why or how they learned to fear a tiny spider, fell in love, fainted at the sight of blood, or learned (classically conditioned) to make a happy or sad facial expression (Poldrack & Packard, 2003). Implicit memory emphasizes the learning and influence of many different kinds of motor and emotional memories and is different from Freud's unconscious, which focuses on the influence of threatening memories (Kihlstrom, 1993).

Unconsciousness

If you have ever fainted, gotten general anesthesia, or been knocked out from a blow to the head, you have experienced being unconscious or unconsciousness.

Unconsciousness, **which can result from disease, trauma, a blow to the head, or general medical anesthesia, results in total lack of sensory awareness and complete loss of responsiveness to one's environment.**

Unconsciousness results from a head knock, disease, or general anesthesia.

For example, a boxer's goal is to knock out the opponent with a quick blow to the head that produces a temporary state of unconsciousness. Being in an accident can damage the brain and cause different levels of unconsciousness and result in different kinds of comas. In some comas, a person appears to be asleep and has absolutely no awareness or responsiveness; this is called a vegetative state. People in vegetative comas are unconscious and in some cases brain-dead, which means they will never again regain consciousness.

Several Kinds

Why is it so mysterious?

Consciousness is so mysterious because it is a continuum of states, which range from the tragic unconsciousness of being in a vegetative coma to the keen alertness of controlled processes during a final exam. Although it is difficult to define consciousness, you know what it feels like to be conscious and aware of your thoughts and surroundings. Neuroscientists find there is no single seat of consciousness; rather it results from interactions among many different areas of the brain, depending upon the kinds of thoughts, images, or stimuli to which you are attending (Edelman, 2003).

Although you have experienced having conscious beliefs and desires, Freud believed that there was also an active, unconscious psychological process that defended you against threatening sexual and aggressive thoughts, of which you are totally unaware. In partial support of Freud's theory, cognitive neuroscientists use the concept of implicit or nondeclarative memory to explain how you can be unaware of perceiving various stimuli, such as words, objects, faces, and emotional events, and even learn simple responses (classical conditioning). Although you are not aware of this unconscious learning, you can be unknowingly influenced by the thoughts, memories, feelings, and behaviors stored in your implicit memory (Guterl, 2002; Petty et al., 2006).

One obvious sign of consciousness is being awake, which is regulated by a clock in the brain, our next topic.

B. Rhythms of Sleeping & Waking

Biological Clocks

How long is a day?

Sleep researchers studied Stefania (left photo), who is shown coming out of her modernized cave after 130 days. Stefania was asked to live in a cave so researchers could study her biological clocks.

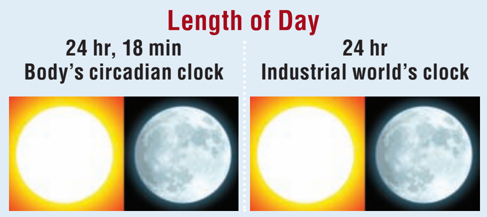
Stefania's sleep-wake cycle in the cave was regulated by a biological clock.

Biological clocks are internal timing devices that are genetically set to regulate various physiological responses for different periods of time.

Biological clocks can be set for hours (secretion of urine), for a single day (rise and fall in internal body temperature), or for many days (women's 28-day menstrual cycle). We are interested in a biological clock that is set for a single day and produces what is called a circadian *(sir-KAY-dee-un)* rhythm (*circa* means "about"; *diem* means "day").

A ***circadian rhythm*** refers to a biological clock that is genetically programmed to regulate physiological responses within a time period of 24 hours (about one day).

Length of Day



Length of day. You are most familiar with the circadian rhythm that regulates your sleep-wake cycle. In previous studies, when researchers removed all time cues (light, clock, radio, television) from cave dwellers like Stefania, the circadian clock day was believed to lengthen from 24 hours to about 25 hours (M. W. Young, 2000). However, in a better controlled study, researchers reported that for both young (mean age 24) and older (mean age 67) adults, the sleep-wake circadian clock is genetically set for a day lasting an average of 24 hours and 18 minutes (Czeisler et al., 1999).

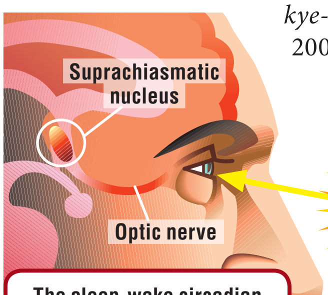
Resetting the circadian clock. Because your circadian clock is genetically set for about 24 hours, 18 minutes, it must be reset each day to match our agreed upon 24-hour-long day. The resetting stimulus is morning sunlight, which stimulates newly discovered light-detecting cells in the eye's retina (see p. 96) (Purves et al., 2008). These *retinal cells,* which are involved in sensing the amount of light and are not involved in seeing, send electrical signals to the brain's circadian clock (described below) and reset it by about 18 minutes each day (Purves et al., 2008).

Problems. If your circadian clock is not properly reset each day, it may result in problems getting to sleep, getting over jet lag, and adjusting to working the night shift (see next page). Although the circadian clock was long known to exist, only recently have researchers identified its exact location in the brain.

Location of Biological Clocks

Where is the circadian clock?

It may seem strange to think of having clocks in your brain. Actually you have several clocks, including the biological circadian sleep-wake clock located in a group of cells in the brain's suprachiasmatic *(SUE-pra-kye-as-MAT-ick)* nucleus (Lee-Chiong, 2008; Wallisch, 2008).



The sleep-wake circadian clock is located in the suprachiasmatic nucleus.

The ***suprachiasmatic nucleus*** is one of many groups of cells that make up the hypothalamus, which lies in the lower middle of the brain. The suprachiasmatic nucleus is a sophisticated biological clock that regulates a number of circadian rhythms, including the sleep-wake cycle. Because this nucleus receives direct input from the eyes, the suprachiasmatic cells are highly responsive to changes in light.

Since light regulates sleep-wake circadian rhythms, the absence of light should disrupt circadian rhythms in blind people and cause sleep problems. Researchers found that many blind people do report sleep problems (Lamberg, 2006; Moreno, 2006). However, some people who are completely blind report no sleep problems because the pathway for transmitting light from their eyes directly to the suprachiasmatic nucleus, which is not involved in seeing, is intact (Barinaga, 2002; Foster, 2009).

Besides the 24-hour sleep-wake circadian clock, you also have other clocks in your brain, including one that measures shorter periods of time, called an interval timing clock (Buhusi & Meck, 2005).

The ***interval timing clock,*** which can be started and stopped like a stopwatch, gauges the passage of seconds, minutes, or hours and helps people and animals time their movements, such as knowing when to start or stop doing some activity (taking a one-hour nap and actually waking up about an hour later). The interval timing clock is located in a part of the brain known as the basal ganglia (see p. 60).

Another clock in your brain is regulated by food.

The ***food-entrainable circadian clock*** (also referred to as the ***midnight-snack clock***) regulates eating patterns in people and animals and might be responsible for late-night eating in people. Thus, obese people, many of whom eat more than half their calories at night, may have an abnormality in their clock, which is located in the hypothalamus (see p. 80) (C. Brownlee, 2006b; Mieda et al., 2006).

Walking around with several fine-tuned biological clocks in your head is great for timing activities. However, if your circadian sleep-wake clock is interfered with or not properly reset, you may have various sleep-wake problems.

Circadian Problems and Treatments

What if your circadian clock is upset?

Here's the basic problem: For most of the industrial world, a day is agreed to be exactly 24 hours long, but for your genetically set sleep-wake circadian clock, a day is an average of 24 hours and 18 minutes. This difference means your sleep-wake clock must be reset about 18 minutes each day. The resetting stimulus is morning sunlight, which our eyes send directly to the suprachiasmatic nucleus. This daily resetting of our sleep-wake clocks about 18 minutes usually occurs automatically. However, if our circadian clocks are not properly reset, we may experience decreased cognitive performance, work-related and traffic accidents, jet lag, and various sleep disorders (Aamodt & Wang, 2008; K. Wright, 2002).

Shift Workers

Staying awake when your sleep-wake clock calls for sleep results in decreased performance in cognitive and motor skills (Drummond, 2000). For example, employees who work the graveyard shift (about 1–8 A.M.) experience the highest number of accidents, reaching their lowest point, or "dead zone," at about 5 A.M., when it is very difficult to stay alert (Stutts et al., 2002).

The reason shift workers and late-night drivers have more accidents is their sleep-wake clocks have prepared their bodies for sleep, which means they feel sleepy, are less attentive and alert, and are often in a lousy mood (Ohayon et al., 2002). Frequent major changes in working hours will likely cause much stress on the body and brain (Aamodt & Wang, 2008).

Next, we'll see how circadian rhythms can also create problems for long-distance travelers, including flight attendants who frequently travel across many time zones.

Jet Lag

If you flew from west coast to east coast, you experienced a 3-hour time difference and most likely had jet lag.

Jet lag **is the experience of fatigue, lack of concentration, and reduced cognitive skills that occurs when travelers' biological circadian clocks are out of step or synchrony with the external clock times at their new locations.**

Generally, it takes about one day to reset your circadian clock for each hour of time change.

Jet lag occurs when a body's circadian clock gets out of synchrony.

Consider how severe jet lag can be for flight attendants who frequently make long trips. Those who do not take breaks to allow their circadian clocks to readjust experience impaired cognitive skills (Aamodt & Wang, 2008).

After 3 months in space, astronauts experience "space lag" or sleeplessness because their circadian clocks are not being reset (Monk et al., 2001).

Next, you'll see how researchers are studying ways to more effectively reset our biological clocks.

Resetting Clock

Researcher Charles Czeisler (1994) spent ten years convincing his colleagues that light could reset circadian clocks. After he finally succeeded, other researchers used his and their own research to obtain patents for light therapy (Nowak, 1994).

Light therapy **is the use of bright artificial light to reset circadian clocks and to combat the insomnia and drowsiness that plague shift workers and jet-lag sufferers. It also helps people with sleeping disorders in which the body fails to stay in time with the external environment.**

For example, researchers report that workers who had been exposed to bright light and then shifted to night work showed improvement in alertness, performance, and job satisfaction (Czeisler et al., 1995). Exposure to bright light (about 20 times brighter) at certain times reset the workers' suprachiasmatic nucleus and resulted in a closer match between their internal circadian clocks and their external shifted clock times.

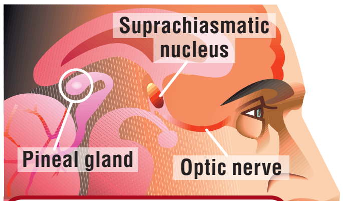
Light therapy has enormous potential for resetting our sleep-wake clocks, and more recently it has been used to treat depression (B. Bower, 2005; Tompkins, 2003a, 2003b).

Another factor involved in setting the sleep-wake clock is a hormone from a gland that was once thought useless.

Melatonin

The discovery of a use for melatonin has been a big scientific breakthrough (Kraft, 2007).

Melatonin **is a hormone that is secreted by the pineal gland, an oval-shaped group of cells that is located in the center of the human brain. Melatonin secretion increases with darkness and decreases with light. The suprachiasmatic nucleus regulates the secretion of melatonin, which plays a role in the regulation of circadian rhythms and in promoting sleep.**



Melatonin is a hormone secreted by pineal gland.

Although early testimonials and studies claimed melatonin reduced jet lag, a later double-blind study reported that melatonin was no better than a placebo in reducing jet lag (Spitzer et al., 1999). However, melatonin helped individuals with medical problems resulting from chronically disrupted circadian clocks sleep better and experience less fatigue (Nagtegaal et al., 2000).

A new experimental drug has shown initial promise in resetting the circadian clock, which may bring relief to shift workers and jet-lag sufferers (Rajaratnam et al., 2009).

Next, we'll examine what happens inside the brain and body during sleep.

C. World of Sleep

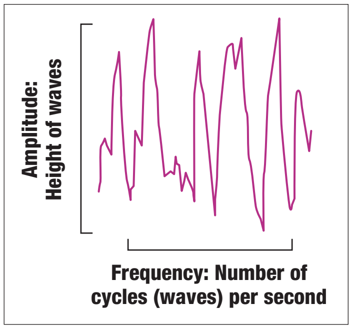
Stages of Sleep

Does my brain sleep?

The first thing to know about sleep is that your brain never totally sleeps but is active throughout the night. To track your brain's activity during sleep, researchers would attach dozens of tiny wires or electrodes to your scalp and body and record electrical brain activity as you passed through the stages of sleep.

Going to sleep involves going through several different stages.

The ***stages of sleep*** refer to distinctive changes in the electrical activity of the brain and accompanying physiological responses of the body that occur as you pass through different phases of sleep.

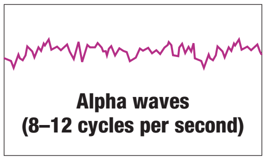


As shown in the graph at the top, brain waves are described in terms of frequency (speed) and amplitude (height). They are recorded by a complex machine called an EEG, or electroencephalogram. Each stage of sleep can be recognized by its distinctive pattern of EEGs, which we'll explain here.

Alpha Stage

Before actually going into the first stage of sleep, you briefly pass through a relaxed and drowsy state, marked by characteristic alpha waves.

The ***alpha stage*** is marked by feelings of being relaxed and drowsy, usually with the eyes closed. Alpha waves have low amplitude and high frequency (8–12 cycles per second).



After spending a brief time relaxing in the alpha stage, you enter stage 1 of non-REM sleep.

Non-REM Sleep

What happens during sleep?

The second thing to know about sleep is that it is divided into two major categories, called non-REM and REM. We'll discuss non-REM first.

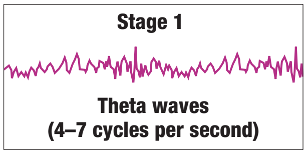
Non-REM sleep is where you spend approximately 80% of your sleep time. Non-REM is divided into sleep stages 1, 2, 3, and 4; each stage is identified by a particular pattern of brain waves and physiological responses. (REM stands for rapid eye movement.)

You begin in sleep stage 1 and gradually enter stages 2, 3, and 4 (Rama et al., 2006).

Stage 1

This is the lightest stage of sleep.

Stage 1 sleep is a transition from wakefulness to sleep and lasts 1–7 minutes. In it, you gradually lose responsiveness to stimuli and experience drifting thoughts and images. Stage 1 is marked by the presence of theta waves, which are lower in amplitude and lower in frequency (4–7 cycles per second) than alpha waves.



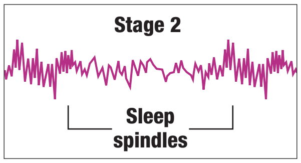
Although stage 1 is usually labeled a sleep stage, some individuals who are aroused from it feel as if they have been awake.

Next, you enter stage 2 sleep.

Stage 2

This is the first stage of what researchers call real sleep.

Stage 2 sleep marks the beginning of what we know as sleep, since subjects who are awakened in stage 2 report having been asleep. EEG tracings show high-frequency bursts of brain activity called sleep spindles.



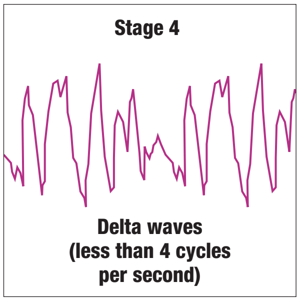
As you pass through stage 2, your muscle tension, heart rate, respiration, and body temperature gradually decrease, and it becomes more difficult for you to be awakened.

Stages 3 and 4

About 30–45 minutes after drifting off into sleep, you pass through stage 3 and then enter into stage 4 sleep.

Stage 4 sleep, which is also called slow-wave or delta sleep, is characterized by waves of very high amplitude and very low frequency (less than 4 cycles per second) called delta waves. Stage 4 is often considered the deepest stage of sleep because it is the most difficult from which to be awakened. During stage 4, heart rate, respiration, temperature, and blood flow to the brain are reduced, and there is a marked secretion of GH (growth hormone), which controls levels of metabolism, physical growth, and brain development.

As you pass through stages 3 and 4, your muscle tension, heart rate, respiration, and temperature decrease still further, and it becomes very difficult for you to be awakened.



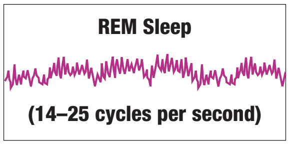
After spending a few minutes to an hour in stage 4, you will backtrack through stages 3 and 2 and then pass into a new stage, called REM sleep, which is associated with dreaming.

REM Sleep

When do you dream?

We have discussed one major category of sleep, non-REM, and now move on to the second major category of sleep, which goes by the initials REM.

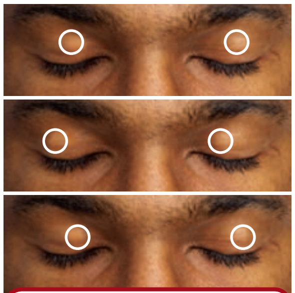
REM sleep **makes up the remaining 20% of your sleep time. It is pronounced "rem" and stands for rapid eye movement sleep because your eyes move rapidly back and forth behind closed lids. REM brain waves have high frequency and low amplitude and look very similar to beta waves, which occur when you are wide awake and alert. During REM sleep, your body is physiologically very aroused, but all your voluntary muscles are paralyzed. REM sleep is highly associated with dreaming.**



You pass into REM sleep about five or six times throughout the night with about 30 to 90 minutes between periods. You remain in each period of REM sleep for 15 to 45 minutes and then pass back into non-REM sleep.

Characteristics of REM Sleep

When REM sleep was first discovered in the early 1950s, researchers found it difficult to believe their unusual findings: Although you are asleep during REM, your body and brain are in a general state of physiological arousal (Aserinsky & Kleitman, 1953). For example, during REM sleep, your heart rate and blood pressure are significantly higher than during non-REM sleep (L. Rosenthal, 2006). Because of this strange combination of being asleep yet physiologically aroused, REM sleep is often called *paradoxical sleep.* (A *paradox* is something with contradictory qualities.)



Eyes dart back and forth as a sign of REM sleep.

Another unusual feature of REM sleep is that its brain waves are very similar to those recorded when a person is wide awake and alert. By looking at brain wave recordings alone, researchers cannot tell whether a person is in REM sleep or wide awake. Only the additional recording of rapid eye movements indicates the occurrence of REM sleep.

Although many physiological responses are greatly increased, you completely lose the muscle tension in your neck and limbs so you are essentially paralyzed. However, involuntary muscles that regulate heart, lungs, and other organs continue to function. Researchers think humans evolved muscle paralysis of their limbs during REM sleep so they would not act out violent dreams by running, fighting, or jumping about and injuring themselves (Schenck, 2003). In fact, this actually happens in REM behavior disorder.

In *REM behavior disorder,* which usually occurs in older people, voluntary muscles are not paralyzed, and sleepers can and do act out their dreams, such as fighting off attackers in dreams. People with this condition have been known to break a hand, punch a wall, or hurt a spouse (Seppa, 2009). In some cases, REM behavior disorder is caused by known neurological damage, but in other cases, the causes are unknown (Tippmann-Peikert et al., 2006).

So not only is REM a paradoxical sleep but it also signals dreaming.

REM—Dreaming and Remembering

Dreaming. One of the biggest breakthroughs in dream research was the finding that about 80–90% of the times when subjects are awakened from a REM period, they report having vivid, complex, and relatively long dreams (Dement, 1999). In contrast, only about 10% of subjects awakened from non-REM sleep report similar kinds of dreams.

One of the first questions asked was what happens when people are deprived of REM sleep and dreaming. Many subjects have been deprived of REM sleep and dreaming without showing any major behavioral or physiological effects (Bonnet, 2005). However, suppressing REM sleep does produce a curious phenomenon called REM rebound.

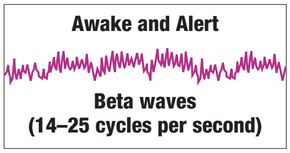
Dreaming usually occurs during REM sleep.

REM rebound **refers to individuals spending an increased percentage of time in REM sleep if they were deprived of REM sleep on the previous nights.**

Remembering. The occurrence of REM rebound suggests a need for REM sleep, and one such need involves memory. In one study, subjects learned to press a button when they spotted a moving target on a screen. Subjects tested on the same day as training showed a modest improvement. However, when subjects were tested the next day, those subjects allowed to get the most REM sleep (slept 8 hours) showed the greatest improvement compared to subjects who got the least REM (slept 6 hours). Researchers concluded that REM sleep helps us store or encode information in memory and advise students to get a good night's sleep so that what they studied the previous day has a chance to be stored in the brain's memory (Stickgold, 2000, 2005).

Awake and Alert

A short time after awakening from sleep, you enter a state of being awake and alert. This state has distinctive brain activity called beta waves (right figure), which are characterized by high frequency and low amplitude and are very similar to those waves observed during REM sleep.



How alert you feel in the morning partly depends on whether you are a morning or an evening person, which we'll discuss in the Research Focus on page 155.

Although you now have an overview of the different sleep stages, you may be surprised to discover that how you go through the different stages is somewhat like riding a roller coaster.

Photo Credits: top, © Stockbyte/Getty Images; bottom, © Digital Vision Ltd./SuperStock

C. World of Sleep

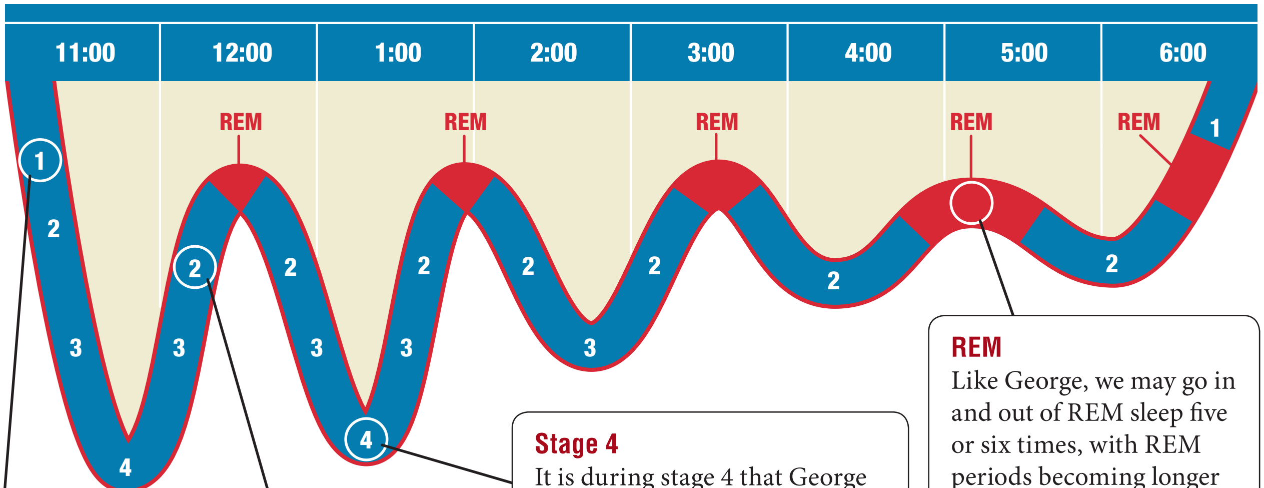
Sequence of Stages

Why is sleep like a roller-coaster ride?

When you go to sleep at night, you may think that you simply sleep for 8 hours, perhaps toss and turn a little, and even do some dreaming. But sleep is not one unbroken state; rather, it is a series of recurring stages, similar to the ups and downs of a roller-coaster ride. We'll describe a typical night's pattern for George, a college sophomore, who goes to bed about 11 P.M. and gets up about 7 A.M. As we take you through the figure below, notice that non-REM sleep is indicated by the wide blue line and REM sleep is indicated by red inserts. The numbers 1 to 4 refer to sleep stages 1, 2, 3, and 4 of non-REM sleep, which we discussed earlier.

A night's sleep is like a roller-coaster ride through different stages of sleep.

Researchers have studied and plotted changes in brain waves, physiological arousal, and dreaming as subjects progressed through the stages of sleep (L. Rosenthal, 2006). Here's what George will experience on a typical roller-coaster-like ride through the different stages of a night's sleep.



Here's what happens during a normal night's sleep.

Stage 1

As George becomes drowsy, he will enter non-REM stage 1, which is the transition between being awake and asleep.

As sleep progresses, he will continue to the next stage, non-REM stage 2, which is the first stage of real sleep. During stage 2, he may experience short, fragmented thoughts, so that if he is awakened, he may think he was dreaming.

He will continue through non-REM stage 3 and finally reach non-REM stage 4. When George enters non-REM stage 4, which is slow-wave, or delta, sleep, he will be very difficult to waken. After staying in stage 4 for some minutes to an hour, he will backtrack to stages 3 and then 2.

Stage 2

After George reaches non-REM stage 2, he does not awaken but rather enters REM sleep. He will remain in REM for 15–45 minutes and, if awakened, will likely report dreaming. When in REM, his body is in a high state of physiological arousal, but his voluntary limb muscles are essentially paralyzed. If George experiences nightmares during REM, he will not act them out or injure himself because he cannot move.

After the REM period, he goes back down through non-REM stages 2, 3, and 4.

Stage 4

It is during stage 4 that George may sleepwalk, sleeptalk, or perform other activities, such as partially awakening to turn off the alarm, pull up the covers, or get up and go to the bathroom. However, George will remember nothing of what happens in non-REM stage 4, such as sleep-talking with his roommate or walking to the kitchen and getting a snack. He will remain in stage 4 for a period of time before again backtracking to non-REM stages 3 and 2, and then to his second REM period of the night.

Children sometimes wake up terrified during non-REM stage 4. These experiences are called night terrors (see p. 163), but the children will have no memory of them the next day. Also, bed-wetting, a condition in which children are unable to control urination while asleep, occurs during non-REM stage 4.

REM

Like George, we may go in and out of REM sleep five or six times, with REM periods becoming longer toward morning. If George wants to remember his dreams, he should try when he first wakes up, since his last REM period may have occurred only minutes before.

Research findings indicate that getting as many REM periods as possible is important in helping the brain store material learned the previous day (Stickgold, 2000).

If George has a difficult time awakening from sleep, it may be because he was in stage 4, the hardest stage to awaken from.

Like George, we all go through the sleep stages in about the same sequence. However, there's a reason that some of us hate mornings more than others.

D. Research Focus: Circadian Preference

Are You a Morning or Evening Person?

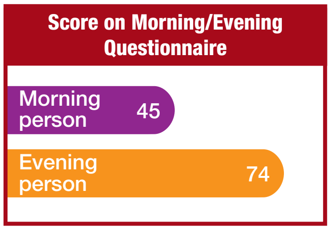
Are you an early bird or a night owl?

Some students are early birds and seem to like morning classes, while night owls hate them. Researchers studied differences between early birds and night owls by developing and using a questionnaire.

A ***questionnaire*** is a method for obtaining information by asking subjects to read a list of written questions and check off or rate their preferences for specific answers.

Morning person

The morning/evening questionnaire asked subjects to rate their preferred times for going to bed, getting up, and engaging in physical and mental activities, as well as their feelings of alertness in the morning and evening. The graph here shows the results from this questionnaire.



Morning persons (score above 74) prefer to get up earlier, go to bed earlier, and engage in morning activities. ***Evening persons*** (score below 45) prefer to get up later, go to bed later, and engage in afternoon-evening activities. Those individuals who scored between 45 and 74 did not express a strong morning or evening preference (J. P. Guthrie et al., 1995).

Researchers found that there was a morning/evening continuum with strong preferences on either end and mixed or no preferences in the middle (Andershed, 2005). One reason a person may have a strong morning or evening preference is that an inherited genetic circadian rhythm regulates body temperature, which, in turn, affects going to sleep at night and getting up in the morning.

Evening person

Body Temperature Differences

One of your body's circadian rhythms is the sleep-wake cycle, which is regulated by the suprachiasmatic nucleus in the hypothalamus. Another circadian rhythm thought to be regulated by the suprachiasmatic nucleus involves body temperature, which falls as we go to sleep and rises after we get up (Ropper & Samuels, 2009).

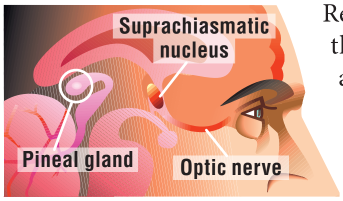
Getting up. Our body temperature is low in the morning and rises throughout the day, when we are most active. The temperature of a morning person rises more quickly, so this person gets up earlier than an evening person. In fact, body temperature in a morning person may rise 1–3 hours earlier than the temperature in an evening person (Duffy, 2002; Tankova et al., 1994).

Going to bed. The body temperature of a morning person peaks earlier in the evening, so this person goes to bed earlier than an evening person. An evening person's body temperature peaks 1–3 hours later, so this person goes to bed later. The suprachiasmatic nucleus regulates the rise and fall of body temperature, which in turn determines whether you are a confirmed morning or evening person.

In addition, there are brain differences between morning and evening people.

Changes in body temperature influence sleep preferences.

Brain Differences



Researchers examined the brains of morning and evening people by taking scans of their brains 10.5 hours after waking. Compared to morning people, evening people demonstrated increased activity in the suprachiasmatic nucleus, an area that regulates the sleep-wake cycle. This suggests that evening people are not as susceptible to fatigue, which gives them the advantage in stamina. These results indicate that the preference for morning or evening may, at least in part, be explained by differences in the activity of the suprachiasmatic nucleus (C. Schmidt et al., 2009).

Given the brain differences between morning and evening people, it is no surprise that there are behavioral and cognitive differences as well.

Behavioral and Cognitive Differences

Researchers found that students who were morning people reported being more alert at 8 A.M., took more morning classes, performed better in morning classes, and studied more in the morning than did students who were evening people (Duffy, 2002; J. P. Guthrie et al., 1995). Students who were evening people but began classes in the morning had more attention problems and poorer performance and complained of daytime sleepiness (Giannotti et al., 2002). The best time for creative thinking, such as brainstorming, is the early morning hours for morning people and the late evening hours for evening people (*Time,* 2006).

Adjust class schedule to your preference for morning or evening.

When looking at personality differences, researchers found that morning people tend to be conscientious introverts while evening people tend to be impulsive extroverts (K. Gilbert, 2006).

Finally, there are no differences between sexes in their preferences for being a morning or evening person. But, over the course of normal aging, people tend to become physiologically and behaviorally more like morning persons after age 50, which explains why grandparents are usually early to bed and early to rise (Duffy, 2002).

Although people differ in being morning or evening persons, they do share similar brain structures involved in putting them to sleep and waking them up, our next topic.

E. Questions about Sleep

Most adults need 7–8 hours of sleep.

By the time you are 25 years old, you have fallen asleep over 9,000 times and have spent about 72,000 hours asleep. There are usually four questions that students ask about sleep: How much sleep do I need? Why do I sleep? What happens if I go without sleep? What causes sleep? We'll discuss each of these questions in turn.

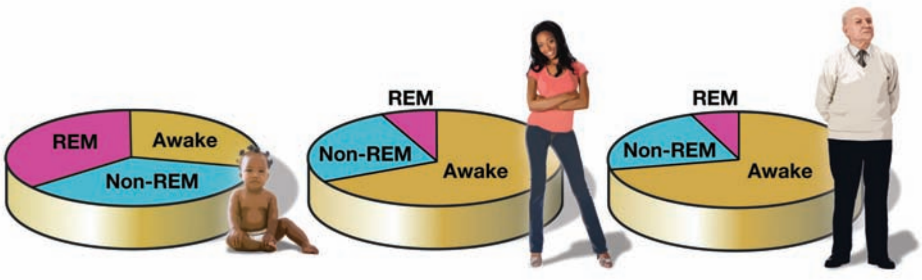
How Much Sleep Do I Need?

What's the best amount for me?

According to a national survey, 16% of adults sleep less than 6 hours a night, 24% sleep 6–6.9 hours, 31% sleep 7–7.9 hours, and 26% sleep 8 or more hours (NSF, 2005). Overall, adults in America sleep an average of about 8 hours a night (NSF, 2008; Robinson & Martin, 2007). If we took a survey of babies, the time spent sleeping would be dramatically different, as shown in the pie charts below. Beginning at birth and continuing through old age, there is a gradual change in the total time we spend sleeping, the percentage of time we spend in REM sleep, and the kinds of sleep problems we have.

Infancy and Childhood

From infancy to adolescence, the total amount of time spent in sleep and the percentage spent in REM gradually decline. For example, a newborn sleeps about 17 hours a day, and 50% of that time is spent in REM; a 4-year-old sleeps about 10 hours a day, and 25–30% of that time is spent in REM.



Adolescence and Adulthood Researchers recently found that, compared to adults, adolescents need more sleep (about 9 hours) and their circadian clocks favor going to bed later and getting up later (Hathaway, 2006; MFMER, 2005). Researchers concluded that adolescents who must get up early (6 or 7 A.M.) for classes are often sleep deprived, which may interfere with their performance (L. Epstein & Mardon, 2007; NSF, 2006). One solution is for high-school classes to start an hour later so adolescents can get sufficient sleep. At about age 20, adolescents adopt the sleep pattern of adults, which is to get approximately 7–8 hours of sleep a night, with about 20% or less being REM sleep.

Old Age

Upon reaching our sixties, total sleep time drops to about 6.5 hours a day, but the percentage of REM sleep remains about the same (20%) (Ropper & Samuels, 2009). In people over 55, 66% experience symptoms of a sleep problem (trouble getting to sleep or staying asleep, interrupted breathing), and they compensate by taking a daytime nap (NSF, 2003, 2004).

Why Do I Sleep?

Is my brain being repaired?

Why we sleep remains one of the greatest mysteries of nature (M. G. Frank, 2006). One reason we know sleep is important comes from studies of animals who are deprived of sleep. Rats can live about 16 days without food (water provided) and about 17 days without sleep (Rechtschaffen, 1997). So far, the longest a human has voluntarily gone without sleep is 11 days (discussed on next page). We'll explain two currently popular theories—the repair and adaptive theories—of why we spend about one-third of each day asleep.

Repair theory says sleep restores brain and body.

The ***repair theory*** suggests that activities during the day deplete key factors in our brain or body that are replenished or repaired by sleep. The repair theory says that sleep is primarily a restorative process.

The repair theory is supported by three findings. First, during sleep there is a marked secretion of growth hormone, which controls aspects of metabolism, physical growth, and brain development (Pandi-Perumal et al., 2008). Second, during sleep there is increased production of immune cells to fight infection (Barth, 2009; M. R. Irwin et al., 2008). Third, during wakefulness there is a decline in the brain's energy stores (glycogen), which are restored during sleep and needed for normal functioning (Geiger, 2002). The brain needs sleep to grow, repair its immune system, and restore its energy and chemicals (J. M. Siegel, 2003).

The ***adaptive theory*** suggests sleep evolved because it prevented early humans and animals from wasting energy and exposing themselves to the dangers of nocturnal predators (W. B. Webb, 1992).

Adaptive theory says sleep helps us avoid dangers.

Support for the adaptive theory comes from observations that large predatory animals, such as lions, sleep a lot and wherever they wish, while prey animals, such as antelope, sleep far less and in protected areas. Many birds sleep with one hemisphere at a time, to guard against predators (Sillery, 2002). Animals (humans) that rely primarily on visual cues and have little night vision have evolved a circadian clock for sleeping at night and thus avoid becoming prey (Hirshkowitz et al., 1997).

The adaptive and repair theories are not really at odds. Both have support but just focus on different reasons for sleep.

What If I Miss Sleep?

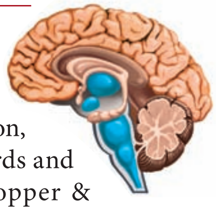
Can you go without sleep?

One method of investigating why sleep is important is to study people or animals who are sleep deprived. The record for sleep deprivation was set by a young adult who went without sleep for 11 days, or 264 hours (L. C. Johnson et al., 1965). On his 11th day without sleep, this young man beat the researcher in a pinball game, which indicates he was still awake and alert. Here's what happens when people are sleep deprived.

Effects on the Body

Sleep deprivation, even for 264 hours, has minimal effect on physiological functions controlled by the autonomic nervous system, such as heart rate or blood pressure (Kato et al., 2000). However, sleep deprivation can lead to serious health problems. Sleep deprivation may compromise our immune system, which increases an individual's vulnerability to viral infections and may lead to inflammation-related diseases (Dement, 1999; M. R. Irwin et al., 2008). Also, sleep deprivation puts the body on alert, increasing production of stress hormones and elevating blood pressure, which are major risk factors for health conditions such as heart disease, stroke, and cancer (R. Stein, 2005a). Sleep deprivation has been linked to changes in appetite-related hormones and elevated amounts of the hormone insulin. Researchers concluded that sleep deprivation increases the risk for obesity and diabetes (K. L. Knutson et al., 2007; Van Cauter et al., 2007).

Effects on the Brain



Sleep deprivation can deplete the brain's vital energy stores (gylcogen) and interfere with completing tasks that require vigilance and concentration, such as recalling and recognizing words and doing math tests (Geiger, 2002; Ropper & Samuels, 2009). Sleep deprivation increases activity of the emotional centers of the brain, particularly in response to negative stimuli, leading to irritability as well as interfering with the ability to make rational or logical decisions (Yoo et al., 2007). In a more extreme case of sleep deprivation, sled-dog racers who averaged 2 hours of sleep a night during the 12-day Iditarod race reported vivid hallucinations, such as seeing blazing fireplaces, only to awake lying in the cold snow (Balzar, 1997).

What Causes Sleep?

How do you go to sleep?

After getting into bed, most of us fall asleep within 5–30 minutes and sleep an average of 7–8 hours (range about 6–10 hours). Going to sleep involves a very complicated process during which different areas of the brain are activated or deactivated. The whole sleep process begins with something flipping the master switch for sleep.

Master Sleep Switch

VPN is sleep switch.

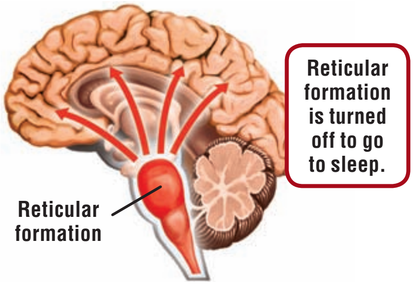
The master switch for sleep is in a nucleus of the brain called the VPN (Purves et al., 2008).

The ***VPN—ventrolateral preoptic nucleus***—is a group of cells in the hypothalamus that act like a master switch for sleep. When turned on, the VPN secretes a neurotransmitter (GABA) that turns off areas that keep the brain awake. When the VPN is turned off, certain brain areas become active and you wake up.

Researchers don't know how the VPN in humans is turned on and off, but they recently found that the VPN in rats is activated by the neurotransmitter adenosine (Gallopin et al., 2005). Next, we'll look at one brain area the VPN turns off.

Reticular Formation

In order for the forebrain to receive and process information from the senses, it must be aroused and alerted by the reticular formation.



The ***reticular formation,*** a column of cells that stretches the length of the brain stem, arouses and alerts the forebrain and prepares it to receive information from all the senses.

The reticular formation is important in keeping the forebrain alert and in producing a state of wakefulness (Ropper, 2006). If the reticular formation is stimulated in sleeping animals, they awaken; if it is seriously damaged in animals or humans, they lapse into permanent unconsciousness or coma.

Going to Sleep

The master sleep switch and the reticular formation are but two of the factors regulating sleep. Here is the probable sequence for going to sleep.

First, the time of day you go to sleep is regulated by the circadian clock, which is influenced by the suprachiasmatic nucleus of the hypothalamus (R. Y. Moore, 2006).

Second, something turns on your master sleep switch, which is located in the VPN (ventrolateral preoptic nucleus). In turn, the VPN turns off areas that arouse your brain, such as the reticular formation (Garcia-Rill et al., 2006).

Third, a number of different chemicals and neurotransmitters, some of which are manufactured in the pons, regulate when you go into and out of non-REM and REM sleep and when you awaken (Czeisler et al., 2006).

Fourth, the circadian rhythm that regulates your body temperature is tied in with sleep, since you go to sleep when your temperature falls and wake up when your temperature rises (Ropper & Samuels, 2009).

Four factors for sleep

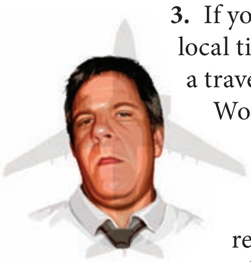
Thus, the reasons you go to sleep and wake up involve a complex interaction among the circadian clock, brain areas, sleep-inducing chemicals, and body temperature.

After the Concept Review, we'll describe a psychological problem whose cause seems related to decreased sunlight.

Concept Review

1. The various levels of awareness of one's thoughts and feelings, as well as of other internal and external stimuli, are referred to as (a) ________. This experience varies on a continuum from very aware and alert to totally unaware and unresponsive. Activities that require full awareness and alertness and may interfere with other ongoing endeavors are called (b) ________. In comparison, activities that require little awareness and minimal attention and that do not interfere with other ongoing endeavors are called (c) ________.

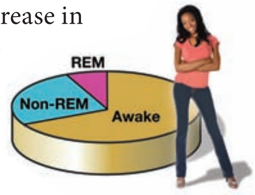
2. The biological clock that is set for a day of about 24 hours is called a (a) ________. This rhythm regulates our sleep-wake cycle, which is set to an average day of 24 hours and 18 minutes. Our circadian clock is reset by 18 minutes each day to match our agreed upon 24-hour day. The circadian clock is located in the brain's hypothalamus, in a small part called the (b) ________.



3. If your circadian rhythm is out of step with local time, you may feel fatigued and disoriented, a traveler's complaint called (a) ________. Workers and drivers have more accidents during the early-morning hours because their sleep-wake clock is telling them it's time to (b) ________. Researchers have reset circadian rhythms by exposing subjects and night workers to periods of bright light; this is called (c) ________ therapy.

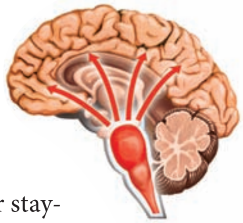
4. Near the center of the human brain is an oval group of cells, collectively called the pineal gland, that secrete a hormone called (a) ________. The gland secretes the hormone during dark periods and stops when it gets light. In many animals, this hormone plays a major role in the regulation of (b) ________ rhythms.

5. During a night's sleep, we gradually pass through five stages. Stage 1, which is a transition between waking and sleeping, has brain waves known as (a) ________. Stage 2 has brain waves with bursts of activity that are called (b) ________. Stage 3 and especially stage 4 are marked by high-amplitude, low-frequency (c) ________. Stage 4 is often considered the deepest stage of sleep because it is the most difficult from which to be awakened. During stage 4, heart rate, respiration, temperature, and blood flow to the brain are (d) ________. Together, stages 1, 2, 3, and 4 are referred to as (e) ________, in which we spend about 80% of our sleep time. About five or six times throughout the night, we enter a paradoxical state called (f) ________, which accounts for the remaining 20% of our sleep time. This stage is characterized by increased physiological arousal, "alert and awake" brain waves, and vivid dreaming.



6. From birth through old age, there is a decrease in total sleep time, from about 17 hours in newborns to 6.5 hours after age 60. In addition, one stage of sleep, called ________, decreases from 50% of sleep time in infancy to 20% in adulthood.

7. There are two different but not incompatible theories of why we sleep. The theory that says the purpose of sleep is to restore factors depleted throughout the day is the (a) ________. The theory that says sleep is based on an evolutionary need to conserve energy and escape nocturnal harm is the (b) ________.



8. Going to sleep is regulated by the following factors. An area in the hypothalamus that is the master sleep switch is called the (a) ________. An area in the hypothalamus that regulates circadian rhythms is called the (b) ________ nucleus. A brain area that contributes to our staying awake by sending neural signals that alert and arouse the forebrain is called the (c) ________. Several different sleep chemicals and (d) ________, some of which are made in the pons, regulate going into and out of the stages of sleep. In addition, we go to sleep several hours after a fall in body (e) ________ and get up when it starts to rise.

Answers: *1. (a) consciousness, (b) controlled processes, (c) automatic processes; 2. (a) circadian rhythm, (b) suprachiasmatic nucleus; 3. (a) jet lag, (b) sleep, (c) light; 4. (a) melatonin, (b) circadian; 5. (a) theta waves, (b) sleep spindles, (c) delta waves, (d) reduced, (e) non-REM sleep, (f) REM sleep; 6. REM sleep; 7. (a) repair theory, (b) adaptive theory; 8 (a) VPN, or ventrolateral preoptic nucleus, (b) suprachiasmatic, (c) reticular formation, (d) neurotransmitters, (e) temperature*

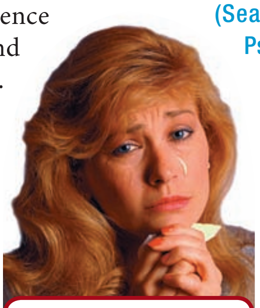
F. Cultural Diversity: Incidence of SAD

Problem and Treatment

Does light affect your mood?

Problem. For many animals, including humans, sunlight has a direct influence on resetting the circadian clock and affecting circadian rhythms. However, it was only recently that researchers found a direct nerve connection from receptors in the retina, which is located in the back of the eye, to a nucleus in the brain (suprachiasmatic nucleus in the hypothalamus, p. 150). This particular nerve pathway is not involved with seeing things but only with sensing the presence and amount of light, either sunlight or artificial light (M. W. Young, 2000). This means that humans have a neural pathway that is very responsive to the presence of light and may be involved in a mental health problem called seasonal affective disorder, or SAD.



Seasonal affective disorder (SAD) occurs in fall/winter.

Seasonal affective disorder, or ***SAD,*** is a pattern of depressive symptoms, such as loss of interest or pleasure in nearly all activities. Depressed feelings cycle with the seasons, typically beginning in fall or winter and going away in spring, when days are longer and sunnier. Along with depression are lethargy, excessive sleepiness, overeating, weight gain, and craving for carbohydrates. Recently, SAD has become a subtype (Seasonal Pattern Specifier) of major depression (American Psychiatric Association, 2000).

Cause and Treatment. What might trigger SAD is the amount of a brain neurotransmitter, serotonin, and the amount of a hormone made mostly at night, melatonin. Researchers suggest that the decreased sunlight in fall and winter causes a decrease in the amount of serotonin and an increase in melatonin, which may both act to trigger SAD (Anstett, 2006; G. W. Lambert et al., 2002).

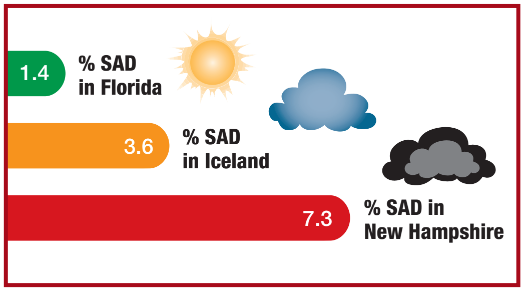
A nondrug treatment for SAD involves exposing a person to bright light in the morning for about one hour (Westrin & Lam, 2007). This treatment helps as many as 70% of individuals diagnosed with SAD (Anstett, 2006).

Because decreased sunlight appears to trigger SAD, you would expect the fewest cases of SAD in southern Florida, more cases in northern New Hampshire with its gloomy winters, and even more cases in northern Iceland, which has harsh winters with little or no sunlight.

Occurrence of SAD

Where is the highest rate of SAD?

As predicted, the graph shows that the incidence of SAD is very low (1.4%) among people who live in sunny Florida but about five times higher (7.3%) among people who live under the gray winter skies of northern New Hampshire (Magnusson, 2000). However, far north of New Hampshire is Iceland (see map), which has far less sunlight in fall and winter than New Hampshire. In spite of having less sunlight, Icelanders have only about half the incidence of SAD (3.6%) compared to residents of New Hampshire (Axelsson et al., 2002).



When researchers try to explain any unusual or unpredicted findings, they first check the methods and procedures used to measure the dependent variable, which in this case is the occurrence of SAD. However, researchers in Iceland used the same methods (questionnaires) and procedures that were used by researchers in the United States (Magnusson, 2000). If research methods and procedures were similar, what else would explain why the highest incidence of SAD was reported in New Hampshire and not in Iceland?

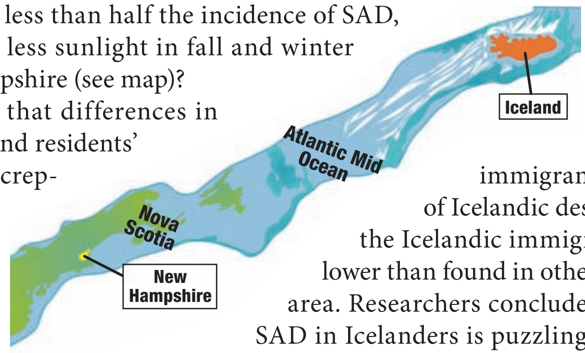
Cultural Differences

What's different about Icelanders?

Why did Icelanders report less than half the incidence of SAD, even though they have far less sunlight in fall and winter than residents of New Hampshire (see map)?

Researchers concluded that differences in methods, questionnaires, and residents' lifestyles or occupations could not explain this discrepancy. Rather, there may be two other explanations that involve cultural and genetic differences.

For 1,000 years, Icelanders have lived rather isolated in a very demanding, low-sunlight environment. Because of very harsh and unyielding environmental demands, Icelanders may have developed an emotional hardiness to deal with especially gloomy winters that trigger almost twice as many cases of SAD among residents of the northeastern United States.



Cultural differences explain why Iceland (far north) has less SAD than New Hampshire.

Another explanation for Icelanders' low incidence of SAD may involve genetic factors. For example, researchers studied a population of immigrants in Canada who were wholly of Icelandic descent. The incidence of SAD in the Icelandic immigrants was unexpectedly much lower than found in other residents of the same general area. Researchers concluded that the lower frequency of SAD in Icelanders is puzzling and may reflect both genetic and cultural differences, such as learning how to deal with isolation and living in harsh environments (Axelsson et al., 2002; Magnusson & Partonen, 2005).

Next, we'll discuss four explanations for something most of us experience every night—dreaming.

G. World of Dreams

Theories of Dream Interpretation

What do dreams mean?

Although some people insist that they never dream, research suggests everyone dreams during the night. In sleep laboratories, people awakened from REM periods report 80–100% of the time that they were having dreams with vivid, colorful, even bizarre images. Less frequently, people awakened from non-REM sleep or right after going to sleep report dreaming of dull, repetitive thoughts or of the colorful images reported after REM sleep (Domhoff, 2003). However, what you think of as dreaming usually occurs during REM sleep.

Everybody dreams, but what do dreams mean? Figuring out the meaning of dreams is a popular and scholarly activity for the more than 400 psychologists, physiologists, anthropologists, artists, "dream workers," and swamis who attend the annual meeting of the Association for the Study of Dreams. The focus of this group is to discover meaning in dreams—no easy task, since there are many theories.

Dreaming of a plane crash creates as much anxiety as hearing about a real crash.

We know these 400 scholars take dream interpretation seriously, but do others? Researchers surveyed people in India, South Korea, and the United States about the meaning of dreams and found that most people from these countries believe dreams contain hidden meanings. This prompted the next question: Are people affected by their dreams? Researchers found that dreaming of a plane crash created greater anxiety than consciously thinking about a plane crash or hearing that the terrorist threat level had been raised, and the same level of anxiety as hearing about an actual crash that took place on the route they planned to take (Morewedge & Norton, 2009).

It seems the majority of people believe dreams have meaning, but how does one go about interpreting dreams? We'll discuss four currently popular psychological theories of dream interpretation, beginning with the most famous and still controversial theory, Freud's theory of dream interpretation.

1 Freud's Theory of Dream Interpretation

In the preface to his famous book *The Interpretation of Dreams,* Freud (1900) wrote, "This book contains, even according to my present-day judgment, the most valuable of all the discoveries it has been my good fortune to make. Insight such as this falls to one's lot but once in a lifetime." Before 1900, psychologists believed that dreams were meaningless and bizarre images. However, Freud's theory changed all that when he said dreams were a way ("the royal road") to reach our unconscious thoughts and desires.

Freud believed dreams reveal repressed desires.

Freud's theory of dreams says that we have a "censor" that protects us from realizing threatening and unconscious desires or wishes, especially those involving sex or aggression. To protect us from having threatening thoughts, the "censor" transforms our secret, guilt-ridden, and anxiety-provoking desires into harmless symbols that appear in our dreams and do not disturb our sleep or conscious thoughts.

Freud made two main points no one had made before: Dreams contained symbols that had meaning, and dreams could be interpreted. For example, Freud (1900) said male sex symbols are long objects, such as sticks, umbrellas, and pencils; female sex symbols are hollow things, such as caves, jars, and keyholes. Freud believed a psychoanalyst's (Freudian therapist's) task was to interpret dream symbols, which were "the royal road" to uncover a client's threatening but unconscious desires, needs, and emotions (B. Bower, 2001).

Current psychoanalysts agree with Freud that dreams have meaning and can represent past, present, or future concerns, fears, or worries (R. Greenberg & Perlman, 1999). However, as you'll see next, many non-Freudian therapists disagree with Freud's idea that a dream's contents are necessarily symbols or disguised thoughts for threatening, unconscious wishes and desires (Domhoff, 2003).

2 Extensions of Waking Life

Many therapists believe that dreams are extensions of waking life (Kramer, 2006b; Pesant & Zadra, 2006).

The theory that ***dreams are extensions of waking life*** means that our dreams reflect the same thoughts, fears, concerns, problems, and emotions that we have when awake.

Therapist and researcher Rosalind Cartwright (1988) says, "People simply don't remember their dreams very well. The therapist's task is often like trying to reconstruct a 500-page novel from just the last page. But dreams collected from a single night in the sleep lab read like chapters in a book. They illuminate current concerns and the feelings attached to them" (p. 36). Cartwright believes that patients suffering from depression or marital problems cope by repeating their fears and concerns in their dreams. She advises that as soon as you awaken from a reoccurring bad dream, you should figure out why the dream is upsetting and then visualize how you would like the dream to end the next time it occurs. With practice, people can gain control over reoccurring bad dreams. Cartwright concludes there is little reason to pay attention to dreams unless they keep you from sleeping or cause you to wake up in a panic (Cartwright, 2002). In these cases, therapists find dream interpretation a useful tool in helping clients better understand the personal and emotional problems that are contributing to their bad dreams.

Therapists believe dreams reflect waking concerns.

Other researchers believe that dreams have a variety of uses, ranging from dealing with threatening situations, resolving personal and emotional problems, sparking artistic creativity, to even solving scientific, mathematical, or other kinds of puzzles (B. Bower, 2001).

The next theory looks at dreams as reflecting neural activity.

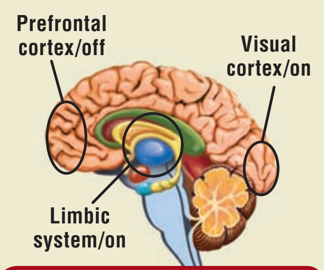
Photo Credit: © AP Images/Peter Dejong

3 Activation-Synthesis Theory

In the late 1970s, psychiatrist and neurophysiologist J. Allan Hobson published a new theory of dreams that totally disagreed with many therapists' as well as Freud's theory of dreams. Recently, Hobson (2002) published a revised version of this 1970s theory.

The ***activation-synthesis theory*** says that dreaming occurs because brain areas that provide reasoned cognitive control during the waking state are shut down. As a result, the sleeping brain is stimulated by different chemical and neural influences that result in hallucinations, delusions, high emotions, and bizarre thought patterns that we call dreams.

Unlike Freud, Hobson believes that dream interpretation is questionable, since there is no way to know whether dreams are just bizarre events or contain useful or valid information about a person's problems.



During REM, prefrontal cortex turned off; visual cortex and limbic system turned on.

Brain scans. The bases for Hobson's revised theory come from brain scans of neural activity taken while subjects were in REM sleep. Researchers reported that during REM sleep, the area responsible for executive functions (prefrontal cortex), such as thinking, planning, and reasoning, had reduced activity, while areas involved in emotions (limbic system) and visual experiences (visual cortex) had increased activity (A. R. Braun et al., 1998). Hobson believes that this pattern of brain activity explains why dreams are emotional (limbic system/on) and full of visual images (visual cortex/on) but are often strange, bizarre, and poorly planned or thought out (prefrontal cortex/off) (Domhoff, 2003). Similar to the other dream theories, the activation-synthesis theory also has critics (Kramer, 2006a). They believe the content of dreams can contain useful and meaningful information about a person's life (Domhoff, 2005a, 2005b).

The fourth theory looks at dreams as having an important evolutionary function.

4 Threat Simulation Theory

Currently, there is one well-known and well-researched evolutionary dream theory that was developed by a Finnish researcher named Antti Revonsuo and is called threat simulation theory (Revonsuo, 2000a, 2000b).

The ***threat simulation theory*** says that dreaming serves a biological function by repeatedly simulating events that are threatening in our waking lives so our brain can practice how it perceives threats and so we can rehearse our responses to these events.

I dreamed of a dangerous bear to rehearse my response to this threat so I was prepared for my upcoming camping trip.

Based on this theory, our ancestors would have dreamed about threatening life events and used their dreams to rehearse the skills needed for survival. This theory may explain why I (H. K.) dreamed of an angry, dangerous bear approaching me just before my planned camping trip in the woods.

Much research has been done to carefully test this theory, and the results have been mixed (Zadra et al., 2006). Research shows that childhood trauma and recurrent dreams are associated with more threatening dreams (Valli et al., 2005; Valli & Revonsuo, 2009). But we all seem to have dreams that do not involve any threatening events (Malcolm-Smith et al., 2008).

Next, we'll examine what people dream about.

Typical Dreams

What do people dream about?

Although many animals, including bats, whales, monkeys, moles, dogs, and cats (but not snakes), have REM sleep, we do not know if they dream. We know that humans dream because they tell us. Thousands of descriptions of dreams have been obtained from people who had just been aroused from REM sleep and others who were asked to record their dreams at home. One researcher (Van de Castle, 1994) has catalogued these descriptions and found that typical dreams have the following characteristics:

- dreams have several characters;
- they involve motion such as running or walking;
- they are more likely to take place indoors than outside;
- they are filled with visual sensations but rarely include sensations of taste, smell, or pain;
- they seem bizarre because we disregard physical laws by flying or falling without injury;
- they may be recurrent—for example, dreams of being threatened, being pursued, or trying to hide;
- they more frequently involve emotions of anxiety or fear than joy or happiness;
- they rarely involve sexual encounters and are almost never about sexual intercourse;
- rarely can we control or dream about something we intend to;
- dreams usually have visual imagery and are in color in sighted people, but in people blind from birth, dreams are never visual but only tactile, olfactory (smell), or gustatory (taste).

Many people dream about flying, running, falling, or hiding.

Researchers conclude that although individual dreams represent unique experiences, the format in which we dream, such as flying, falling, running, or hiding, is shared by others (Domhoff, 2003). One common question is: Why do some better remember their dreams? One researcher found that the ability to remember dreams was positively related or correlated with how well one can create mental images during waking and was not related to verbal ability, which might influence dream recall (Foulkes, 2003).

Sometimes dreams can turn into nightmares, which we'll discuss next in considering sleep problems and treatments.

H. Application: Sleep Problems & Treatments

Occurrence

How big is the problem?

In the United States, about 50–70 million people experience some kind of sleep problem (Gupta, 2006). For example, some adults stop breathing in their sleep (sleep apnea); some have trouble going to or staying asleep (insomnia); a small percentage go from being wide awake to a very deep sleep quickly and without warning (narcolepsy); and 69% of all children experience some type of sleep disturbance at least a few nights a week (Carskadon, 2006). We'll discuss a number of these sleep problems as well as possible treatments, beginning with one of the more common problems, insomnia.

Insomnia

In the United States, about 33% of adults report some type of insomnia (Ohayon & Guilleminault, 2006).

Insomnia **refers to difficulties in either going to sleep or staying asleep through the night. Insomnia is associated with a number of daytime complaints, including fatigue, impairment of concentration, memory difficulty, and lack of well-being.**

Psychological causes. Common psychological causes of insomnia include experiencing an overload of stressful events, worrying about personal or job-related difficulties, grieving over a loss or death, and coping with mental health problems. For many middle-aged working people, job stress is a major cause of insomnia and other sleep problems (Kalimo et al., 2000). For students, common causes of insomnia are worry about exams, personal problems, and changes in sleep schedule, such as staying up late Saturday night and sleeping late on Sunday morning. Then Sunday night students are not tired at the usual time and may experience insomnia.

Physiological causes. Common physiological causes of insomnia include changing to night-shift work, which upsets circadian rhythms, having medical problems or chronic pain, and abusing alcohol or other substances (sedatives). All can disrupt going to and staying asleep.

There are effective nondrug (psychological) and drug treatments for bouts of insomnia.

Nondrug Treatment

Nondrug treatments for insomnia may differ in method, but all have the same goal: to stop the person from excessive worrying and reduce tension, which are major psychological causes of insomnia. One proven cognitive-behavioral method of reducing insomnia is to establish an optimal sleep pattern (Bootzin & Rider, 1997).

Establishing an Optimal Sleep Pattern

Follow these eight steps so that sleeping becomes more regular and efficient.

1. Go to bed only when you are sleepy, not by convention or habit.

2. Put the light out immediately when you get into bed.

3. Do not read or watch television in bed, since these are activities that you do when awake.

4. If you are not asleep within 20 minutes, get out of bed and sit and relax in another room until you are tired again. Relaxation can include tensing and relaxing your muscles or using visual imagery, which involves closing your eyes and concentrating on some calm scene or image for several minutes.

5. Repeat step 4 as often as required, and also if you wake up for any long periods of time.

6. Set the alarm to the same time each morning, so that your time of waking is always the same. This step is very important because oversleeping or sleeping in is one of the primary causes of insomnia the next night.

7. Do not nap during the day because it will throw off your sleep schedule that night.

8. Follow this program rigidly for several weeks to establish an efficient and regular pattern of sleep.

Results. In one study, participants who had chronic insomnia reduced their time awake (after going to sleep) by 54% using cognitive-behavioral therapy, compared to 16% using relaxation exercises and 12% using a placebo treatment (Edinger et al., 2001).

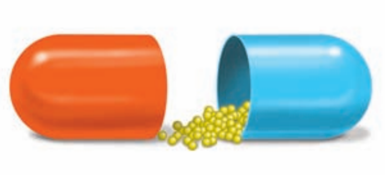
Serious problems with chronic insomnia may be treated, in the short term, with drugs.

Drug Treatment

Many stressful situations, such as losing a loved one, going through a divorce, or dealing with a physical injury, may result in chronic insomnia, which is defined as lasting longer than three weeks. In these cases, doctors may prescribe one of the following sleep-inducing drugs.

Benzodiazepines ***(ben-zo-die-AS-ah-peens)*** **(Dalmane, Xanax, Restoril) reduce anxiety, worry, and stress and are effective and relatively safe when taken in moderate doses in the short-term (2–4 weeks) treatment of insomnia (Czeisler et al., 2006).**

However, prolonged use of benzodiazepines, especially at higher doses, may lead to dependence on the drug and serious side effects, such as memory loss and excessive sleepiness. Reduced side effects are one advantage of the next drugs.



Nonbenzodiazepines **(Ambien, Sonata, Lunesta) are rapidly becoming popular sleeping pills because they are fast acting, reduce daytime drowsiness, have fewer cognitive side effects, and are less likely to lead to dependence (Lee-Chiong & Sateia, 2006).**

In the United States alone, about 42 million sleeping pill prescriptions were filled in 2005 and sales of sleeping pills reached $2.8 billion (Saul, 2006; Szabo, 2006). However, studies have found that cognitive-behavioral therapy is either as effective as or superior to sleeping pills in treating and reducing chronic insomnia (Perlis et al., 2003; Sivertsen et al., 2006).

Photo Credits: left, © Rob Bartee/SuperStock; center, © Laurence Monneret/Getty Images

Sleep Apnea

In the United States, about 20 million adults have insomnia because they stop breathing, a problem called sleep apnea.

Sleep apnea **refers to repeated periods during sleep when a person stops breathing for 10 seconds or longer. The person may repeatedly stop breathing, momentarily wake up, resume breathing, and return to sleep. Repeated awakenings during the night result in insomnia and leave the person exhausted during the day but not knowing the cause of the tiredness.**

The chances of developing sleep apnea increase if a person is an intense and frequent snorer, is overweight, uses alcohol, or takes sedatives (benzodiazepines) (Chokroverty, 2000). Some people with sleep apnea may wake up an astonishing 200–400 times a night, which also results in insomnia (Czeisler et al., 2006).

The simplest treatment for sleep apnea is to sew tennis balls into the back of a pajama top so the person cannot lie on his or her back, which increases the chances of sleep apnea. For more severe cases, the most effective therapy is a device that blows air into a mask worn over the nose that helps keep air passages open (see photo below). An alternative treatment is for people to wear a mouth device that helps to move the lower jar forward and thus open the airway (H. Fields, 2006). In severe cases, people may undergo surgery to remove tonsils or alter the position of the jaw (A. E. Sher, 2006).

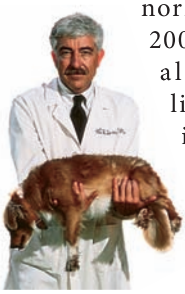
Narcolepsy

As a child, Rainer would nod off in classes. As an adult, he may fall asleep in the middle of a meeting, during a conversation, or while driving! He has fleeting urges to sleep throughout the day and always feels fatigued (Marschall, 2007). Rainer has narcolepsy.

Narcolepsy ***(NAR-ko-lep-see)*** **is a chronic disorder that is marked by excessive sleepiness, usually in the form of sleep attacks or short periods of sleep throughout the day. The sleep attacks are accompanied by brief periods of REM sleep and loss of muscle control (cataplexy), which may be triggered by big emotional changes.**

Narcoleptics describe their sleep attacks as irresistible. They report falling asleep in very inappropriate places, such as while carrying on a conversation or driving a car. In many cases, these sleep attacks make it difficult for narcoleptics to lead normal lives.

Like humans, some dogs get narcolepsy, such as the one held below by famous sleep researcher William Dement. Researchers have recently discovered that narcolepsy occurred in dogs and mice when certain brain cells, called hypocretin neurons, either were absent or did not respond normally (Mignot, 2000). Researchers also found very little hypocretin in the spinal fluid of narcoleptics (Mignot, 2002). When "narcoleptic" dogs were given the missing hypocretin, their narcoleptic symptoms were reversed. Researchers believe that a hypocretin-based medicine could soon be on the market and provide a new and effective way to treat narcolepsy, which affects about 150,000 Americans (Marschall, 2007).



Sleep Disturbances

Night Terrors

A 4-year-old boy sits up in the night and begins screaming. This is an example of a night terror.

Night terrors, **which occur during stage 3 or 4 (delta sleep), are frightening experiences that often start with a piercing scream, followed by sudden waking in a fearful state with rapid breathing and increased heart rate. However, the next morning the child has no memory of the frightening experience. About 3–7% of children have night terrors.**

A child in the grip of night terrors is difficult to calm and, even if severely shaken, may need several minutes to regain full awareness. Night terrors are most common in children aged 5–7 and disappear by adolescence (Heussler, 2005). Caregivers should take enough time to comfort and soothe the frightened child, who usually will go back to sleep.

Nightmares

Besides night terrors, about 25–70% of all children aged 3–6 have nightmares, and about 47% of college students report having them once a month (Picchioni et al., 2002).

Nightmares, **which occur during REM sleep, are very frightening and anxiety-producing images that occur during dreaming. Nightmares usually involve great danger—being attacked, injured, or pursued. Upon awakening, the person can usually describe the nightmare in great detail.**

Nightmares usually stop when the person wakes, but feelings of anxiety or fear may persist for some time; it may be difficult to go back to sleep. One effective treatment for nightmares involves regular use of anxiety-reduction techniques (described in Module 21).

Sleepwalking

One of the more unusual sleep disturbances is sleepwalking.

Sleepwalking **usually occurs in stage 3 or 4 (delta sleep) and consists of getting up and walking while literally sound asleep. Sleepwalkers generally have poor coordination, are clumsy but can avoid objects, can engage in very limited conversation, and have no memory of sleepwalking.**

Occasional sleepwalking is considered normal in children; frequent sleepwalking in adults may be caused by increased stress, sleep deprivation, or mental problems (Cartwright, 2006). Sleepwalking can be a serious problem because of the potential for injury and harm to oneself and others (imagine sleepwalking out of the house onto the highway).

Sleep researchers estimate that as many as 70 million Americans have one or more of the sleep problems discussed above. Sleep disorders clinics have been set up to treat the more serious problems (R. S. Rosenberg, 2006).

Summary Test

A. Continuum of Consciousness

1. The awareness of our own thoughts and feelings, as well as of other internal and external stimuli, is called (a) ________________, which occurs on a continuum from being very alert to being very unresponsive. Those activities that require our full awareness and concentration to reach some goal are called (b) ________________. Those activities that require little awareness and minimal attention and that do not interfere with other ongoing activities are called (c) ________________.

2. Fantasizing or dreaming while awake, which often occurs during automatic processes, is called (a) ________________. If, under the influence of drugs, meditation, or hypnosis, we perceive our internal and external environments in ways that differ from normal, we may be said to have entered (b) ________________ of consciousness. Sigmund Freud suggested that we push unacceptable wishes or desires into our (c) ________________. A blow to the head or general anesthesia can produce complete loss of awareness, which is called (d) ________________. Mental and emotional processes that, although we are unaware of them, influence our conscious thoughts and behaviors form a kind of memory called (e) ________________.

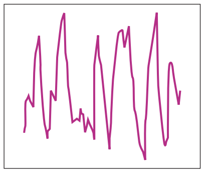
B. Rhythms of Sleeping & Waking

3. A biological clock that is set to run on a time cycle of 24–25 hours is called a (a) ________________. In animals (and probably humans) the biological clock for the sleep-wake cycle is located in a part of the hypothalamus called the (b) ________________.

4. If we travel across time zones and our circadian rhythm gets out of phase with the local clock time, we experience difficulty in going to sleep and getting up at normal times, a condition known as (a) ________________. Researchers have been able to reset circadian rhythms in workers by exposing them to bright light during certain times; this is called (b) ________________ therapy.

5. In the center of the animal and human brain is the pineal gland, a small group of cells that secrete the hormone ________________. This hormone has a major role in regulating the sleep-wake cycle in animals; its role in humans is less clear.

C. World of Sleep



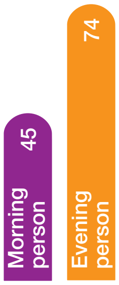
6. Researchers study sleep and wakefulness by recording the activity of brain cells and muscles. Electrical brain activity is recorded in tracings called an (a) ________________. The height of a wave is called its (b) ________________, and the number of wave cycles that occur in one second is called the (c) ________________.

7. If you are awake and alert, your brain waves have a very high frequency and low amplitude and are called (a) ________________ waves. If you close your eyes and become relaxed and drowsy, your brain waves remain low in amplitude but decrease slightly in frequency; these are called (b) ________________ waves.

8. Researchers divide sleep into five stages. Stage 1, the transition from wakefulness to sleep, is marked by (a) ________________ waves and a feeling of gradually losing responsiveness to the outside world. Stage 2 represents the first real phase of sleep and is marked by high-frequency bursts of brain activity called (b) ________________. In stage 3 and especially stage 4, there are high-amplitude, low-frequency brain waves called (c) ________________. Stage 4 may be considered the deepest stage of sleep, since it is the most difficult from which to wake someone. Together, stages 1, 2, 3, and 4 are referred to as (d) ________________ sleep, which makes up about 80% of sleep time.

9. About every 30–90 minutes throughout sleep, you leave stage 4 (delta sleep) and progress backward to stage 2. From stage 2, you enter a new stage of sleep marked by high-frequency, low-amplitude brain waves that look identical to (a) ________________ waves. This stage is called (b) ________________ sleep because your eyes move rapidly back and forth underneath closed eyelids. During this stage, you are asleep and lose muscle tension in the neck and limbs. However, your brain waves are like those when you are awake and alert, and there is increased arousal of many physiological responses. When awakened from this stage, people usually (80–100% of the time) report that they have been (c) ________________.

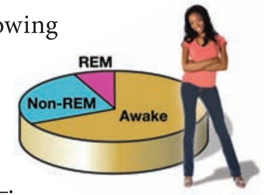
D. Research Focus: Circadian Preference



10. People who prefer to get up earlier, go to bed earlier, and engage in morning activities and whose body temperature rises more quickly in the morning and peaks earlier at night are called (a) ________________. People who prefer to get up later, go to bed later, and engage in afternoon-evening activities and whose body temperature rises more slowly in the morning and peaks later at night are called (b) ________________.

Photo Credit: top left, © Michael S. Yamashita/Corbis

E. Questions about Sleep



11. Going to sleep is regulated by the following factors. An area in the hypothalamus that is the master sleep switch is called the (a) ______________. An area in the hypothalamus that regulates circadian rhythms is called the (b) ______________. A brain area that contributes to our staying awake by sending neural signals that alert and arouse the forebrain is called the (c) ______________. Several different sleep chemicals and (d) ______________, some of which are made in the pons, regulate going into and out of the stages of sleep. In addition, we go to sleep several hours after a fall in body (e) ______________ and get up when it starts to rise.

12. From infancy through old age, there is a gradual reduction in total (a) ______________ time, from about 17 to 6.5 hours, and a reduction in the percentage of (b) ______________ sleep, from about 50% to 20%.

13. The theory that says we sleep because we use up vital factors during the day that must be replaced at night is called the (a) ______________ theory. The theory that says we sleep to conserve energy and avoid potential harm and injury from nocturnal predators is called the (b) ______________ theory.

14. When we are sleep deprived, the next day we have difficulty performing tasks that require (a) ______________. Sleep deprivation also affects the body by compromising our (b) ______________ system, which increases our vulnerability to viral infections.

F. Cultural Diversity: Incidence of SAD

15. The occurrence of a pattern of depressive symptoms that generally begin in the fall and winter and disappear in the spring is called (a) ______________. Although the incidence of this disorder is lower in Florida and higher in the northeastern United States, it is not higher in Iceland, which is much farther north than New Hampshire. One reason Icelanders report a lower incidence of SAD is because of their (b) ______________ values.

G. World of Dreams

16. According to Freud's theory, we have a "censor" that protects us from (a) ______________. This involves transforming threatening, unconscious desires into harmless symbols. According to Hobson's revised theory, called the (b) ______________, the sleeping brain produces hallucinations, delusions, high emotions, and bizarre thoughts that we call dreams. During REM sleep, some parts of the brain are turned on, (c) ______________, and some are turned off, (d) ______________. According to many therapists and sleep-dream researchers, such as Cartwright, dreams are (e) ______________ of waking thoughts and concerns, especially emotional ones, and provide clues to a person's problems. An evolutionary dream theory developed by Revonsuo is (f) ______________ theory.

H. Application: Sleep Problems & Treatments

17. A common sleep problem that includes difficulty in going to sleep or remaining asleep throughout the night is called (a) ______________. A nondrug treatment is to use a proven (b) ______________ method. Drug treatment for insomnia usually involves prescribing (c) ______________. Insomnia caused when the sleeper stops breathing and wakes up is called (d) ______________.

18. If children wake up screaming and in a great fright, they have experienced (a) ______________ but will remember nothing the next morning. When adults experience emotionally charged, frightening images during their dreams, they are having (b) ______________. If a person walks or carries out other behaviors during sleep, it is called (c) ______________, which may be caused by increased stress. A relatively rare condition that involves irresistible attacks of sleepiness, brief periods of REM, and often loss of muscle control is called (d) ______________.

Answers: *1. (a) consciousness, (b) controlled processes, (c) automatic processes; 2. (a) daydreaming, (b) altered states, (c) unconscious, (d) unconsciousness, (e) implicit or nondeclarative memory; 3. (a) circadian rhythm, (b) suprachiasmatic nucleus; 4. (a) jet lag, (b) light; 5. melatonin; 6. (a) electroencephalogram, or EEG, (b) amplitude, (c) frequency; 7. (a) beta, (b) alpha; 8. (a) theta, (b) sleep spindles, (c) delta waves, (d) non-REM; 9. (a) beta, (b) REM, (c) dreaming; 10. (a) morning people, (b) evening people; 11. (a) ventrolateral preoptic nucleus, (b) suprachiasmatic nucleus, (c) reticular formation, (d) neurotransmitters, (e) temperature; 12. (a) sleep, (b) REM; 13. (a) repair, (b) adaptive; 14. (a) concentration, (b) immune; 15. (a) SAD, or seasonal affective disorder, (b) cultural; 16. (a) threatening desires/wishes, (b) activation-synthesis theory, (c) limbic system and visual cortex, (d) prefrontal cortex, (e) extensions, (f) threat simulation; 17. (a) insomnia, (b) cognitive-behavioral, (c) benzodiazepines or nonbenzodiazepines, (d) sleep apnea; 18. (a) night terrors, (b) nightmares, (c) sleepwalking, (d) narcolepsy*

Texting: How Distracting Can It Be?

YouTube has videos of young adults texting while driving, and Facebook has a group called *I Text Message People While Driving and I Haven't Crashed Yet!* Many people are routinely texting while on the move, whether it's waiting in line for coffee, walking across the street, or driving.

QUESTIONS

1 Which type of brain wave occurs when you are text messaging?

Is texting a big enough distraction to put people at risk of danger? The American College of Emergency Physicians believes so. They report that many people arrive in the emergency department with serious, sometime fatal injuries because they weren't paying attention to their surroundings while texting. A large-scale, devastating train crash outside of the Los Angeles area demonstrates the real danger of texting. In this accident, 25 people died and 113 were injured when a commuter train collided head-on with a freight train. An investigation found that text messaging (the driver of the commuter train had texted just seconds before the crash) was likely the distraction that led to the tragic accident.

2 How might perception explain why the train driver collided with another train?

Be honest—how many times have you been talking on your cell phone or texting while driving and looked up only to be surprised you haven't been paying attention to the road and felt thankful to be alive? Use of a cell phone in any way while driving increases the risk of an accident, and texting is more dangerous than talking. A driver's risk of getting into an accident is believed to increase sixfold when texting and fourfold when talking on a handheld cell phone.

3 Why have you forgotten that you're driving while talking or texting?

Such life-threatening distractions are not limited to drivers. Research shows that pedestrians talking on cell phones are less likely to look for traffic before walking into the street and are slower in crossing the road, thereby increasing their risk of getting into an accident with a vehicle. Just imagine how much more serious the distractions would be if they were texting!

4 What type of research setting is used to observe people's behaviors in their normal environments?

5 How is walking across the street while talking on your cell phone different from walking while chewing gum?

Not only is texting distracting during our waking day, but for some, it can be a problem during sleep. Teens and young adults, in particular, go to sleep with their phones plugged in right by their beds. With every beep of a new text message, they awaken, disrupting their sleep and thereby affecting their cognitive and physical performance the next day. There have even been rumors of sleep texting—that is, texting during sleep only to discover in the morning the texts sent in the middle of night. The dangers of texting seem countless: injuring oneself or others, death, and tremendous embarrassment (who knows what you might text while asleep!). (Adapted from ACEP, 2008; S. Flagg, 2008; Hatfield & Murphy, 2006; Leming, 2008; Michels, 2008; Novotney, 2009; Villarreal, 2008)

6 What stage of sleep must people be in if they're unknowingly texting during the night?

Study Guide and WebTutor

Work through the corresponding module in your Study Guide for tips on how to study effectively and for help learning the material covered in the book. WebTutor (an online Study Tool accessed through your eResources account) provides an interactive version of the Study Guide.

Suggested Answers to Critical Thinking

1. When you are awake and alert, concentrating on your text messaging, you experience brain wave activity called beta waves, which have high frequency and low amplitude.

2. At its simplest, driving requires that the driver perceive what is going on in the driving environment, such as perceiving that a train is rapidly approaching. If the driver's attention is focused on texting, the driver could miss perceiving the train approaching and therefore not take the necessary action to escape the dangerous situation.

3. The problem with talking or texting while driving is that we have the ability to focus all of our attention on only one thing, which is an example of controlled processes. The focused attention required to carry out controlled processes (use of cell phone) interferes with the execution of other ongoing activities (driving).

4. Watching people's behaviors as they cross the street is an example of research in the naturalistic setting, a relatively normal environment in which researchers gather information by observing individuals' behaviors without attempting to change or control the situation.

5. Walking across the street while talking on your cell phone is an example of controlled processes (talking on your cell phone requires most of your attention, leaving little focus on walking across the street). Walking while chewing gum is an example of automatic processes (walking across the street receives most of your attention while you are almost automatically chewing gum, which doesn't interfere with crossing the street).

6. Stage 4 sleep is when you have delta brain waves and your body can move. This is when sleeptalking and sleepwalking may occur. As such, people may be texting (probably incoherent messages) during stage 4 sleep. For people who have REM behavior disorder, it may be possible to text during REM sleep, as the voluntary muscles that should be paralyzed are not.

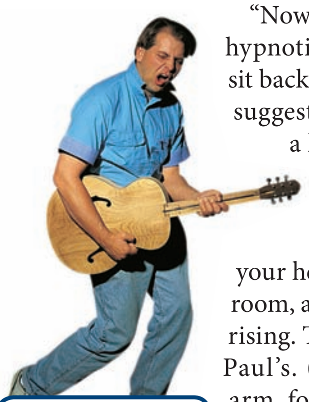
Hypnosis

Why do people do stupid things?

Consider the experience of one of us (R.P.) some years ago. One night a friend and I were sitting in the front row of one of the longest-running nightclub acts in San Diego. We were going to watch a psychologist-turned-performer who entertained locals and tourists by hypnotizing volunteers from the audience and asking them to perform funny, strange, and somewhat embarrassing acts on a stage. Before the hypnotist appeared, my friend Paul repeated for the tenth time that nothing would get him up on that stage.

Finally the lights dimmed, and the hypnotist appeared. He was a very good performer and soon had the audience laughing at his jokes and believing that he was a wonderful, trustworthy human being.



After being hypnotized, shy Paul imitated Elvis.

"Now we come to the interesting part," the hypnotist said in a low, soothing voice. "Just sit back and relax and, if you wish, follow my suggestions." The hypnotist slowly repeated a list of suggestions: "You cannot bend your right arm . . . you cannot close your eyes . . . your left arm will become rigid and slowly rise above your head." As I looked around the dimly lit room, a number of rigid left arms were slowly rising. To my surprise, one of those arms was Paul's. (I could not or would not raise my arm, for fear that some of my students were in the audience and would never let me forget whatever foolish behavior I might have performed.)

At the end of the show, we all filed out. Paul said nothing until we were in the car. Then he turned and asked, "Why did you let me get on stage and be hypnotized? You better not tell anyone."

I smiled and replied, "You were terrific. That was the best imitation of Elvis Presley ever done by a reluctant friend." Then I added, "I might have been tempted to try Mick Jagger."

Although I have changed Paul's name and minor details to protect his pride and reputation, his story is essentially true and illustrates some of the strange behaviors that occur under hypnosis.

For over 200 years, psychologists have puzzled over what hypnosis really is (Lynn et al., 2007a). Some believe hypnosis is a special state during which individuals experience hallucinations (seeing an imaginary fly), carry out suggestions (swatting an imaginary fly), or report decreased pain after receiving a painful stimulus (M. R. Nash, 2001). Recently, researchers have questioned whether hypnosis is a special state, since they found that nonhypnotized individuals responded to imaginative suggestions (see an imaginary fly) just as if they were hypnotized (Kirsch & Braffman, 2001). We'll discuss the debate over what hypnosis really is.

Local newspapers often carry ads claiming that hypnosis can help you stop smoking, lose weight, get rid of phobias, induce immediate relaxation, reduce pain, or increase motivation to tackle difficult projects. We'll discuss whether these claims for hypnosis are true as well as current medical uses of hypnosis.

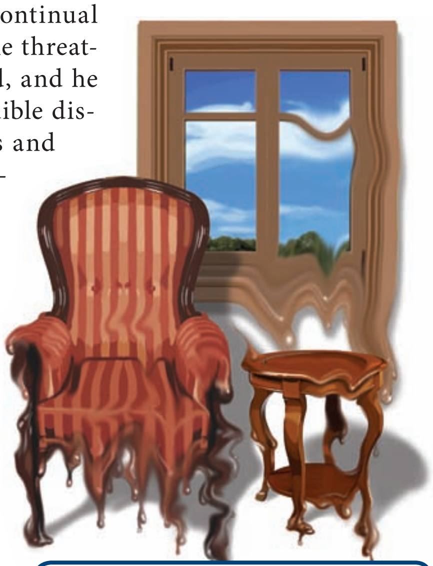
Drugs

What was the first bicycle trip?

Although only some psychologists believe that hypnosis may change a person's state of consciousness, most agree that there are a number of drugs, legal and illegal, that can alter consciousness. One example of how a drug greatly altered consciousness happened quite by chance and began with a bike ride.

On April 19, 1943, Albert Hofmann left his laboratory, got on his bike, and began pedaling his regular route home. As Albert pedaled, the world around him began to change into threatening, wavering forms that appeared distorted, as if he was looking into a curved mirror.

Once he reached home and entered his house, the familiar objects and pieces of furniture assumed grotesque and threatening forms that were in continual motion. After a while, the threatening forms disappeared, and he began to enjoy an incredible display of visual sensations and illusions. Albert saw fantastic images that opened and closed in circles and spirals that seemed to explode into colored fountains. Even stranger, sounds such as the passing of a car or opening of a door were transformed into visual images with changing forms and colors (adapted from A. Hofmann, 1983).



Albert Hofmann tried out his newly discovered drug (LSD) and watched his furniture change into strange shapes.

The cause of Albert Hofmann's startling visual experiences was a drug that Hofmann had previously discovered in his laboratory and had taken before his bike ride. The drug was LSD (*d*-lysergic acid diethylamide) and is now well known to cause strange and bizarre visual experiences, called hallucinations. Because Hofmann had not known about LSD's great potency (compared to other drugs, a very small dose of LSD has a very large effect), he had actually taken a dose that was four times the usual amount. We will discuss LSD as well as other illegal and legal drugs that can alter consciousness.

What's Coming

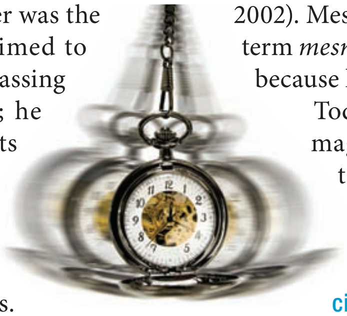
We'll discuss what hypnosis is, how a person is hypnotized, what a person does and does not do under hypnosis, and the uses of hypnosis. We'll examine the use and abuse of both legal and illegal drugs, such as stimulants, hallucinogens, opiates, marijuana, and alcohol. We'll discuss how drugs affect the nervous system, their dangers, and the treatments for drug abuse.

Let's begin with an interesting and supposedly mind-altering force called animal magnetism.

A. Hypnosis

Definition

What is hypnosis?



In the late 1700s, Anton Mesmer was the hit of Paris, France, as he claimed to cure a variety of symptoms by passing a force into a patient's body; he called this force animal magnetism. So many patients testified to the success of animal magnetism as a treatment that a committee of the French Academy of Science was appointed to investigate. The committee concluded that many of Mesmer's patients were indeed cured of various psychosomatic problems. However, the committee thought it safer to ban the future use of animal magnetism because they could neither identify what it was nor verify Mesmer's claims that such a force existed (Shermer, 2002). Mesmer's name lives on in our vocabulary: We use the term *mesmerized* to describe someone who is acting strangely because he or she has been spellbound or hypnotized.

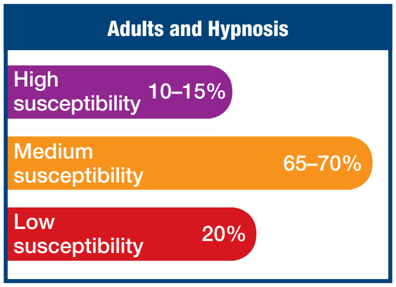
Today we know that Mesmer was not creating animal magnetism but rather was inducing hypnosis. Here's the definition agreed to by the American Psychological Association's Division of Psychological Hypnosis (1993):

Hypnosis **is a procedure in which a researcher, clinician, or hypnotist suggests that a person will experience changes in sensations, perceptions, thoughts, feelings, or behaviors.**

We'll begin by answering three questions that are often asked about hypnosis.

Who Can Be Hypnotized?

Despite what you may have seen on television or at a stage show, not everyone can be easily hypnotized.



As shown in the graph above, there is considerable variation in susceptibility to being hypnotized: About 20% of adults have low susceptibility to hypnosis, which means that they cannot be easily hypnotized. About 65–70% of adults have medium susceptibility, and the remaining 10–15% have high susceptibility to being hypnotized (Song, 2006a; Spiegal, 2005).

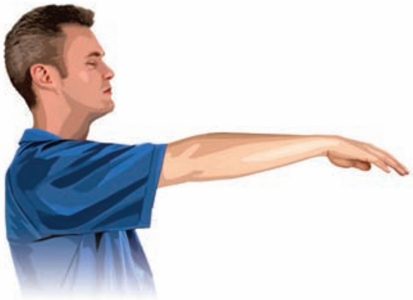
Hypnotic susceptibility is not correlated with introversion, extraversion, social position, intelligence, willpower, sex, compliance, gullibility, being highly motivated, or being a placebo responder (Kirsch & Lynn, 1995; M. R. Nash, 2001).

The one trait that is highly correlated with susceptibility to hypnosis is a remarkable ability to respond to imaginative suggestions. Individuals who have this trait are highly susceptible to being hypnotized (Kirsch & Braffman, 2001).

Who Is Susceptible?

The standard test for susceptibility is to hypnotize a person and then give a fixed set of suggestions (Weitzenhoffer, 2002). The best-known test is the Stanford Hypnotic Susceptibility Scale, which asks the individual to carry out a series of both simple suggestions—for example, "Your arm is moving up"—and complex suggestions—for example, "Your body is heavy and you cannot stand up."

For instance, the person in the photo below is carrying out the hypnotic suggestion, "Your right arm is weightless and moving up." One such scale has a series of 12 activities.



This man is being tested for susceptibility to being hypnotized.

Individuals who score high on the Stanford scale are usually easily hypnotized and tend to remain so across their lifetimes (M. R. Nash, 2001).

The process used to hypnotize a person is called hypnotic induction.

How Is Someone Hypnotized?

Although different procedures are used, most use some of the following suggestions for hypnotic induction.

Hypnotic induction **refers to inducing hypnosis by first asking a person to either stare at an object or close his or her eyes and then suggesting that the person is becoming very relaxed.**

Inducing hypnosis may involve 3 steps.

For example, here is a commonly used method for hypnotic induction:

1. The hypnotist creates a sense of trust, so that the individual feels comfortable.
2. The hypnotist suggests that the subject concentrate on something, such as the sound of the hypnotist's voice, an object, or an image.
3. The hypnotist suggests what the subject will experience during hypnosis—for example, becoming relaxed, feeling sleepy, or having a floating feeling. The hypnotist may say, "I am going to count from one to ten, and with each count you will drift more and more deeply into hypnosis" (B. L. Bates, 1994).

This procedure works on both individuals and groups, provided the individuals are all susceptible to hypnosis.

During hypnosis, subjects are not asleep, keep their ability to control their behaviors, are aware of their surroundings, adhere to their usual moral standards, and are capable of saying no or of stopping hypnosis. For these reasons, hypnosis is not a dangerous procedure when used by an experienced researcher or clinician, and hypnosis has useful medical and therapeutic benefits (Lynn & Cardena, 2007; Sandor & Afra, 2005).

Perhaps the biggest debates surrounding hypnosis are what actually happens when a person is hypnotized and whether hypnotic induction is even needed. These are our next questions.

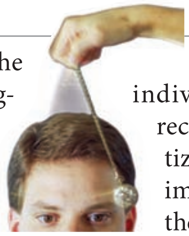
Theories of Hypnosis

What happens during hypnosis?



The explanation of why Paul got on the stage and imitated Elvis has changed significantly over the past 40 years. Early on, being hypnotized was believed to put a person into a trancelike state. In the late 1990s, the trancelike state was dropped for lack of evidence and some believed that being hypnotized put individuals into an altered state of consciousness. More recently, researchers believe that some individuals, hypnotized or not, have the amazing personal ability to respond to imaginative suggestions (Lynn et al., 2007a). We'll discuss these two different views of hypnosis.

Altered State Theory of Hypnosis

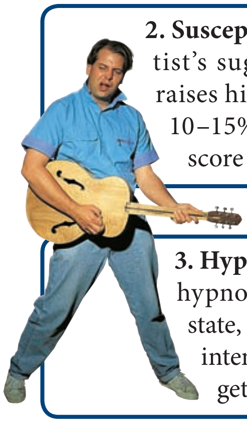
Perhaps Paul got on stage and imitated Elvis because hypnosis put him into an altered or disconnected state (Naish, 2006).

The ***altered state theory of hypnosis*** holds that hypnosis puts a person into an altered state of consciousness, during which the person is disconnected from reality and so is able to experience and respond to various suggestions (M. R. Nash, 2001).

For example, individuals were hypnotized and given suggestions that their raised hands were getting heavy or that they would feel no pain. When no longer hypnotized, these individuals said, "My hand became heavy and moved down by itself" or "Suddenly I found myself feeling no pain" (M.R. Nash, 2001, p. 49). Researcher Michael Nash (2001), editor-in-chief of *The International Journal of Clinical and Experimental Hypnosis,* believes hypnosis disconnects an individual from reality so that the individual does things without conscious intent. Nash explains that with hypnosis, scientists can temporarily create hallucinations, compulsions, certain types of memory loss, false memories, and delusions (bee buzzing around your head).

Explanation: Altered or disconnected state. Here's how the altered or disconnected state theory of hypnosis explains why shy Paul got on stage and imitated Elvis Presley.

1. Hypnotic induction. The hypnotist uses hypnotic induction: "Just sit back, relax, and follow my suggestions." The hypnotist slowly repeats a list of suggestions: "You cannot bend your right arm . . . you cannot close your eyes . . . your left arm will become rigid and slowly rise above your head . . . ," etc.



2. Susceptibility. Paul easily responds to the hypnotist's suggestion and, without conscious intent, raises his left arm. This means that he is one of the 10–15% who are easily hypnotized and would score high on a hypnotic susceptibility scale.

3. Hypnosis. According to the altered state theory, hypnosis disconnects Paul from reality. In this state, he may automatically and without conscious intent follow a wide range of suggestions, such as getting up on stage and imitating Elvis.

Conclusion. Interestingly, even though hypnotized people may believe they are in an altered state, brain research does not show altered patterns of activity (Lynn et al., 2007b). Next, we'll learn about a theory that states hypnosis is a normal state of consciousness.

Sociocognitive Theory of Hypnosis

Perhaps Paul got on stage and imitated Elvis because of personal abilities and social pressures—the sociocognitive theory (Lynn, 2007).

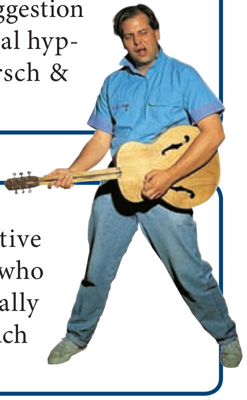
The ***sociocognitive theory of hypnosis*** says that behaviors observed during hypnosis result not from being hypnotized, but rather from having the special ability of responding to imaginative suggestions and social pressures (Kirsch & Braffman, 2001).

Psychologist Irving Kirsch, who has published more than 85 articles on hypnosis, found that all the phenomena produced during hypnosis have also occurred in subjects who were not hypnotized.

Explanation: Special abilities and social pressures. Here's how the sociocognitive theory of hypnosis explains why shy Paul got on stage and imitated Elvis Presley.

NO hypnotic induction. According to the sociocognitive theory of hypnosis, individuals do not have to be hypnotized because about 30% or more already have a special and amazing ability called imaginative suggestibility (Lynn & Kirsch, 2006; Lynn et al., 2008).

1. Imaginative suggestibility. The reason Paul does NOT need to be hypnotized is that he is one of those 30% or more who have imaginative suggestibility. This is a special ability to alter one's experiences and produce hallucinations, experience partial paralysis, have selective amnesia, and reduce pain. Individuals who have imaginative suggestibility can perform these unusual behaviors from suggestion alone, without having to go through formal hypnotic induction (being hypnotized) (Kirsch & Braffman, 2001).



2. Imaginative suggestions without hypnosis. According to the sociocognitive theory, Paul is one of those individuals who has the special ability to respond in a totally focused way to imaginative suggestions, such as getting up on stage and imitating Elvis.

Conclusion. Recent research supports that hypnosis occurs mostly as a result of people's expectations about hypnosis rather than an altered hypnotic state. As research continues, we'll learn more about what happens during hypnosis (Lilienfeld & Arkowitz, 2008b).

Next, we'll discuss some of the unusual behaviors that can be experienced and performed by individuals who, according to one theory, have been hypnotized or, according to another theory, have the trait of imaginative suggestibility.

A. Hypnosis

Behaviors

What are some of the unusual behaviors?

Stage hypnotists can get volunteers to perform a variety of unusual behaviors, such as pretending they are chickens, falling asleep after counting to 5, or singing like Elvis. However, keep in mind that individuals responsive to hypnosis most likely have the trait of imaginative suggestibility, which means that they can perform these behaviors with or without being hypnotized (Kirsch & Braffman, 2001).

Hypnotic Analgesia

Hypnosis has long been known to reduce pain; this is called hypnotic analgesia.

***Hypnotic analgesia** (an-nall-GEEZ-ee-ah)* refers to a reduction in pain reported by clients after they had undergone hypnosis and received suggestions that reduced their anxiety and promoted relaxation.

Researchers used PET scans to show that hypnosis reduced subjects' unpleasant feelings of pain though not the sensations of pain (Rainville et al., 1997). When subjects put their hands into hot water, they felt pain as usual but, depending on the hypnotic suggestions, reported it as more or less unpleasant. Hypnotic analgesia proved useful in helping patients cope with painful medical and dental treatments (F. J. Keefe et al., 2005; Milling et al., 2006; Montgomery, 2008).

Posthypnotic Suggestion

If subjects perform some behavior on cue after hypnosis, it's called a posthypnotic suggestion.

A ***posthypnotic suggestion*** is given to the subject during hypnosis about performing a particular behavior to a specific cue when the subject comes out of hypnosis.

Some believe that subjects who follow posthypnotic suggestions are acting automatically in response to a predetermined cue, such as laughing when they hear the word *student*. However, researchers have shown that subjects perform posthypnotic suggestions if they believe it is expected of them but stop performing if they believe the experiment is over or they are no longer being observed (Spanos, 1996).

Posthypnotic Amnesia

DON'T REMEMBER

"When you wake up, you will not remember what happened." This suggestion is used to produce posthypnotic amnesia.

Posthypnotic amnesia is not remembering what happened during hypnosis if the hypnotist suggested that, upon awakening, the person would forget what took place during hypnosis.

One explanation is that the person forgets because the experiences have been repressed and made unavailable to normal consciousness. However, there is good evidence that, after they come out of hypnosis, what people remember or forget depends on what they think or believe the hypnotist wants them to remember or forget (Spanos, 1996). For instance, people who are instructed to not remember anything usually report not remembering, but when pressed, many of these same people admit they do in fact remember the information (Kirsch & Lynn, 1998).

Age Regression

Could the 31-year-old woman shown at the left be hypnotized and sent back to being the 3-year-old child shown below? This phenomenon is called age regression.

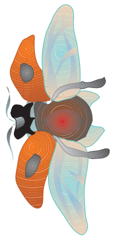
Age regression refers to subjects under hypnosis being asked to regress, or return in time, to an earlier age, such as early childhood.

Researchers have found that during age regression, hypnotized subjects do not relive their earlier experiences as some believe but rather play the role of being a child. After an exhaustive review of more than 100 years of hypnosis research on age regression, one researcher concluded that there was no evidence that adults actually went back or regressed in time (Kirsch et al., 1993). Thus, researchers believe that, during age regression, hypnotized adults are not reliving childhood experiences but merely acting as they expect children to behave (Lynn et al., 2009).

Imagined Perception

When a hypnotized subject responds to a suggestion such as "Try to swat that fly," it is called an imagined perception.

An ***imagined perception*** refers to experiencing sensations, perceiving stimuli, or performing behaviors that come from one's imagination.



Hypnotherapists use many forms of imagined perceptions in treating clients' problems. For example, one client imagined he was an armored knight on a great horse. After several therapy sessions, the therapist asked the client to remove the armor and discover his true self, which turned out to be a person afraid of his flaws (Eisen, 1994).

Conclusions

Researchers agree that hypnotized subjects are not faking or acting out their responses but seem to be actually experiencing such behaviors as hypnotic analgesia, imagined perception, age regression, and posthypnotic suggestion and amnesia. What researchers disagree about is why these behaviors occur. Some researchers believe that these behaviors occur because hypnosis puts individuals into an altered or disconnected state (M. R. Nash, 2001). Other researchers believe that individuals who are highly susceptible to hypnosis have a trait called imaginative suggestibility, which allows these individuals to totally focus and carry out suggestions, whether or not they are hypnotized (Kirsch & Braffman, 2001).

Next, we'll examine some of the uses of hypnosis.

Medical and Therapeutic Applications

How is hypnosis used?

You have probably seen hypnosis used in entertainment, such as when people in the audience volunteer to come up on stage and be hypnotized and then perform unusual and often funny behaviors, such as Paul's wild imitation of Elvis.

However, there are also serious and legitimate uses of hypnosis in medical, dental, therapeutic, and behavioral settings.

Medical and Dental Uses

Client is hypnotized before painful dental work.

In both medical and dental settings, hypnosis can be used to reduce pain through hypnotic analgesia, to reduce fear and anxiety by helping individuals relax, and to help patients deal with health problems by motivating them to make the best of a difficult situation (Patterson & Jensen, 2003). Also, those clients who are highly susceptible to hypnosis are better able to respond to suggestions for pain reduction than are clients who have low susceptibility (Milling, 2008).

Hypnosis has benefited many patients undergoing painful surgeries. In research experiments, hypnotized patients undergoing surgery required less pain medication and even recovered sooner than surgical patients who did not receive hypnosis (Askay & Patterson, 2007; Spiegal, 2007).

Hypnosis can also be helpful in preparing people for anxiety-provoking procedures. For instance, the woman above seeks hypnosis to help cope with her fear about having painful dental work performed. As part of her hypnosis, she hears, "Your jaw, mouth, gums, and throat become so relaxed that the muscles get soft . . . and as your jaw is opened gently and your gums are examined, your entire body will feel more and more relaxed."

Next, we'll look at what happens in the brain during hypnotic analgesia.

Brain scans. Researchers used PET scans (p. 71) to measure activity in different parts of the brain after subjects were hypnotized and told to place their hands in lukewarm (95°F) or "painfully hot" (115°F) water. Hypnotic suggestions to think of pain as *more unpleasant* (more painful) resulted in *decreased* brain activity in the frontal lobe (anterior cingulate cortex), while hypnotic suggestions to think of pain as *less unpleasant* (less painful) resulted in *increased* brain activity in the same area. In comparison, hypnotic instructions that pain was more or less unpleasant did not increase or decrease brain activity in the parietal lobe (somatosensory cortex), which indicates the reception of pain sensations (Rainville et al., 1997). Researchers concluded that hypnotic suggestions can change a person's *perception* of pain as more or less unpleasant, but hypnotic suggestions do not affect *receiving* pain sensations. This means that during hypnotic analgesia, subjects feel pain, but how much it bothers them depends on whether hypnotic suggestions are to think of pain as being more or less unpleasant. That is, the hypnotized subjects' thoughts or expectations actually change their perceptions of pain (Ploghaus et al., 2003).

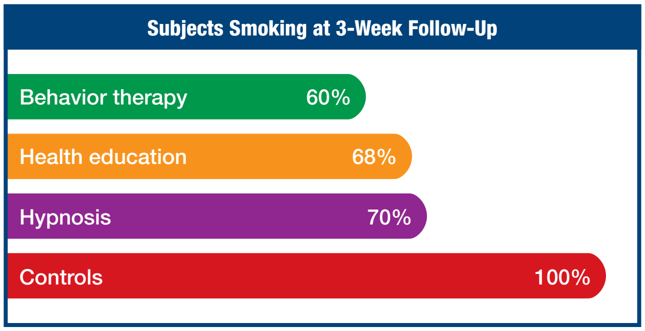
Therapeutic and Behavioral Uses

Hypnosis has been used in therapy for the past 100 years. In the early 1900s, Sigmund Freud (1905) used hypnosis with his patients. More recently, Milton Erickson (1980/1941), who is generally acknowledged to be the world's leading practitioner of therapeutic hypnosis, said that hypnosis made clients more open and receptive to alternative ways of problem solving. However, hypnosis is not for all clients; some people find hypnosis frightening because they fear losing control or because they believe it indicates a lack of willpower (Kirsch, 1994).

Therapists who often use hypnosis along with other techniques generally report that it is very useful in helping clients reveal their personalities, gain insights into their lives, and arrive at solutions to their problems. Research on hypnotherapy indicates that hypnosis can be a powerful tool that leads to successful outcomes when used in therapeutic settings (M. R. Nash, 2001).

Clients who are highly susceptible to hypnosis generally respond better to suggestions aimed at treating a wide range of psychosomatic problems, which involve mind-body interactions. For example, hypnosis has been successfully used to reduce pain, decrease asthma attacks, remove warts, and relieve tension. But hypnosis is not as successful with problems of self-control, such as helping clients quit smoking, stop overeating, stop excessive drinking, or overcome other habits that interfere with optimal functioning (B. L. Bates, 1994; Green & Lynn, 2000).

The graph below shows the percentages of subjects who continued to smoke after receiving three different treatment programs. Notice that after three weeks of treatment, hypnosis was not statistically more successful in motivating people to stop smoking than was health education or behavior modification. From these results, we can conclude that all three programs were about equally effective and significantly better than controls (no treatment program) (Green & Lynn, 2000; Rabkin et al., 1984). Clinicians generally conclude that hypnosis by itself is not a miracle treatment but can be a useful technique when combined with other procedures (Lynn et al., 2000).



Although helpful in a therapeutic setting, evidence obtained under hypnosis is not allowed in most U.S. courts. That's because an examiner's questions or suggestions may bias or mislead a hypnotized witness into agreeing to something that did not actually occur. Generally, hypnotized witnesses give unreliable testimony (Lynn et al., 2009).

Next, we'll discuss the use, abuse, and effects of drugs.

B. Drugs: Overview

Reasons for Use

Why do people use drugs?

For the past 6,000 years, humans have used legal and illegal drugs, and current usage continues to increase as do drug-related problems (Glantz & Hartel, 1999). For example, Americans spend over $150 billion a year on legal and illegal drugs, and the resulting problems—personal, medical, legal, and job related—cost society a whopping $500 billion a year (Volkow, 2007).

Americans spend $150 billion annually on drugs.

The reasons people use drugs include obtaining pleasure, joy, and euphoria; meeting social expectations; giving in to peer pressure; dealing with or escaping stress, anxiety, and tension; avoiding pain; and achieving altered states of consciousness (R. Goldberg, 2010).

One researcher, reviewing 200 years of drug use in the United States, concluded that we have gone through regular cycles of tolerant and intolerant attitudes toward drug usage. Because history tends to repeat itself, the researcher warns that our society will continue to face various physical and psychological problems related to drugs (Musto, 1999).

In the sections that follow, we'll discuss stimulants, opiates, hallucinogens, alcohol, marijuana, and other commonly used psychoactive drugs.

Psychoactive drugs **are chemicals that affect our nervous systems and, as a result, may alter consciousness and awareness, influence how we sense and perceive things, and modify our moods, feelings, emotions, and thoughts. Psychoactive drugs are both licit (legal)—coffee, alcohol, and tobacco—and illicit (illegal)—marijuana, heroin, cocaine, and LSD.**

Although all psychoactive drugs affect our nervous systems, how they affect our behaviors depends on our psychological state and other social factors, such as peer pressure and society's values. To illustrate how drug usage involves both pharmacological and psychological factors, we'll describe a famous person who had a serious drug problem.

Definition of Terms

What famous therapist had a drug problem?

When this famous person was 38, his doctor told him to stop smoking because it was causing irregular heart beats. Although he tried to cut down, he was soon back to smoking his usual 20 cigars a day. When his heart problems grew worse, he stopped again. However, he experienced such terrible depression and mood swings that he started smoking to escape the psychological torture. When he was 67, small sores were discovered in his mouth and diagnosed as cancer. During the next 16 years, he had 33 operations on his mouth and jaw for cancer but continued smoking. By age 79, most of his jaw had been removed and replaced by an artificial one. He was in continual pain and was barely able to swallow or talk. However, he continued to smoke an endless series of cigars. In 1939, at age 83, he died of cancer caused by 45 years of heavy smoking (Brecher, 1972; E. Jones, 1953).

Freud died of cancer caused by 45 years of nicotine addiction.

Our famous person is none other than Sigmund Freud, the father of psychoanalysis. Freud had a serious drug problem most of his professional life—he was addicted to tobacco (nicotine). In spite of his great insights into the problems of others, he tried but could not treat his own drug addiction. Freud's struggle with smoking illustrates four important terms related to drug use and abuse—addiction, tolerance, dependency, and withdrawal symptoms (American Psychiatric Association, 2000).

Addiction

One reason Freud continued to smoke despite a heart condition was that he had an addiction.

Addiction **refers to a behavioral pattern of drug abuse that is marked by an overwhelming and compulsive desire to obtain and use the drug; even after stopping, the person has a strong tendency to relapse and begin using the drug again.**

The reason Freud relapsed each time he tried to give up smoking was that he was addicted to nicotine.

Tolerance

One reason Freud smoked as many as 20 cigars daily was that he had developed a tolerance to nicotine.

Tolerance **means that after a person uses a drug repeatedly over a period of time, the original dose of the drug no longer produces the desired effect, so that a person must take increasingly larger doses of the drug to achieve the same behavioral effect.**

Becoming tolerant was a sign that Freud had become dependent on nicotine.

Dependency

Another reason Freud found it difficult to quit smoking was that he had developed a dependency on nicotine.

Dependency **refers to a change in the nervous system so that a person now needs to take the drug to prevent the occurrence of painful withdrawal symptoms.**

Addiction and dependency combine to make stopping doubly difficult.

Withdrawal Symptoms

Being dependent on nicotine, Freud had withdrawal symptoms when he stopped smoking.

Withdrawal symptoms **are painful physical and psychological symptoms that occur after a drug-dependent person stops using the drug.**

Freud described his withdrawal symptoms as being depressed, having images of dying, and feeling so tortured that it was beyond his human power to bear (E. Jones, 1953).

Next, we'll examine a number of specific drugs that people use.

Photo Credit: © James Porto

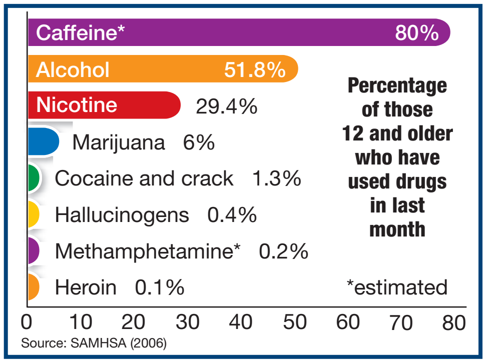
Use of Drugs

Which drugs do people use?

The graph on the right shows current users of legal and illegal drugs in the United States. (A current user is defined as someone who reported using a drug in the past month.)

The most recent national statistics show that almost 20 million Americans spend over $64 billion on illegal drugs each year (ONDCP, 2001; SAMHSA, 2008).

Because drug treatment programs are more cost-effective than imprisonment, many health professionals recommend reducing illegal drug use by spending more on drug education, counseling, and treatment (Caulkins et al., 2005; Vastag, 2003).



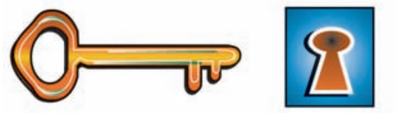
Source: SAMHSA (2006)

Because of the cost and relative ineffectiveness of the current "drug war," doctors, federal judges, and political writers have proposed controlling illegal drugs either by legalization, which means illegal drugs can be used but with age restrictions, or by decriminalization, which means drugs remain illegal but criminal penalties are replaced with fines. No one knows the effect drug legalization or decriminalization might have on drug use or related personal and social problems in a country as large as the United States (Huggins, 2005).

Whether legal or illegal, psychoactive drugs alter one's consciousness, emotions, and thoughts by affecting the brain's communication network.

Effects on Nervous System

How do drugs work?



Neurotransmitters act like specific chemical keys.

Neurotransmitters' keys open or close chemical locks that increase or decrease neural activity.

You may remember from Module 3 that the nervous system communicates by using chemical messengers called neurotransmitters. You can think of neurotransmitters as acting like chemical keys that open or close chemical locks on neighboring neurons (right figure). Many drugs act by opening or closing chemical locks, which in turn results in increased or decreased neural activity. However, how drugs affect each person's nervous system partly involves genetic factors. For example, researchers found that identical twins, who share 100% of their genes, were much more similar in their use and abuse of drugs than fraternal twins, who share only 50% of their genes. These findings apply in countries where there are high rates of drug problems (United States) and in those with low rates (Norway) (Kendler et al., 2000a, 2006). This means that genetic factors influence the development and functioning of the nervous system, which in turn can increase or decrease the risk of a person using and abusing drugs. We'll discuss ways that drugs affect the nervous system and activate the brain's reward/pleasure center to cause addiction and dependency.

Drugs Affect Neurotransmitters

Your nervous system makes several dozen neurotransmitters as well as many other chemicals (neuromodulators) that act like chemical messengers. After neurons release neurotransmitters, they act like chemical keys that search for and then either open or close chemical locks to either excite or inhibit neighboring neurons, organs, or muscles. For example, morphine's chemical structure closely resembles that of the neurotransmitter endorphin (see p. 113). As a result of this similarity, morphine acts like, or mimics, endorphin by affecting the same chemical locks, which decreases pain. Thus, some drugs produce their effects by ***mimicking*** the way neurotransmitters work (Ropper & Samuels, 2009).

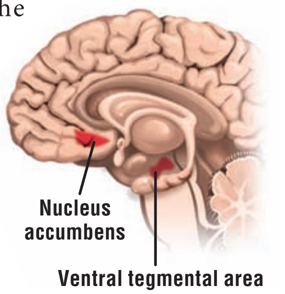
Morphine and heroin are similar to brain's neurotransmitters.

After being excited, neurons secrete neurotransmitters, which move across a tiny space (synapse) and affect neighboring neurons' receptors (see p. 54). However, after a brief period, the neurotransmitters are reabsorbed back into the neuron. The action by which neurotransmitters are removed from the synapse through reabsorption is called ***reuptake.*** If reuptake did not occur, neurotransmitters would remain in the synapse, and neurons would be continuously stimulated. Thus, some drugs, such as cocaine, block reuptake, which leads to increased neural stimulation that causes increased physiological and psychological arousal (Mendelson et al., 2006).

Some drugs have a powerful effect on the brain's reward/pleasure center.

Drugs Affect Brain's Reward/Pleasure Center

Many drugs, especially cocaine and methamphetamine, activate the brain's ***reward/pleasure center.*** This center includes the nucleus accumbens and ventral tegmental area (right figure) and involves the neurotransmitter dopamine (Saey, 2008a). These drugs produce their effects by directly activating the brain's reward/pleasure center. The reward/pleasure center is also activated when one eats a favorite food, has sex, and does other pleasurable activities (Higgins, 2008).



Addiction/dependency. Some drugs, such as cocaine and methamphetamine, activate the reward/pleasure center by increasing dopamine levels. However, repeated drug usage depletes dopamine levels, so the user must continue to use more drugs to activate the reward/pleasure center and avoid feeling depressed. When the reward/pleasure center becomes dependent on outside drugs, the user is addicted and dependent. Thus, drug addiction and dependency involve real changes in the brain's chemistry (Lemonick, 2007b).

Next, we'll examine the more frequently used drugs.

C. Stimulants

Definition

What are stimulants?

"Two pills beat a month's vacation." This marketing slogan was used to sell amphetamines in Sweden in the 1940s. It resulted in epidemic usage that peaked in the mid-1960s.

In the 1940s, American doctors prescribed amphetamines as safe energizers, mood enhancers, and appetite suppressors. By the 1960s, billions of doses of amphetamines were being used in the United States and their usage had become a serious problem.

In the 1940s, Japanese workers used amphetamines to keep factory production high during World War II. After the war, many students, night workers, and people displaced by the war began to use "wake-amines." Amphetamine use spread until, in 1954, 2 million Japanese had become abusers and addicts (Brecher, 1972).

Amphetamine slogan in the 1940s: "Two pills beat a month's vacation."

By the early 1970s, most countries had brought amphetamine usage under control by regulating prescriptions, decreasing supply, and imposing stiffer penalties. However, at present, amphetamine-like stimulants, such as methamphetamine (crystal) and cocaine, are widely available on the black market.

All ***stimulants,*** including cocaine, amphetamines, caffeine, and nicotine, increase activity of the central nervous system and result in heightened alertness, arousal, euphoria, and decreased appetite. Dose for dose, cocaine and amphetamines are considered powerful stimulants because they produce a strong effect with a small dose; caffeine and nicotine are considered mild stimulants.

We'll discuss the more widely used stimulants—amphetamines, cocaine, caffeine, and nicotine.

Amphetamines

Is it still a problem?

During the 1960s, amphetamine pills were heavily prescribed to treat a wide range of problems, including fatigue, depression, and being overweight. This was also the time young adults, called "flower children," took large doses of amphetamines that caused true paranoid psychotic symptoms, which resulted in their being called "speed freaks." Amphetamine usage peaked in the mid-1960s, when over 31 million prescriptions were written for dieting and about 25 tons of legitimately manufactured amphetamines were diverted to illegal sales (G. R. Hanson & Venturelli, 1998). Finally, in 1971, the Food and Drug Administration (FDA) outlawed the prescription of amphetamines for everything except attention-deficit/hyperactivity disorder (ADHD) (p. 39) and narcolepsy (p. 163).

Following a "drug war" on cocaine in the 1980s, there was a dramatic increase in using a form of amphetamine called methamphetamine, which is manufactured in illegal home laboratories. In many countries, the possession or use of methamphetamine is illegal, and yet the use of methamphetamine is quickly spreading in the United States and worldwide. Karen Tandy, a U.S. drug enforcement official, commented on the nation's use of methamphetamine: "Meth has spread like wildfire across the Unites States. It has burned out communities, scorched childhoods, and charred once happy and productive lives beyond recognition" (Eggen, 2005). In Japan, methamphetamine has become the most popular illegal drug (Ujike & Sato, 2004).

Drug

In 2001, authorities raided about 8,000 illegal crystal methamphetamine laboratories in the United States. Methamphetamine labs are becoming increasingly common in the West, Southwest, and Midwest (Crea, 2003; Sanchez, 2001).

Methamphetamine (D-methamphetamine) is close to amphetamine in both its chemical makeup and its physical and psychological effects. Unlike amphetamine, which is taken in pill form, methamphetamine (meth, speed, crank, crystal, ice) can be smoked or snorted and produces an almost instantaneous high. Both amphetamine and methamphetamine cause marked increases in blood pressure and heart rate and produce feelings of enhanced mood, alertness, and energy. However, both have a high risk for addiction and dependency.

"It's the ultimate high. . . . It makes you feel so powerful. You have tons of energy. . . . I loved it. I craved it" (Witkin, 1995, p. 50). So said 23-year-old Tara, who became addicted to and dependent on meth and whose euphoria eventually turned into a terrible nightmare.

Nervous System

The primary effect of amphetamines and related drugs (methamphetamine) is to increase the release of the neurotransmitter dopamine and also to block its reuptake (Mendelson et al., 2006). Researchers are learning that the release of dopamine occurs during a wide range of pleasurable activities, such as sex (Esch & Stefano, 2005). Thus, drugs like methamphetamine are both desirable and dangerous because they increase the release of dopamine, which causes very pleasurable feelings (Bamford et al., 2008).

Dangers

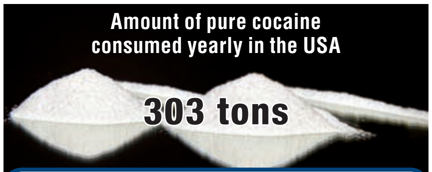
At first, users of methamphetamine have periods of restless activity and perform repetitive behaviors. Later, the initial euphoria is replaced with depression, agitation, insomnia, and true paranoid feelings. Recently, methamphetamine users were found to have 15% fewer dopamine receptors, which are involved in the reward/pleasure center (Riddle et al., 2006; Volkow et al., 2003). Fewer dopamine receptors decrease one's ability to experience normal pleasures and contribute to further drug usage. Long-term risks include stroke, liver damage, heart disease, memory loss, and extreme weight loss (Dickerson, 2007; Jefferson, 2005). Large doses of methamphetamine can overstimulate the brain, leading to severe convulsions and possibly death (Iversen, 2008).

Another powerful stimulant is cocaine, which we'll discuss next.

Cocaine

Why has it been used for 3,000 years?

For 3,000 years, the ancient Incas and their descendants, the indigenous Andean people of Peru, have chewed coca leaves as they made demanding journeys through the high mountains. Some minutes after chewing the leaves, which contain cocaine, they reported feeling more vigor and strength and less fatigue, hunger, thirst, and cold. Coca leaves contain very little cocaine and produce stimulation equivalent to that experienced by coffee (caffeine) drinkers (McCarry, 1996). Few psychological or physical problems are observed in those who chew coca leaves, partly because they consume very little cocaine and because this activity is part of their culture. However, natives who have switched from chewing coca leaves to using the more concentrated cocaine powder have reported many more problems (R.K. Siegel, 1989).



Americans spend about $35 BILLION annually on cocaine.

In the United States, an increase in usage of one illegal drug is partly due to which other drug is being targeted for enforcement. For example, the U.S. government's crackdown on amphetamine usage in the 1970s was largely responsible for the increased popularity of cocaine, whose usage reached epidemic proportions in the 1980s. In turn, the 1980s were marked by the government's "war" on cocaine, which was partly responsible for an upsurge in methamphetamine usage in the 1990s.

Since the cocaine epidemic of the late 1980s, usage of cocaine in the United States is reportedly down by 10–35%. For more than 25 years, law enforcement has been working to eliminate cocaine and other drugs. The United States recently spent nearly $5 billion to eliminate Colombia's coca crops, but the availability of cocaine in the United States is unchanged (Forero, 2006). The figure at left shows that cocaine is now a $35-billion-a-year illegal industry with about 2.1 million users (Brodzinsky, 2006; SAMHSA, 2008).

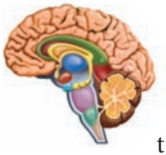
Drug

Cocaine can be sniffed or snorted, since it is absorbed by many of the body's membranes. If cocaine is changed into a highly concentrated form, which is called *crack,* it can be smoked or injected and produces an instantaneous but short-lived high.

Cocaine, **which comes from the leaves of the coca plant, has physiological and behavioral effects very similar to those of amphetamine. Like amphetamine, cocaine produces increased heart rate and blood pressure, enhanced mood, alertness, increased activity, decreased appetite, and diminished fatigue. With higher doses, cocaine can produce anxiety, emotional instability, and suspiciousness.**

When humans or monkeys have unlimited access to pure cocaine, they will use it continually, to the point of starvation and death. Only extreme shock will reduce an addicted monkey's use of cocaine, and only extreme problems involving health, legal, or personal difficulties will reduce an addicted human's intake.

Nervous System



Researchers have recently found that the primary effect of cocaine is to block reuptake of the neurotransmitter dopamine, which means that dopamine stays around longer to excite neighboring neurons (Mendelson et al., 2006).

Researchers also found that cocaine excites one kind of neural receptor (dopamine) to produce pleasure/euphoria and another kind of receptor (glutamate) to produce a craving for more of the drug (Uys & LaLumiere, 2008). Like amphetamine, cocaine results in increased physiological and psychological arousal.

When applied to an external area of the body, cocaine can block the conduction of nerve impulses. For this reason, cocaine is classified as a local anesthetic and that is its only legal usage.

Dangers

In ***moderate doses,*** cocaine produces a short-acting high (10–30 minutes) that includes bursts of energy, arousal, and alertness. Users tend to believe they are thinking more clearly and performing better, but they overestimate the quality of their work. In ***large doses,*** cocaine can result in serious physical and psychological problems, including hallucinations and feelings of bugs crawling under the skin as well as addiction. An overdose can lead to death (Paulozzi, 2006).

Many physical problems result from cocaine abuse, including lack of appetite, headaches, insomnia, irritability, heart attacks, strokes, seizures, damage to cartilage of the nose (if snorted), and increased risk of HIV (if injected). Also, respiratory failure, which may lead to sudden death, can result from relatively low doses (NIDA, 2006a).

Heavy cocaine usage has been found to significantly reduce the levels of dopamine receptors in the brain's reward/pleasure center. This reduction results in two disastrous consequences: First, the user must take larger doses of cocaine to experience the same pleasure and this continues the addiction; second, the user will find decreased pleasure in previously normal experiences (a good meal or companionship) and seek pleasure in continued use of drugs. This motivates the user to continue to gain pleasure by using cocaine and to avoid seeking treatment (Begley, 2001).

Cocaine users often go through the vicious circle of feeling depressed as the effect wears off, wanting and using more cocaine to relieve the depression, and so on (Ropper & Samuels, 2009). Thus, heavy users often require professional help to break out of their addictive vicious circles (Lamberg, 2004).

Next, we turn to two legal drugs that are the most widely used stimulants—caffeine and nicotine.

Photo Credit: top, © DIOMEDIA/Alamy

C. Stimulants

Caffeine

What's the most widely used drug in the world?

Caffeine has been used for the past 2,000 years and is the most widely used psychoactive drug in the world (Peng, 2008b). In the United States, 80–90% of people routinely consume caffeine and 170 million are addicted to it (Gupta, 2007; Lemonick, 2007; Price, 2008a). One 8-ounce cup of regular coffee, two cups of regular tea, two diet colas, and four regular-sized chocolate bars all contain about 100 milligrams of caffeine. The average amount of caffeine consumed in the United States is 238 milligrams per person per day, compared to 400 milligrams in Sweden and England and a worldwide average of 76 milligrams (Bowman, 2005).

Drug

Many users do not consider caffeine an addicting drug.

***Caffeine*, a mild stimulant, produces physiological and psychological arousal, including decreased fatigue and drowsiness, feelings of alertness, and improved reaction times.**

Moderate doses of caffeine improved performance in sleep-deprived drivers but had little effect on reducing motor impairment from alcohol (Fillmore et al., 2002; Reyner & Horne, 2000).

Nervous System

Caffeine belongs to a group of chemicals called xanthines *(ZAN-thenes)*, which have a number of effects. One effect is to block certain receptors (adenosine receptors) in the brain, which results in stimulation and mild arousal (Keisler & Armsey, 2006).

Dangers

Researchers found that mild to heavy doses of caffeine (125–800 milligrams; two cups of coffee = 200 mg) can result in addiction and dependency similar to those produced by alcohol, nicotine, and cocaine (Strain et al., 1994). The high doses of caffeine in today's energy drinks (up to 500 mg) place people at particular risk for caffeine's dangerous side effects (Griffiths, 2008; Mieszkowski, 2007).

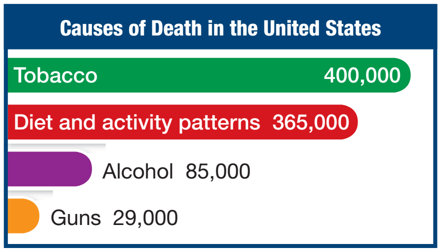
For 40–70% of people who abruptly stop the consumption of caffeine, especially medium to heavy doses, a number of uncomfortable withdrawal symptoms occur, such as headaches, fatigue, jitteriness, nausea, cramps, tremors, and sleeplessness (Gupta, 2007; Lemonick, 2007). Obviously, caffeine is a real drug, as is the nicotine in tobacco products.

Nicotine

What causes the most deaths?

After caffeine, nicotine is the world's most widely used psychoactive drug (Julien, 2005). In the United States, 45 million active cigarette smokers use nearly 400 billion cigarettes each year (M. Kaufman, 2006a). More than 700,000 people become smokers each year (Price, 2008c).

The graph at the right shows that, in the United States, the highest number of deaths (400,000) results from using tobacco (Price, 2008c). For this reason, the U.S. Surgeon General concluded that cigarette smoking is the single largest avoidable cause of death in our society and the most important public health issue of our time (USDHHS, 2006).



Drug

Nicotine has long been classified a stimulant drug, but not until 1997 was it officially classified an addictive drug (Koch, 2000).

***Nicotine* is a stimulant because it triggers the brain's reward/pleasure center to produce good feelings. In low doses, nicotine improves attention, concentration, and short-term memory. Regular use of nicotine causes addiction and dependency, and stopping leads to withdrawal symptoms.**

Researchers now think they know why about 30 million American smokers try to quit each year and fail.

Nervous System

Nicotine stimulates the production of dopamine, which is used by the brain's reward/pleasure center to produce good feelings. Nicotine also stops other controlling cells from turning off the pleasure areas, so the overall result is that smoking produces a relative long-lasting good feeling (Mansvelder et al., 2003). Thus, smokers find it so difficult to quit because they are addicted to nicotine and really crave the good feeling.

Dangers

Nicotine is a very addicting drug, and it has serious health consequences. Over 400,000 American smokers die each year from lung and heart problems, and for thousands more, smoking causes sexual problems, including impotency (McKay, 2005; Price 2008c). In 2006, the U.S. Surgeon General concluded that secondhand smoke kills tens of thousands of nonsmokers a year and reported there is no safe level of secondhand smoke exposure (ALA, 2006; O'Neil, 2006).

Because nicotine is addictive, a habitual smoker will experience withdrawal symptoms when trying to quit. Withdrawal symptoms range in severity and include irritability, attentional deficits, cramps, sleep disturbances, increased appetite, and a strong craving to light up again (NIDA, 2006c). Stop-smoking programs, including counseling and some combination of nicotine patch, pill, or gum, are all about equally effective—10% to 25% remained smoke free one year later (Vergano, 2001). This means that about 75% of smokers who tried to quit failed to do so, despite receiving nicotine.

Unlike stimulants, the next group of drugs, called opiates, produce the opposite effect.

Photo Credit: top left, Craig McClain

Opium, Morphine, Heroin

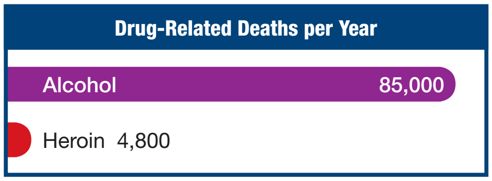
How popular is heroin?

Beginning in 6000 B.C., opiates have been used around the world. Opiates were legal in the early 1800s, when the active ingredient in the juice of the opium poppy was found to be morphine. In the late 1800s, morphine was chemically altered to make heroin, which like opium is addictive. Law enforcement agencies usually refer to opiates as *narcotics.*

In the early 1900s, the sale and use of narcotics (opium, morphine, and heroin) were made illegal and a wildly lucrative opium black market began. In spite of restrictive laws and billions spent on enforcement, opiates are still readily available in most major U.S. cities (Schuckit, 2000). In fact, the production of illegal opiates has reached record levels (*Time,* 2007a).

In 1980, heroin was about 7% pure, but current heroin is about 50% pure, which means instead of being injected, it can be smoked. Smoking appeals to and is more popular with new users; the beginning age has dropped to 18 years (Leinwand, 2000).

The number of Americans who use heroin regularly is estimated to be 136,000 (SAMHSA, 2006). The graph at left shows that compared to 85,000 drug-related deaths a year from alcohol, there were about 4,800 heroin-related deaths (SAMHSA, 2000, 2005). The possession or use of opium, morphine, and heroin is illegal.



Drug

Opiates produce similar effects, but users generally prefer to inject heroin because then it reaches the brain more quickly and produces the biggest "rush."

***Opiates,* such as opium, morphine, and heroin, produce three primary effects: analgesia (pain reduction); opiate euphoria, which is often described as a pleasurable state between waking and sleeping; and constipation. Continued use of opiates results in tolerance, addiction, and dependency.**

One rock star (Anthony Kiedis of "Red Hot Chili Peppers") described using heroin for the first time as "a great feeling. . . . It's like you're opening a door that leads you into a different world. You discover a brand new universe" (NY Rock, 2002). However, with constant usage, his brain developed a tolerance to heroin, which means he had to take larger and larger doses to achieve a high and ended up developing many life problems (Kiedis, 2004).

Nervous System

In the 1970s, researchers discovered that the brain has naturally occurring receptors for opiates (Pert et al., 1974). When morphine reaches the brain's receptors, it produces feelings of euphoria and analgesia. In addition, the gastrointestinal tract has opiate receptors, whose stimulation results in constipation.

Researchers discovered that the brain not only has its own opiate receptors but also produces its own morphinelike chemicals. These chemicals, which function as neurotransmitters, are called *endorphins* and are found to have the same analgesic properties as morphine (Pleuvry, 2005).

Dangers

Anthony Kiedis, who injected heroin, said, "If you haven't ever put a needle in your arm, don't ever do it . . . it's horrible, and I don't want anyone to ever have to feel like I'm feeling right now. Let me do the suffering for you" (Kiedis, 2004, p. 179).

After several weeks of regular use, a person's brain produces less of its own endorphins and relies more on the outside supply of opiates. As a result, a person becomes addicted to taking opiates and must administer one or more doses daily to prevent withdrawal symptoms.

Withdrawal symptoms, which include hot and cold flashes, sweating, muscle tremors, nausea, and stomach cramps, are not life threatening and last 5–8 days. An overdose of opiates depresses the neural control of breathing, and a person dies from respiratory failure (Mendelson et al., 2006).

Treatment

In Great Britain, where heroin addiction is considered a health problem, heroin addicts who chose methadone injections instead of heroin use showed significant reductions in drug use and crime during a 12-month period (Metrebian et al., 2001). In contrast, in the United States, heroin addiction is considered a criminal problem, and addicts have typically had limited access to regular medical treatment. In a 33-year follow-up study of heroin addicts in the United States, researchers reported that only 6% were in a medical treatment program, 40% had used heroin in the past year, and many had severe health problems or spent time in prison (Hser et al., 2001). Researchers concluded that, if heroin users do not quit by age 30, they are unlikely ever to stop. The most common treatment for heroin addiction is to maintain addicts on methadone, which is an addictive, synthetic drug similar to opium. Methadone treatment programs, which are becoming widely available, can be relatively effective in preventing heroin use, reducing criminal activities, and preventing employment loss (Vocci et al., 2005).

Opium poppy contains morphine.

A recent treatment for heroin addiction in the United States is a new federally approved drug (buprenorphine) that blocks the craving for heroin. This drug has several advantages, including increased accessibility (it is given in a doctor's office), lower risk of overdose, and about equal effectiveness as methadone (Kakko et al., 2007).

Next, we'll consider hallucinogens, which alter brain chemistry to produce strange experiences and perceptions.

Photo Credit: bottom, © Dr. Jeremy Burgess/Photo Researchers, Inc.

E. Hallucinogens

Definition

What is a hallucinogen?

In many parts of the world and in many different cultures, plants and fungi (mushrooms) have long been used to produce visions or hallucinations as part of cultural or religious experiences. However, Caucasians in the United States rarely used hallucinogens until the 1950s and 1960s, when these drugs gained popularity as part of the hippie subculture. Researchers have once again begun to study the potential therapeutic uses of hallucinogens, which have also gained back some of their former popularity (Golub et al., 2001).

Hallucinogens **are psychoactive drugs that can produce strange and unusual perceptual, sensory, and cognitive experiences, which the person sees or hears but knows that they are not occurring in reality. Such nonreality-based experiences are called *hallucinations.***

We'll focus on four of the more commonly used hallucinogens: LSD, psilocybin, mescaline, and a designer drug called ecstasy.

LSD

What does LSD do?

At the beginning of this module, we told you about the strange bike ride of Albert Hofmann, who in 1943 discovered LSD (*d*-lysergic acid diethylamide). However, LSD did not become popular in America until the mid-1960s. In 2007, there were about 279,000 new LSD users (age 12 and older), compared to the 906,000 who began using cocaine (SAMHSA, 2008). Possession or use of LSD is illegal.

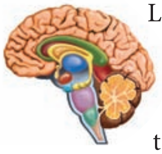
Drug

LSD is a very potent drug because it produces hallucinogenic experiences at very low doses.

LSD **produces strange experiences, which include visual hallucinations, perceptual distortions, increased sensory awareness, and intense psychological feelings.**

An LSD experience, or "trip," may last 8–10 hours.

Nervous System



LSD resembles the naturally occurring neurotransmitter serotonin. LSD binds to receptors that normally respond to serotonin, and the net effect is increased stimulation of these neurons (D. L. Nelson, 2004). The majority of serotonin receptors are located on neurons in the brain's outermost layer, the cerebral cortex, which is involved in receiving sensations, creating perceptions, thinking, and imagining.

Dangers

LSD's psychological effects partially depend on the setting and the person's state of mind. If a person is tense or anxious or in an unfamiliar setting, he or she may experience a bad trip. If severe, a bad trip may lead to psychotic reactions (especially paranoid feelings) that require hospitalization. Sometime after the hallucinogenic experience, users may experience frightening flashbacks that occur for no apparent reason. There have been no reports of physical addiction to LSD or death from overdose, but users do quickly develop a tolerance to LSD (R. Goldberg, 2010).

Psilocybin

What are "magic mushrooms"?

Magic or psychedelic mushrooms are native to Mexico and have earned the "magic" name due to the mystical experiences they cause people to have (Talan, 2006b). According to one researcher, people who used magic mushrooms "had a sense of pure awareness. They described feeling infinite love, tenderness and peace. Everything was experienced in the present; the past and future had no meaning" (Griffiths, 2006). However, some people have adverse reactions to magic mushrooms, such as intense fears and paranoia (Griffiths, 2006). Possession or use of psilocybin is illegal.

Drug

The active ingredient in magic mushrooms is psilocybin.

Psilocybin **in low doses produces pleasant and relaxed feelings; medium doses produce perceptual distortions in time and space; high doses produce distortions in perceptions and body image and sometimes hallucinations.**

Nervous System

Psilocybin is chemically related to LSD and, like LSD, binds to serotonin receptors. The hallucinatory effects produced by psilocybin are comparable to those from LSD but last half as long (Carter et al., 2005).

Dangers

The dangers of psilocybin come not from physical harm to the brain or body but rather from its potential for inducing psychotic states that may persist long after the experience is expected to end (Espiard et al., 2005). In addition, accidental poisonings are common among those who eat poisonous mushrooms, mistaking them for magic mushrooms.

Mescaline

What is peyote?

In the 1500s, Spanish soldiers noted that the Aztec Indians of South America ate peyote cactus as part of their religious ceremonies. Peyote cactus contains about 30 psychoactive chemicals; one of the more potent is the drug mescaline.

In 1965, the Native American Church of North America won a battle in the U.S. Supreme Court for the legal right to use peyote as a sacrament in their Christian ritual. Participants in this ritual usually sit around a fire and eat peyote buttons. This is followed by meditation, during which the participants feel removed from earthly cares and experience unusual visual perceptions, such as seeing a vast field of golden jewels that move and change (Liska, 1994). Beginning about 15 years ago, Native American Indians in the U.S. armed forces were allowed to use peyote in religious rituals (A. Gardner, 2005).

The possession or use of mescaline is illegal for all except those who belong to the Native American Church.

Drug

Mescaline is about 2,500–4,000 times less potent than LSD.

Mescaline is the active ingredient in the peyote cactus. At high doses, mescaline produces very clear and vivid visual hallucinations, such as latticework, cobweb figures, tunnels, and spirals, which appear in various colors and intense brightness. Mescaline does not impair the intellect or cloud consciousness.

As with most hallucinogens, the setting and user's psychological state influence the experience.

Nervous System

Mescaline reaches maximum concentration in the brain about 2–4 hours after someone eats buttons of peyote cactus. Mescaline primarily increases the activity of the neurotransmitters norepinephrine and dopamine (S. M. Stahl, 2000). In addition, mescaline activates the sympathetic nervous system to produce physiological arousal, such as increased heart rate and temperature and sometimes vomiting.

Dangers

During a mescaline experience, which can last 6–8 hours, users may experience headaches and vomiting. When street samples of mescaline were analyzed in a number of cities, researchers found that the chemical was rarely mescaline. Instead "street mescaline" was usually other hallucinogens, such as LSD or PCP (G. R. Hanson et al., 2006).

Designer Drugs

Can hallucinogens be made?

The mid-1980s saw the appearance of so-called designer drugs.

Designer drugs refer to manufactured or synthetic drugs that are designed to resemble already existing illegal psychoactive drugs and to produce or mimic their psychoactive effects.

A drug designer can start with an amphetamine molecule and alter it in hundreds of ways. Because designer drugs are manufactured in home laboratories, users have no guarantees these drugs are safe to use. Of the many designer drugs available, we'll focus on MDMA, which was first used in the 1970s with the street name "ecstasy." In the late 1990s, ecstasy increased in popularity across the United States. Today, ecstasy is the most popular hallucinogen, accounting for half (500,000) of all hallucinogen users (age 12 and older) (SAMHSA, 2008). Ecstasy is the drug of choice at rave parties (left photo), which feature all-night music and dancing. The U.S. government banned research on MDMA in 1985, and only recently have researchers received permission to study its effects (Kohn, 2004). Possession or use of MDMA is illegal.

Drug

After alcohol and marijuana, ecstasy is the drug of choice among teens (Leinwand, 2002).

MDMA, or ***ecstasy,*** resembles both mescaline (hallucinogen) and amphetamine (stimulant). MDMA heightens sensations, gives a euphoric rush, raises body temperature, and creates feelings of warmth and empathy.

For these reasons, some suggest that ecstasy may be useful in some kinds of therapy (D. J. Brown, 2007).

Nervous System

MDMA causes neurons to release large amounts of two neurotransmitters, serotonin and dopamine, which stimulate the brain's reward/pleasure center. Afterward, users may feel depressed and have attention and memory deficits. The worry is that MDMA may cause brain damage (Kohn, 2004).

Dangers

In recreational doses, MDMA trips can last 6 hours and include euphoria, high energy, jaw clenching, teeth grinding, increased body temperature, and insomnia. At higher doses, trips include panic, rapid heart beat, high body temperature, paranoia, and psychotic-like symptoms (Baylen & Rosenberg, 2006). Also, MDMA depletes some of the brain's transmitters (serotonin and dopamine) (Montoya et al., 2002).

Longer-term, heavy use of MDMA can lead to serious cognitive impairments, such as memory loss, weakened immune system, and depression (Falck et al., 2006; Laws & Kokkalis, 2007; Schilt et al., 2007; J. Ward et al., 2006).

The psychoactive drug we'll examine next is widely used, potentially very dangerous, and legal.

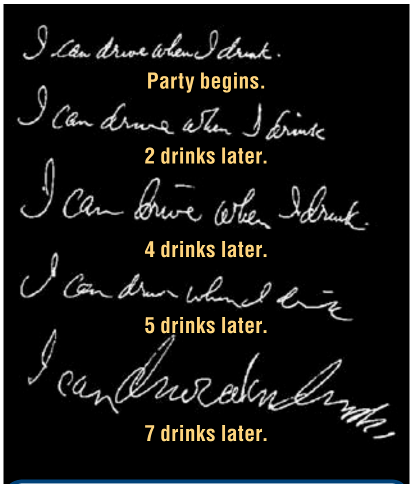
F. Alcohol

History and Use

What if alcohol was banned?

The first brewery appeared in Egypt in about 3700 B.C., making alcohol the oldest drug to be made by humans (Samuel, 1996). Alcohol has grown in popularity, and its usage has been associated with a wide range of problems, such as motor coordination (right figure). If alcohol causes so many problems, why not just ban it?

In 1919, the U.S. Congress passed the Eighteenth Amendment, which prohibited the sale and manufacture of alcohol. However, Americans did not want to give up alcohol, so a lucrative black market developed and supplied illegal alcohol. After 14 years of black-market alcohol and failed prohibition, the U.S. Congress repealed prohibition in 1933. The lesson learned from prohibition was that it is impossible to pass a law to ban a drug that is so popular and widely used (Musto, 1996).



I can drive when I drink.
Party begins.
I can drive when I drink
2 drinks later.
I can drive when I drink.
4 drinks later.
5 drinks later.
7 drinks later.

127 million Americans drink alcohol and 19 million have problems.

In 2007, about 127 million Americans age 12 and older drank alcohol. Of these, 23% were binge drinkers (consumed 5 drinks in a row at same occasion), and about 7% were heavy drinkers (5 drinks in a row on 5 different days in the past month). The heavy drinkers are most likely to be alcoholics, who develop a variety of behavioral, neurological, social, legal, and medical problems (SAMHSA, 2008). Alcoholism occurs most frequently in men, Whites, Native Americans, poor people, and young, unmarried adults (Hasin et al., 2007).

We'll discuss alcoholism in the Cultural Diversity section (p. 185), but first we'll explain alcohol's effects on the user's brain, body, and behaviors.

Definition and Effects

Although we'll use the term *alcohol,* we actually mean *ethyl alcohol,* which is safe to drink. The level of alcohol is measured in percentage in the blood, which is called blood alcohol content, or BAC. For example, after 3 or 4 drinks in an hour, the average person's BAC will range from 0.08 to 0.1. The national legal definition of being drunk is now 0.08. A drink is defined as one cocktail, one 5-ounce glass of wine, or one 12-ounce bottle of beer (Gelles, 2009). It makes no difference whether you drink hard liquor, wine, or beer, since they all contain ethyl alcohol, which affects the nervous system and results in behavioral and emotional changes.

Drug

Alcohol is not a stimulant but a depressant.

Alcohol **(ethyl alcohol) is a psychoactive drug that is classified as a depressant, which means it depresses activity of the central nervous system. Initially, alcohol seems like a stimulant because it reduces inhibitions, but later it depresses many physiological and psychological responses.**

The effects of alcohol depend on how much a person drinks. After a couple of drinks (0.01–0.05 BAC), alcohol causes friendliness and loss of inhibitions. After four or five drinks (0.06–0.10 BAC), alcohol seriously impairs motor coordination (driving), cognitive abilities, decision making, and speech. After many drinks (0.4 BAC and higher), alcohol may cause coma and death. For example, an 18-year-old California college student died after a hazing ritual required him to binge drink. At the time of death, his BAC was 0.4, nearly five times the legal driving limit (*USA Today,* 2009).

Nervous System

Alcohol affects many parts of the nervous system. For example, alcohol stimulates the brain's GABA *(GAH-bah)* neural receptors, which leads to feeling less anxious and less inhibited (Schuckit, 2006). Alcohol also impairs the anterior cingulate cortex, which monitors the control of motor actions. When this area is impaired, drinkers will fail to recognize their impaired motor performance (driving a car) and continue to drive (Ridderinkhof et al., 2002). In very high doses (0.5 BAC), alcohol depresses vital breathing reflexes in the brain stem (medulla), and this may totally stop breathing and result in death.

Dangers

The morning after a bout of heavy drinking (3–7 drinks), a person usually experiences a ***hangover,*** which may include upset stomach, dizziness, fatigue, headache, and depression. There is presently no cure for hangovers, which are troublesome and painful but not life threatening.

Repeated and heavy drinking can result in tolerance, addiction, and dependency. ***Tolerance*** means that a person must drink more to experience the same behavioral effects. ***Addiction*** means an intense craving for alcohol, and ***dependency*** means if the person stops drinking, he or she will experience serious ***withdrawal symptoms,*** which may include shaking, nausea, anxiety, diarrhea, hallucinations, and disorientation.

Another serious problem is ***blackouts,*** which occur after heavy and repeated drinking. During a blackout, a person seems to behave normally but when sober cannot recall what happened. If the blackout lasts for hours or days, it is probable that the person is an alcoholic.

Repeated and heavy drinking can also result in liver damage, alcoholism, and brain damage.

Risk Factors

Who's at risk for becoming an alcoholic?

Of the 126 million Americans who drink alcohol, almost 19 million will develop alcoholism. Researchers believe that a number of psychological and genetic risk factors increase the chances that a person will drink alcohol AND become an alcoholic. For example, one's risk of becoming an alcoholic is 3–4 times higher if one comes from a family whose parents are alcoholic. However, it's important to remember that risk factors increase the chances but do not guarantee that someone who drinks will become an alcoholic.

19 million alcoholics in the United States

We'll discuss both genetic and psychological risk factors that may lead to a person abusing alcohol.

Psychological Risk Factors

Researchers found that children whose parents (either or both) are alcoholics develop a number of unusual, abnormal, or maladaptive psychological and emotional traits that are called ***psychological risk factors*** (Schuckit, 2000). For example, these childhood risk factors include being easily bored, engaging in risk-taking or sensation-seeking behaviors, and acting impulsively or overemotionally when faced with stressful situations (Legrand et al., 2005; Song, 2006b).

When children with these psychological risk factors become adults, they may have a tendency to imitate the behavior of their alcoholic parent and abuse alcohol when faced with personal, social, stressful, or work-related difficulties. However, besides psychological risk factors for abusing alcohol, there are also genetic risk factors (Edenberg & Foroud, 2006).

Genetic Risk Factors

Besides psychological risk factors, there are also ***genetic risk factors,*** which refer to inherited biases or predispositions that increase the potential for alcoholism. For example, if one identical twin is an alcoholic, there is a 39% chance that the other twin is also. In comparison, if one fraternal twin is an alcoholic, there is a 16% chance that the other twin is also. Based on genetic studies, researchers estimate that genetic factors contribute 50–60% to the reasons a person becomes an alcoholic (Price, 2008b; Schuckit, 2006).

One way genetic factors work is by making a person less sensitive to the effects of alcohol, meaning a person has to drink more to feel its effects, and drinking more is a risk factor for becoming an alcoholic (Schuckit, 2006). Recent research found that teenagers whose mothers drank alcohol during pregnancy are at high risk for alcoholism because their developing senses came to prefer alcohol's taste and smell in the womb (Youngentob et al., 2007a, 2007b). Researchers find that genes set a person's sensitivity by affecting a number of different neurotransmitter systems (GABA, NMDA, dopamine, and serotonin) (DePetrillo, 2003; Li, 2000). Researchers caution there is not one "alcoholic" gene that puts one at risk for alcoholism but perhaps as many as eight genes, which in turn interact with the environment to increase the risk for alcoholism (Edenberg & Foroud, 2006).

Because neither every child of an alcoholic parent nor both members of a pair of identical twins become an alcoholic, genetic risk factors alone do not lead to alcoholism. Rather, researchers believe that alcoholism results from the interaction between genetic and psychological risk factors (Lesch, 2005).

The use and abuse of alcohol are associated with a wide range of problems.

Problems with Alcohol

Why is alcohol so dangerous?

The reason alcohol is considered such a dangerous drug is that its use and abuse are linked to many problems in the United States:

✔ 80–90% of all campus rapes involve drinking on the part of the assailant, victim, or both;

✔ 68% of manslaughter convictions and 63% of assaults involve alcohol;

✔ 63% of episodes in which husbands batter their wives involve alcohol;

✔ 40% of traffic deaths involve alcohol (17,941 deaths); 40% of 21-year-olds drive after drinking;

✔ 44% of college students and 75% of fraternity/sorority students said they had binged—women drank 4 or men drank 5 successive drinks at least once in the last two weeks; alcohol use is one of the most common disorders in college students;

44% of college students and 75% of fraternity/sorority students report having binged.

✔ 37% of pedestrians killed by an automobile were under the influence of alcohol at the time;

✔ 40% of suicides and fatal falls involve alcohol;

✔ alcoholism is a factor in 25% of all hospital admissions;

✔ alcohol is the leading cause of mental retardation due to fetal alcohol syndrome (FAS);

✔ alcohol is the most serious problem facing U.S. high schools, surpassing apathy and poor discipline by a wide margin;

✔ alcoholism and alcohol abuse cost an estimated $150 billion per year in lost production, health and welfare services, property damage, and medical expenses (AAA, 2007; Blanco et al., 2008; Fromme, 2008; Hingson & Winter, 2003; Morse, 2002; NIAAA, 2009; Norungolo, 2005; Schuckit, 2000).

Because alcohol is involved in so many medical, social, emotional, legal, job-related, and personal problems, many consider it one of the most dangerous drugs (Naimi et al., 2003).

After you have had a chance to test your knowledge with the Concept Review, we'll discuss the worldwide problem of alcoholism.

Concept Review

1. Under hypnosis, individuals may think they return to an earlier stage in life, which is called (a) ________________; they may experience a reduction in pain, which is called (b) ________________; or they may experience loss of memory, called (c) ________________. Hypnotized subjects may perceive stimuli that do not exist, which is called (d) ________________, or they may perform some behavior after coming out of hypnosis, which is called a (e) ________________.

2. According to the (a) ________________ theory, hypnotized subjects perform suggested behaviors because they are in a special state. According to the (b) ________________ theory, subjects perform suggested behaviors because of social pressures and because they have the ability of responding to imaginative suggestions.

3. After using a drug repeatedly, a person must take increasingly larger doses to achieve the original behavioral effect; this is called (a) ________________. A change in the nervous system that requires a person to take a drug to prevent the occurrence of painful withdrawal symptoms is called (b) ________________. A behavioral pattern of drug abuse that is marked by a person's overwhelming and compulsive desire to obtain and use the drug is called an (c) ________________. Painful physical and psychological symptoms that occur after a drug-dependent person stops using the drug are called (d) ________________.

4. Drugs that affect the nervous system and result in altered awareness and consciousness, as well as changes in mood, cognition, and perception, are called ________________.

5. Some drugs act like (a) ________________ keys that are so similar to neurotransmitters that these drugs open the chemical (b) ________________ of nearby neurons by acting like or (c) ________________ the action of regularly occurring neurotransmitters. Some drugs prevent the neuron's reabsorption of neurotransmitters by slowing down a process called (d) ________________. Some drugs act on the nucleus accumbens and ventral tegmental area, which are parts of the brain's (e) ________________ center.

6. Those drugs that result in increased arousal, alertness, and euphoria are called (a) ________________. The potent stimulant that comes from a plant, can be sniffed or smoked, and produces short-acting alertness and euphoria is (b) ________________. The potent stimulant that is a form of amphetamine, is smoked, and produces longer-lasting alertness and euphoria is known on the street as (c) ________________. The world's most widely used stimulant, which produces mild arousal and alertness, is (d) ________________. The drug that is the single greatest avoidable cause of death in the United States is (e) ________________. This drug triggers dopamine, which stimulates the brain's reward/pleasure center.

7. Drugs that produce unusual or distorted perceptual, sensory, and cognitive experiences that do not correspond to external reality are called (a) ________________. One of the most powerful of these drugs, which can cause trips that last 8–10 hours, is (b) ________________. A drug that is found in certain mushrooms is (c) ________________; one that is found in peyote cactus is (d) ________________.

8. Synthetic drugs that are variations of known psychoactive drugs and are manufactured in illegal laboratories are called (a) ________________. One designer drug that is part stimulant and part hallucinogen is (b) ________________.

9. Drugs that have three primary effects—analgesia, a state of waking sleep, and constipation—are called (a) ________________. Continued use of these drugs causes the user to become (b) ________________; if the user stops using the drug, he or she will experience painful (c) ________________.

10. The psychoactive drug that depresses the functions of the central nervous system is (a) ________________. At low doses, it causes friendliness and loss of (b) ________________; at medium doses, it impairs social (c) ________________; and, at higher doses, it seriously impairs (d) ________________ coordination.

11. Certain individuals may develop or inherit different factors that make them at risk for becoming alcoholics. For example, a child raised by alcoholic parents may develop unusual, abnormal, or maladaptive psychological and emotional traits; these are called (a) ________________ risk factors. In addition, a child may inherit predispositions for abusing alcohol, such as being less sensitive to alcohol; these are called (b) ________________ risk factors.

Answers: *1. (a) age regression, (b) hypnotic analgesia, (c) posthypnotic amnesia, (d) imagined perception, (e) posthypnotic suggestion; 2. (a) altered state, (b) sociocognitive; 3. (a) tolerance, (b) dependence, (c) addiction, (d) withdrawal symptoms; 4. psychoactive drugs; 5. (a) chemical, (b) locks, (c) mimicking, (d) reuptake, (e) reward/pleasure; 6. (a) stimulants, (b) cocaine, (c) methamphetamine (crack, crystal, or ice), (d) caffeine, (e) nicotine; 7. (a) hallucinogens, (b) LSD, (c) psilocybin, (d) mescaline; 8. (a) designer drugs, (b) MDMA or ecstasy; 9. (a) opiates, (b) addicted, (c) withdrawal symptoms; 10. (a) alcohol (ethyl alcohol), (b) inhibitions, (c) judgment, (d) motor; 11. (a) psychological, (b) genetic*

Definition and Differences in Rates

What is alcoholism?

One of the interesting questions that applies to all drugs is why some people can use a drug usually in moderation and rarely abuse it, while others use the same drug but often abuse it and usually develop serious problems. For example, of the approximately 110 million U.S. citizens who drink alcohol, about 10 to 14 million abuse it, drink to excess, and develop alcoholism.

Alcoholism involves heavy drinking (sometimes a quart a day) for a long period of time, usually many years. Alcoholics are addicted (have intense craving) and are dependent on alcohol (must drink to avoid withdrawal symptoms). They continue to use alcohol despite developing major substance-related life problems, such as neglecting family, work, or school duties, having repeated legal or criminal incidents, and experiencing difficulties in personal or social relationships (American Psychiatric Association, 2000).

First signs of alcoholism appear in the early 20s.

One answer to why only certain drinkers abuse the drug and become alcoholics comes from studying various risk factors, such as psychological and genetic influences, which we discussed earlier. Now, we'll examine another risk factor—cultural influences.

Genetic Risk Factors

After the very first drink of alcohol, some individuals respond with a sudden reddening of the face. This reaction is called ***facial flushing*** and is caused by the absence of a liver enzyme involved in metabolizing alcohol.

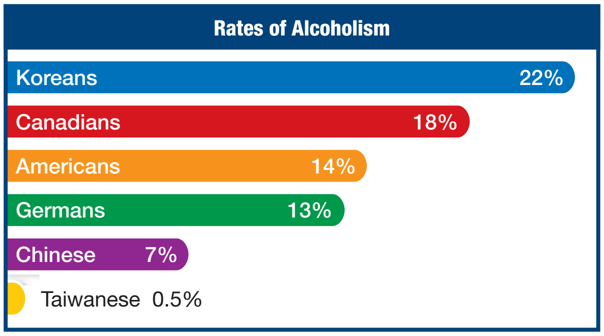
Facial flushing from alcohol is a genetic trait and rarely occurs in Caucasians (Whites) but does occur in about 30–50% of Asians (photo below) (Schuckit, 2000). Asians with significant facial flushing, such as Taiwanese, Chinese, and Japanese, tend to drink less and have lower rates of alcoholism than Asians who show less facial flushing, such as Koreans (Assanangkornchai et al., 2003). These findings show that facial flushing, which occurs in some cultures more than others, is linked to a ***genetic risk factor*** that influences the chances of becoming an alcoholic.

Asians with most facial flushing have lower rates of drinking and alcoholism.

Cultural Risk Factors

Different cultures have different values and pressures that may encourage or discourage alcohol abuse. For instance, researchers studied 48,000 adults (age 18 and older) in six different cultures to answer two questions: Do rates of alcoholism differ across cultures? What cultural values influence the rate of alcoholism?

The answer to the first question is shown in the graph below. Rates of alcoholism did differ across cultures, from a low of 0.5% among Taiwanese to a high of 22% among Koreans (Helzer & Canino, 1992).



The answer to the second question—What cultural values influence the rate of alcoholism?—was also partly answered. For example, the high rate of alcoholism in Korea was almost entirely in men, who are encouraged by cultural pressures to drink heavily in certain social situations, such as at the end of the workday, when coworkers are encouraged to have drinking contests. The medium rate of alcoholism found in Germany, the United States, and Canada was related to the stresses of living in heavily industrialized societies. The below-average rate of alcoholism found in China and especially Taiwan was influenced by the Confucian moral code, which has strong cultural-religious taboos against drinking or showing drunken behavior in public. These findings indicate that ***cultural risk factors*** can either encourage or discourage the development of alcoholism.

However, despite the different rates of alcoholism across cultures, there are some striking similarities.

Across Cultures

Although rates of alcoholism differed widely across cultures, from 0.5% to 22%, researchers found many similarities in how people developed alcoholism and the problems they had (Helzer & Canino, 1992; Peele, 1997). Here are some similarities that occurred across cultures:

- the average age when the first symptoms of alcoholism appear was in the early twenties or mid-twenties;
- the average number of major life problems among alcoholics was 4–6;
- the average duration of alcoholism was 8–10 years;
- the average pattern of drinking involved daily heavy drinking, often a quart a day;
- men were five times more likely to develop alcoholism than were women;
- depression was about twice as likely to be diagnosed in alcoholics as in nonalcoholics;
- the overall mortality rate from alcoholism did not differ among cultures.

Researchers concluded that although cultural—genetic and psychological—risk factors had a significant influence on the ***rate*** of alcoholism, cultural factors had little effect on the ***development,*** symptoms, sex differences, and mental disorders associated with alcoholism.

Next, we'll focus on the most widely used illegal drug in the United States.

H. Marijuana

Use and Effects

What's the most widely used illegal drug?

The most widely used illegal drug in the United States is marijuana. In this country, 42% of people have tried marijuana and 14.4 million are current users (SAMHSA, 2008; *Time,* 2008). No deaths have been reported from marijuana usage, however, it can still cause health problems (Cloud, 2002).

Marijuana is believed to be the leading U.S. cash crop; growers make an estimated $25 billion yearly (D. Campbell, 2003). In comparison, corn growers make $19 billion.

Medical marijuana. Research shows that marijuana can be effective in treating nausea and vomiting associated with chemotherapy, appetite loss in AIDS patients, eye disease (glaucoma), muscle spasticity, and some forms of pain (S. O. Cole, 2005). For these reasons, several states passed laws and others are considering laws that allow marijuana to be prescribed by doctors and used legally for medical problems (Associated Press, 2006a; N. Johnson, 2006). However, these state laws are in conflict with federal laws, which outlaw all uses of marijuana, including medical. This federal/state conflict will receive increasing attention as drug manufacturers release promising medications based on extracts of high-grade marijuana plants. Already, one such drug (Sativex) has proven effective in treating chronic pain symptoms of patients with multiple sclerosis and arthritis, but it is now available only in Canada (J. Davis, 2005).

Gateway effect. There are 600,000 marijuana arrests a year. One reason for enforcing tough penalties against marijuana usage is the *gateway effect,* which says that using marijuana leads young people to try harder drugs (cocaine, heroin). However, the gateway effect has been challenged by researchers who found that genetic and environmental predispositions explain equally well why some marijuana users go on to try harder drugs (Morral et al., 2002). In any case, marijuana is illegal and can cause problems.

Drug

As is true of many psychoactive drugs, some of marijuana's effects depend on the user's initial mood and state of mental health. For example, older patients who used marijuana to treat glaucoma or nausea complained about its "strange side effect," which was feeling high or euphoric, which is the very effect that young users seek in smoking marijuana (Tramer et al., 2001).

Marijuana **is a psychoactive drug whose primary active ingredient is THC (tetrahydrocannabinol), which is found in the leaves of the cannabis plant. The average marijuana cigarette ("joint") contains 2.5–11.0 mg of THC, which is a tenfold increase over the amount of THC found in marijuana in the 1970s. THC is rapidly absorbed by the lungs and in 5–10 minutes produces a high that lasts for several hours. The type of high is closely related to the dose: Low doses produce mild euphoria; moderate doses produce perceptual and time distortions; and high doses may produce hallucinations, delusions, and distortions of body image (G. R. Hanson et al., 2002).**

Depending on the user's state of mind, marijuana can either heighten or distort pleasant or unpleasant experiences, moods, or feelings.

Nervous System

In 1964, researchers identified and synthesized THC, the main mind-altering substance in marijuana.

In 1990, researchers discovered a specific receptor for THC in the brains of rats and humans (Matsuda et al., 1990). These THC receptors are located throughout the brain, including the hippocampus, which is involved in short-term memory; the cerebral cortex, which is involved in higher cognitive functions; the limbic system, which is involved in emotions; and the cerebellum and basal ganglia, which are involved in motor control, timing, and coordination (Iversen, 2000). Mammalian brains (such as humans) contain extremely high levels of THC receptors, which suggests they may be involved in important brain functions (Iversen, 2000).

In 1993, researchers found that the brain itself makes a chemical, called anandamide, that stimulates THC receptors. Anandamide, a naturally occurring brain chemical, has been shown to be one of the brain's neurotransmitters, whose actions are currently under study (Piomelli, 1999).

Thus, the brain not only has receptors for THC but also makes a THC-like chemical, called anandamide.

Dangers

Marijuana can cause temporary changes in cognitive functioning, such as interfering with short-term memory and ability to drive a car, boat, or plane, because it impairs reaction time, judgment, and peripheral vision (Schuckit, 2000). Long-term frequent doses may cause toxic psychoses, including delusions, paranoia, and feelings of terror, and are associated with depression and anxiety (Fergusson et al., 2005; Hall, 2006; R. M. Murray et al., 2007). However, there is no conclusive evidence that prolonged marijuana use causes permanent brain or nervous system damage (Cloud, 2002).

Marijuana causes many of the same kinds of respiratory problems as tobacco, including bronchitis and asthma attacks. Because marijuana smoke contains 50% more cancer-causing substances and users hold smoke in their lungs longer, the effects of smoking one joint of marijuana are similar to those of five cigarettes (*Time,* 2007c).

Some, but not all, regular heavy users of marijuana develop addiction and dependency. And when heavy users stop, some experience withdrawal symptoms, including irritability, restlessness, and anxiety as well as strong cravings for more (N. T. Smith, 2002; Wolfing et al., 2008).

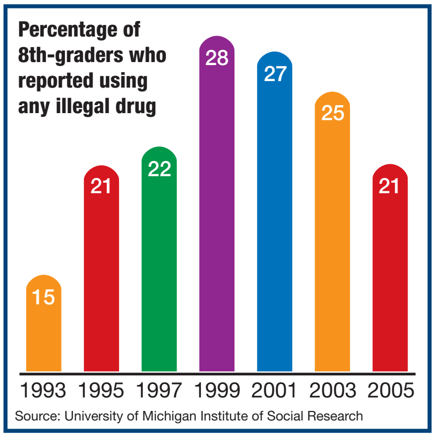
Now we'll examine a popular program to prevent drug usage in teenagers.

Photo Credits: top, © Rachel Whenman/Alamy; left, © RayArt Graphics/Alamy

How Effective Is the DARE Program?

For over 30 years, schools have tried dozens of drug prevention programs, such as providing knowledge about drugs and their risks, helping students make the right decisions, and recently, developing skills to resist social and peer pressures to use drugs. We want to focus on a popular and well-financed school-based drug prevention program called DARE.

DARE (Drug Abuse Resistance Education) is based on the idea of using social influence and role-playing to discourage adolescents from starting drug use and to encourage them to refuse drugs in the future. This program is taught in grade-school classrooms by trained, uniformed police officers.



Source: University of Michigan Institute of Social Research

Begun in 1983, DARE has become the most popular drug education school program, with an annual budget of about $700 million. Currently, thousands of DARE police officers speak to 26 million grade-school children in nearly 80% of the school districts in the United States and in 54 other countries (D. J. Hanson, 2007).

The question you might ask is: Why has DARE remained so popular even though the left graph shows that teenage use of illegal drugs almost doubled from 1993 to 1999 and dropped only slightly in recent years (NIDA, 2006b)? This question brings us to one of the major uses of research: to evaluate the effectiveness of intervention programs that claim to change behavior. Here's how and what researchers discovered when they evaluated the effectiveness of the DARE program.

Method and Procedure

Researchers selected 36 elementary schools in urban, suburban, and rural areas in Illinois. Schools were paired to control for ethnic differences and income levels of parents. Students in one school of a pair were the experimental group and received DARE training, while students in the other school of the pair were the control group and did not receive DARE training. A total of 1,803 students took part in the study.

Before DARE began, students were pretested to determine their attitudes toward drugs and their use of drugs. Then students in the experimental schools began the DARE program, which consisted of educational sessions lasting 45–60 minutes that are taught in the classroom by uniformed police officers.

Immediately after the DARE program and also 1, 2, and 3 years later, students were retested on their attitudes toward drugs and their actual use of drugs.

Although the DARE program was very popular with police and school officials, researchers found that it was mostly ineffective.

Photo Credit: Courtesy of D.A.R.E. America

Results and Discussion

Researchers found that going through project DARE had no statistically significant effect on whether students did or did not start smoking, drinking alcohol, or drinking to get drunk. These disappointing results were found immediately after the DARE program ended, as well as 1, 2, and 3 years later. There was a significant increase in self-esteem, but this gain was short-lived and was apparently not strong enough to help students resist using drugs in the future.

Researchers concluded that, although the police officers were well trained and popular among students, there was little evidence that DARE had any direct influence on adolescents' use of drugs or on attitudes and skills related to preventing drug use (Ennett et al., 1994).

Research studies have repeatedly found the DARE program to be ineffective in reducing alcohol and other drug use in teenagers (D. J. Hanson, 2007). For example, a 10-year follow-up of the DARE program found it had no effect on preventing the future use of drugs among teens (Janofsky, 2000; Lynam et al., 1999). In fact, there have been instances in which the DARE program was counterproductive, meaning it was worse than doing nothing (D. J. Hanson, 2007).

Conclusion

Despite DARE's large federal financial support and widespread popularity among police, politicians, school administrators, and parents, researchers have repeatedly found that the DARE program was ineffective in preventing future drug use in teenagers. In fact, researchers have found that almost all school-based prevention programs have failed to reduce teen drug usage in the long term (more than 1 year) (Cuijpers, 2003).

The DARE program became so popular and well financed because it received such glowing testimonials from its police officers, school officials, and politicians. However, as discussed in Module 2, evidence from testimonials is questionable because they are based on personal experiences, which have great potential for error and bias. The best way to evaluate the effectiveness of any program designed to change behavior, such as DARE, is to use the scientific method, which limits error and bias. This Research Focus shows the importance of basing evaluations on hard scientific evidence rather than on glowing testimonials, which may be distorted by error and bias.

Because of the program's proven ineffectiveness, police officers are no longer lecturing on the dangers of drugs. Instead, the new DARE program uses interactive learning, such as mock courtroom exercises, to help students stay away from drugs (E. S. McConnell, 2006).

If a teenager or adult does develop a drug habit, what kind of help does he or she receive in a drug treatment program?

J. Application: Treatment for Drug Abuse

Developing a Problem

What are the risks for drug abuse?

Here's a case study that shows how psychological risks helped push Martin into abusing alcohol and becoming an alcoholic.

In high school, Martin got good grades but still felt insecure, especially about his sexual abilities. His solution was to act like a "rugged, hard-drinking person." But, instead of helping, hard drinking made him feel more insecure in relationships and made it more difficult for him to perform sexually.

When Martin entered college, he continued to have low self-esteem and feared that someone would discover that his sexual performance did not match his bragging. As he had done in high school, he buried his fears in having 5–10 drinks on weekends.

Many start out believing that alcohol is the solution.

Despite his drinking bouts, Martin's knack for learning helped him finish college with good grades and even get into medical school. However, between college and medical school, he took a job driving a beer truck and drank half a dozen beers after work.

In medical school, Martin drank regularly because alcohol reduced his feelings of "self-loathing" and gave him an "instant" sense of self-worth. Despite heavy drinking, Martin's talents for mastering academic subjects helped him finish medical school.

After medical school, Martin settled in the Midwest, developed a successful medical clinic, got married, and had a family. However, throughout this period, he continued to drink heavily and began having blackouts. His wife could stand his drinking no longer, and one day she took the children and left. Martin began using painkillers, writing his own prescriptions.

Finally, one cold afternoon as Martin sat home with his booze and painkillers, the police arrested him for writing illegal prescriptions. Martin was forced to enter a psychiatric hospital for drug treatment (adapted from Khantzian & Mack, 1994).

Some of the psychological risks that pushed Martin to become a drug abuser are clear: For most of his life, he suffered from feelings of low self-esteem, worthlessness, and fears of not performing sexually. Hoping to solve his problems with drugs, Martin instead made them worse with substance abuse, the most common mental health problem among men (Kessler et al., 1994).

Many scientists now believe the process of a voluntary drug user turning into an addict, as happened to Martin, results from a combination of psychological risks and actual changes inside the brain. Based on considerable research, it has been found that changes in the brain's structure and function from heavy drug use result in making a person more sensitive to stress and more likely to use drugs again to reduce anxiety (Wenner, 2008b). For this reason, scientists caution against blaming addicts for their drug addiction. Instead they recommend programs that treat both the brain disease by reducing drug usage and the psychological problems by actively involving the user in returning to normal functioning without drugs (Leshner, 2001).

Substance Abuse and Treatment

What is a drug problem?

Like Martin, about 5–15% of those who use legal or illegal drugs develop a serious drug problem called substance abuse.

Individuals with substance abuse usually need professional help.

Substance abuse **refers to a maladaptive behavioral pattern of using a drug or medicine so frequently that significant problems develop: failing to meet major obligations and having multiple legal, social, family, health, work, or interpersonal problems. These problems must occur repeatedly during the same 12-month period (American Psychiatric Association, 2000).**

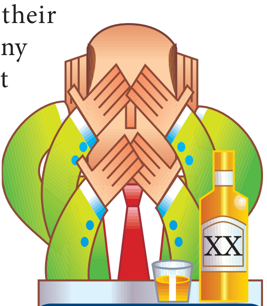
Substance abuse is one of the most challenging behaviors to change (Ray & Hutchinson, 2007). Most substance abusers need professional treatment to get straightened out. Martin entered a treatment program based on the Minnesota model, which is used in 95% of inpatient drug treatment centers in the United States. The *Minnesota model* recognizes that the drug user has lost control over drugs, may be vulnerable to using other mood-altering substances, cannot solve the drug problem alone, must rebuild his or her life without drugs, and must strive for abstinence (McElrath, 1997; Owen, 2003).

We'll follow Martin's progress as he goes through a typical drug treatment program based on the Minnesota model.

Step 1. Admit the Problem

Why don't people seek treatment?

The fact that Martin did not seek help for his drug problem until he was arrested points out an important difference between most individuals treated for drug problems and those treated for mental health problems.



Alcoholics deny that they have a problem.

Generally, individuals with mental health problems seek help voluntarily because they want to stop their suffering or unhappiness. In contrast, many individuals with drug problems do not recognize that they have a problem and do not seek help voluntarily. Thus, the first step in getting treatment is admitting that one has a drug problem. Although this step appears obvious, in reality it represents a hurdle that many drug abusers have a difficult time getting over. What happens is that drug users believe that drugs are the solution to their problems, fears, insecurities, and worries.

For almost 10 years, Martin believed that alcohol was the solution to his sexual and social fears. In fact, the opposite was true. Heavy drug use became the problem, even though Martin and most users refuse to admit it. Convincing heavy drug users to seek treatment often requires the efforts of their family, loved ones, and employer, as well as a judge or doctor (Schuckit, 2000).

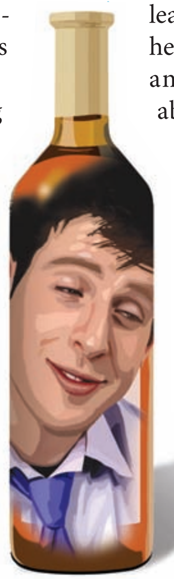
Figure/Text Credit: Adapted from "How AA Works and Why It's Important for Clinicians to Understand," by E. J. Khantzian and J. E. Mack, 1994, *Journal of Substance Abuse Treatment, 11,* 77–92.

Step 2. Enter a Program

Every day in the United States, about 2.7 million people receive treatment for alcoholism in either an inpatient (hospital) or outpatient (clinic) setting (SAMHSA, 2008). In Martin's case, he was required to enter an inpatient (hospital) drug treatment program because he was both addicted and depressed, would not admit to having a problem, and would not seek help on his own. In comparison, most alcoholics (85%) are treated in clinics as outpatients.

Most in- or outpatient drug treatment programs involve the following steps and goals: Martin receives a complete medical checkup and a two-week period of detoxification (getting drug free), and then a team consisting of a physician, psychologist, counselor, and nurse discusses the treatment's four goals with Martin (Winters et al., 2000).



Three different therapies, including AA, were equally effective.

First goal. Help Martin face up to his drinking problem. It is not uncommon for a drug abuser to deny that he or she has a problem with drugs, even though it is obvious to everyone else.

Second goal. Have Martin begin a program of stress management, so that he can reduce his anxiety and tension without drinking. Stress management involves the substitution of relaxation exercises and other enjoyable activities (sports, hobbies) for the escape and enjoyment that alcohol has provided.

Third goal. Give Martin an opportunity to share his experiences in group therapy. Group sessions helped Martin realize that he was not suffering alone, that it was important for him to make plans for the future, and that he might have to make new, nondrinking friends once he left the program.

Fourth goal. Perhaps the most important goal is to help Martin face and overcome his psychological risk factors, which include personal and social problems that had contributed to his drug abuse.

Photo Credit: © Gabe Palmer/Alamy

Step 3. Get Therapy

Regarding the fourth goal, you may wonder which kind of therapy is most effective in helping drug abusers. One answer comes from a 8-year study on over 1,700 individuals, all diagnosed as alcohol-dependent. This study compared the effectiveness of three different programs.

Three therapies. After volunteering for this study, individuals were randomly assigned to a 12-week treatment program that involved one of the following three therapies. ***Cognitive-behavioral therapy*** focuses on helping patients develop skills to control their thoughts about alcohol and learn to control their urges to drink. ***Motivational therapy*** helps clients recognize and utilize their personal resources and encourages them to take personal responsibility to abstain from drinking. The ***12-step approach*** is used in traditional Alcoholics Anonymous (AA) programs. The AA therapy or program promotes spiritual awakening, and its 12 steps serve as a guide for recovery and abstinence. AA believes that drug abuse is a disease, that a person must surrender to and ask God for help, and that total abstinence is the only solution.

Because these three therapies represent three different philosophies or approaches, many professionals believed that one therapy might be more effective than another.

Effectiveness. Researchers found that, before therapy, all individuals drank heavily on about 25 out of 30 days per month. In comparison, a year after finishing therapy, 35% reported not drinking at all, while 65% had slipped, or relapsed, into drinking again. Of the 65% who had relapsed, 40% reported periods of at least 3 consecutive days of heavy drinking.

There was little difference in the effectiveness of the three programs, which was somewhat surprising in view of their different approaches to drug treatment (Project Match Research Group, 1997). The effectiveness of a drug treatment program is measured by how many clients remain abstinent (do not use drugs) for a period of one year. Success rates range from 30 to 45%, which means that 55 to 70% relapse or return to drinking during the year following treatment (Fuller & Hiller-Sturmhofel, 1999). For most drug treatment programs, the goal is total abstinence. However, there is an ongoing debate over whether alcoholics can learn to use drugs in moderate amounts. So far, there is very little research to show that long-term alcoholics can learn to drink moderately and responsibly (Rivera, 2000).

New drugs. Medications approved to treat alcoholism include naltrexone and acamprosate, which reduce cravings, and Antabuse, which makes people physically ill if they consume alcohol (K. Hobson, 2006). These drugs have shown modest success when used alone and greater success when combined with therapy to help alcoholics rebuild their lives (K. Hobson, 2006; Schuckit, 2002).

Following a drug treatment program, patients are encouraged to join a support group in their community.

Step 4. Stay Sober

After treatment, recovering alcoholics as well as other drug addicts are encouraged to join a community support group to help fight relapse, or returning to drugs. The most popular and successful aftercare program for alcoholics is Alcoholics Anonymous (AA); a similar program for other drug users is Narcotics Anonymous (NA). After drug treatment, AA and NA provide programs to help prevent relapse, which occurs in 55% to 70% of former drug users.

Relapse can be triggered by a single exposure to the drug, by being with people or in places associated with using the drug, or by acute and chronic stressors.

To help patients deal with relapse, therapists have developed a program called relapse prevention therapy, which includes helping patients recognize high-risk situations that might trigger relapse, rehearsing strategies for dealing with high-risk situations, such as avoiding old drinking buddies, and learning how to deal with drug cravings. Because the majority of drug users relapse, this therapy also helps patients recover from a relapse (Foxhall, 2001).

About 55–70% of recovering alcoholics suffer relapse.

Thus, a person with a drug problem initially needs help to get off a drug, then treatment to recover, then a support group, and finally relapse therapy to deal with relapse and try to remain drug free.

Summary Test

A. Hypnosis

1. Hypnosis is defined as an altered state of awareness, attention, and alertness, during which a person is usually much more open to the (a) ________ of a hypnotist or therapist. About 10–15% of adults are easily hypnotized, while 20% are difficult to hypnotize. The procedure used to hypnotize someone is called (b) ________.

2. Under hypnosis, subjects will experience or perform the following ________: age regression, imagined perception, posthypnotic amnesia, posthypnotic suggestions, and hypnotic analgesia.

3. According to the (a) ________ theory, hypnotized subjects perform suggested behaviors because they are in a special state. According to the (b) ________ theory, subjects perform suggested behaviors, not because they are hypnotized, but because these individuals have the amazing ability of responding to imaginative suggestions and because of social pressures.

4. In dental and medical settings, hypnosis is used to help patients deal with painful procedures by producing (a) ________. In therapeutic settings, hypnosis is used in combination with other behavioral and cognitive treatments to help clients reveal their personalities and gain insights. However, hypnosis is not very successful in dealing with problems that involve (b) ________.

B. Drugs: Overview

5. Regular use of a drug usually results in one or more of the following. A behavioral pattern of drug abuse that is marked by an overwhelming and compulsive desire to obtain and use the drug is called an (a) ________. If the nervous system becomes accustomed to having the drug and needs the drug for normal functioning, the user is said to have developed a (b) ________. If a habitual user suddenly stops taking the drug, he or she will experience unpleasant or painful (c) ________. After using a drug over a period of time, a person must take a larger dose to achieve the original behavioral effect because this person has developed a (d) ________ for the drug.

6. Drugs that affect the nervous system by altering consciousness, awareness, sensations, perceptions, mood, and cognitive processes are called ________ drugs.

7. Some drugs act like (a) ________ keys that open neurons' chemical (b) ________, and some prevent the neuron's reabsorption of neurotransmitters, called (c) ________. Some drugs act on the brain's powerful (d) ________ center.

C. Stimulants

8. Drugs that increase activity of the nervous system and result in heightened alertness, arousal, and euphoria and decreased appetite and fatigue are called ________.

9. In moderate doses, cocaine produces short-lived enhancement of ________. In heavy doses, it can produce addiction; serious psychological effects, such as frightening hallucinations; and serious physical problems, such as heart irregularity, convulsions, and death.

10. A form of amphetamine called ________ produces a quick high, is very addictive, and has become a major drug problem.

11. The most widely used legal psychoactive drug in the world is ________, which affects brain receptors and, depending on the dose, produces physiological arousal, a mild feeling of alertness, increased reaction time, and decreased fatigue and drowsiness.

12. The legal drug that is second to caffeine in worldwide usage is ________, which triggers the production of dopamine.

D. Opiates

13. All opiates produce three primary effects: a reduction in pain, which is called (a) ________; a twilight state between waking and sleeping, which is called (b) ________; and (c) ________, which permits their use as a treatment for diarrhea. With continued use of opiates, users develop tolerance, addiction, and an intense craving for the drug. The brain also produces its own morphinelike chemicals, called (d) ________.

E. Hallucinogens

14. Drugs that act on the brain (and body) to produce perceptual, sensory, and cognitive experiences that do not match the external reality are called (a) ________. Sometime after using LSD, a user may suddenly have a frightening, drug-related experience called a (b) ________. Examples of hallucinogenic drugs are LSD, psilocybin, and mescaline. Drugs that are manufactured or altered to produce psychoactive effects are called (c) ________; an example is (d) ________.

Photo Credits: (#1), © Will & Deni McIntyre/Photo Researchers, Inc.; (#8) © DIOMEDIA/Alamy; (#13) © Dr. Jeremy Burgess/Photo Researchers, Inc.; (#14) © Robert Pickett/Corbis

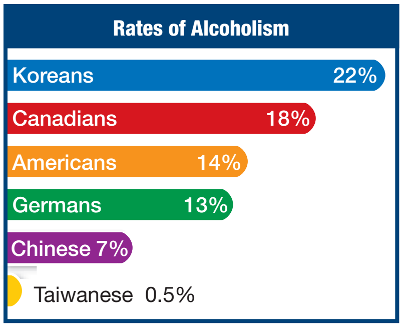
F. Alcohol

15. Alcohol is classified as a (a) ________ because it decreases the activity of the central nervous system by stimulating neural receptors called (b) ________ receptors. Heavy and repeated drinking can result in periods of seemingly normal behavior that the drinker, when sober, cannot recall at all; these periods are called (c) ________. Alcohol abuse is a major contributor to personal problems, fatal traffic accidents, birth defects, homicides, assaults, date rape, and suicide.

16. A drinker's risk of becoming an alcoholic increases 3–4 times if members of his or her family are alcoholics. The risk of developing alcoholism is increased by having difficulties in showing trust and being overdependent in relationships, which are called (a) ________ factors, and also by the inheritance of predispositions for alcoholism, which are called (b) ________ factors.

G. Cultural Diversity: Alcoholism Rates

17. About 10–14% of American drinkers become ________, defined as people who have drunk heavily for a long period of time, are addicted to and have an intense craving for alcohol, and have developed major life problems because of drinking.



18. One reason the Chinese and Taiwanese have low rates of alcoholism is that these societies are heavily influenced by the Confucian moral code, which discourages ________ in public.

H. Marijuana

19. The most widely used illegal drug in the United States is (a) ________. In low doses it produces mild euphoria, in moderate doses it produces distortions in perception and time, and in high doses it may produce hallucinations and delusions. Researchers discovered that the brain has neural locks, or THC (b) ________, that are highly concentrated in the brain and respond to the THC in marijuana. The brain makes its own chemical, called (c) ________, which is one of the brain's own (d) ________ and closely resembles THC. Throughout the brain are many THC receptors that are involved in a number of behaviors, including (e) ________.

I. Research Focus: Drug Prevention

20. The most popular program to prevent drug use in teenagers is called (a) ________, which involves police officers lecturing to students about the dangers of drugs. However, researchers found that this popular and well-financed program was not effective in preventing future drug use. One reason DARE grew in popularity was because school officials and police officers gave DARE glowing (b) ________. Compared to scientific evidence, testimonials are much less reliable because they have a relatively high potential for (c) ________.

J. Application: Treatment for Drug Abuse

21. A maladaptive pattern of continued usage of a substance—drug or medicine—that results in significant legal, personal, or other problems over a 12-month period is called ________.

22. Programs that treat drug abusers have four steps: The first step is admitting that one has a (a) ________. The second step is entering a (b) ________, which has four goals. The third step is to get (c) ________ to help overcome drug abuse. The fourth step is to remain (d) ________.

23. Researchers found that three different kinds of therapy—cognitive-behavioral, motivational, and AA's 12-step approach—were about (a) ________ in helping alcoholics stop drinking. Although 35% of individuals stopped drinking, 65% started drinking again, which is called (b) ________. Part of recovery is learning how to deal with relapse, called (c) ________ therapy. In addition, recovering addicts are encouraged to join a community (d) ________ group, which helps them remain drug free.

Answers: *1. (a) suggestions, (b) hypnotic induction; 2. behaviors; 3. (a) altered state, (b) sociocognitive; 4. (a) analgesia, (b) self-control; 5. (a) addiction, (b) dependence, (c) withdrawal symptoms, (d) tolerance; 6. psychoactive; 7. (a) chemical, (b) locks, (c) reuptake, (d) reward/pleasure; 8. stimulants; 9. activity, mood, or energy; 10. methamphetamine; 11. caffeine; 12. nicotine; 13. (a) analgesia, (b) opiate euphoria, (c) constipation, (d) endorphins; 14. (a) hallucinogens, (b) flashback, (c) designer drugs, (d) MDMA, or ecstasy; 15. (a) depressant, (b) GABA, (c) blackouts; 16. (a) psychological risk, (b) genetic risk; 17. alcoholics; 18. drunkenness; 19. (a) marijuana, (b) receptors, (c) anandamide, (d) neurotransmitters, (e) memory, emotions, motor control, higher cognitive functions; 20. (a) DARE, (b) testimonials, (c) error and bias; 21. substance abuse; 22. (a) drug problem, (b) treatment program, (c) therapy, (d) drug free; 23. (a) equally effective, (b) relapse, (c) relapse, (d) support*

Critical Thinking

Brain-Boosting Drugs: Myth or Fact?

Currently, there is major controversy among scientists, educators, and others over the rapidly increasing number of healthy people turning to "brain-boosting" drugs to enhance their mental performance. The main drugs being used for this purpose are Ritalin (nicknamed "Vitamin R" by some), which is used to treat ADHD, and Provigil, which is used to treat sleep disorders. College campus surveys show that nearly 25% of college students use these medications without a prescription, not while partying to get a high but to help with studying. Even professors and scientists (reportedly as many as 20%) admit to using these brain-boosting drugs to improve their concentration, memory, or problem-solving skills.

Research shows these drugs can improve a variety of mental skills in healthy people, such as increasing concentration time on a task, reducing time needed to solve puzzles, and improving memory of a series of numbers. Provigil can even help people go for days without sleeping, all while improving their mental performance. As impressive as these drugs may sound, their long-term risks on healthy people are unknown. Use of any drug entails a risk, perhaps especially when used in an unintended way, and only time will determine if their advantages outweigh their possible dangers.

Of course, dosing up on stimulant medications to improve focus and energy is nothing new. Amphetamines and other stimulant drugs have long been used for this purpose. And let's remember that almost all of us drink caffeinated beverages to feel more upbeat, alert, and focused. Many college students drink caffeinated beverages, sometimes caffeine-pumped energy drinks, to stay awake studying for an exam or completing a term paper. But how much does caffeine actually boost our brains? Is it possible that in addition to keeping us from nodding off, caffeine can make us more intelligent?

Research shows that after consuming caffeine (two cups of coffee), people have faster reaction times and increased activity in the areas of the brain responsible for memory and attention. Drinking caffeine may improve your memory and attention, but this doesn't mean it makes us smarter. As a research psychologist, Harris Lieberman, says, "I use the word intelligence as an inherent trait, something permanently part of your makeup" (Lemonick, 2006, p. 95). He explains that caffeine cannot change intelligence, but what it can do is improve your attention, mood, and energy level. For instance, when you're feeling drowsy and you take caffeine, many intellectual functions, such as attention, logical reasoning, and reaction time, improve. Thus, though caffeine cannot make you more intelligent, it can help you to better use the intellectual abilities you already have. The same can be said about other so-called brain-boosting drugs, such as Ritalin and Provigil. (Adapted from S. Baker, 2009; Billingsley, 2005; Greely et al., 2008; Hibbert, 2007; Koppelstaetter et al., 2005; Lemonick, 2006; Steenhuysen, 2008b; Talbot, 2009; Wire Reports, 2007)

QUESTIONS

1 Which illegal drug is Ritalin most similar to?

2 What are an advantage and disadvantage of the survey research method?

3 What are some of the dangers of sleep deprivation?

4 How do stimulant drugs work?

5 Which type of research method must be used to conclude that caffeine, and not something else, was the cause of improved memory?

6 Can drinking more than two cups of coffee improve these intellectual functions even more?

Suggested Answers to Critical Thinking

1. Ritalin's effects are most similar to those of amphetamine, a powerful and illegal stimulant drug. (p. 27)
2. An advantage of a survey is that it is an efficient way to obtain much information from a large number of people. A disadvantage is that such information can contain errors or be biased because people may not remember accurately or answer truthfully. (p. 28)
3. There are many dangers associated with sleep deprivation, some of which are a weakened immune system, increased levels of stress hormones, elevated blood pressure, irritability, and difficulty making rational or logical decisions. (p. 157)
4. Stimulant drugs work by increasing the release of the neurotransmitter dopamine and blocking its reuptake, which means dopamine remains longer to excite neighboring neurons. (pp. 176–177)
5. A placebo-controlled, double-blind experiment would determine if caffeine was the true cause of improved memory scores because it eliminates chances of error and determines cause and effect. (pp. 36–37)
6. There is no research to support that drinking more than two cups of coffee will lead to further improvement of intellectual functions. On the contrary, high caffeine consumption can make a person feel jittery and anxious and may interfere with sleep.

It's Only Aftershave

What happened to Carla?

"I've got an unusual problem and I thought you might be able to explain what happened." Carla, one of my (R. P.) students, looked troubled.

"I'll help if I can," I replied, and asked her to sit down.

"It all started when my dentist told me that I needed a lot of work on my teeth and gums. I spent many mornings in the dentist's chair, and even though he gave me Novocain, it was painful and very uncomfortable. But here's the strange part that I wish you would explain. I had recently bought my boyfriend a new aftershave, and as the dentist worked on my teeth, I noticed that he was using the same one. You'll think this is silly, but now when I smell my boyfriend's aftershave, I start to feel tense and anxious."

aftershave

How can smelling aftershave cause anxiety?

Carla stopped and waited to see if I would tell her that she was just being silly. I didn't, and she continued.

"Finally, I told my boyfriend that he would have to stop using the aftershave I had bought him because it was the same as my dentist's and the smell made me anxious. Well, we got into a big argument because he said that he was nothing like my dentist and I was just being silly. So now my teeth are great, but I feel myself getting anxious each time we get close and I smell his aftershave."

I assured Carla that she was not being silly and that many people get conditioned in the dentist's chair. In fact, patients have reported feeling anxious when they enter the dentist's office, smell the antiseptic odor, or hear the sound of the drill (Settineri et al., 2005; Taani et al., 2005). I explained that, without her knowing, she had been conditioned to feel fear each time she smelled her dentist's aftershave and how that conditioning had transferred to her boyfriend's aftershave. Before I explained how to get "unconditioned," I told her how after only one terrifying experience, I too had been conditioned.

It's Only a Needle

What happened to Rod?

I was about 8 years old when I had to get an injection from my local doctor, whom I really liked. He warned me in a kindly way that the injection might hurt a little. I was feeling OK until I saw the long needle on the syringe. I tried to be brave and think of my fuzzy dog, but as soon as I felt that long needle enter my little butt, everything started to spin. I remember sinking slowly to the floor, and then everything went dark. When I came to, the doctor told me that I had fainted.

How can the sight of a syringe and needle cause terror?

Even after all these years, the sight of a needle can still strike terror into me. To prevent fainting, I always lie down when getting an injection or giving blood. But I'm not alone in my fear of needles and injections; about 10 to 20% of the general population report a similar fear and many others have some aversion to needles (Page et al., 1997; Sibbitt, 2006).

Besides learning to fear needles and blood, people can unknowingly learn to feel sick and nauseated, just as Michelle did.

It's Only Dish Soap

What happened to Michelle?

Michelle was nervous and afraid as the nurse put a needle into the vein in her left arm and then opened a valve that allowed chemicals to drip into her bloodstream. Michelle was in the process of receiving chemotherapy to treat her cancer. One serious side effect of chemotherapy is severe nausea, which Michelle experienced after each treatment.

What Michelle wasn't prepared for was how other things could trigger her nausea. In one case, the odor of her dishwashing liquid, which smelled similar to the chemotherapy room, made her feel nauseated. She had to change her brand of detergent because its odor made her salivate, which was the first sign of oncoming nausea (Wittman, 1994). Without her awareness, Michelle had been conditioned to feel nauseated by numerous stimuli involved in her chemotherapy (McRonald & Fleisher, 2005).

How can smelling dish soap cause nausea?

The cases of Michelle, Carla, and myself show how we had been conditioned to fear relatively ordinary things, such as aftershave lotion, needles, and the smell of detergent. This conditioning illustrates one kind of learning.

Learning is a relatively enduring or permanent change in behavior or knowledge that results from previous experience with certain stimuli and responses. The term ***behavior*** includes any observable response (fainting, salivating, vomiting).

In all three cases, conditioning resulted in a relatively enduring change in behavior. In fact, mine has lasted 50 years. What happened to each of us involved a particular kind of learning, called classical conditioning, which we'll discuss in this module.

What's Coming

We'll first discuss three different kinds of learning and then focus on one, classical conditioning. We'll examine how classical conditioning is established and tested, how we respond after being classically conditioned, what we learn during classical conditioning, and how classical conditioning is used in therapy. Let's begin with a look at three different kinds of learning.

Photo Credit: © Digital Stock Corporation

A. Three Kinds of Learning

Why is some learning easier?

Some things are difficult to learn, such as all the terms in this module. Other things are easy to learn, such as fear of an injection. To understand why some learning is easy and some hard, we'll visit three different laboratories. You'll see how psychologists identified three different principles that underlie three different kinds of learning: classical conditioning, operant conditioning, and cognitive learning.

Classical Conditioning

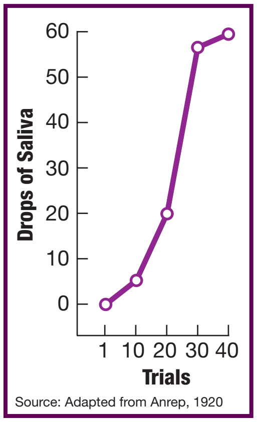
Why does the dog salivate?

It is the early 1900s, and you are working as a technician in Russia in the laboratory of Ivan Pavlov. He has already won a Nobel Prize for his studies on the reflexes involved in digestion. For example, he found that when food is placed in a dog's mouth, the food triggers the reflex of salivation (Evans, 1999).

As a lab technician, your task is to place various kinds of food in a dog's mouth and measure the amount of salivation. But soon you encounter a problem. After you have placed food in a dog's mouth on a number of occasions, the dog begins to salivate merely at the sight of the food.

At first, Pavlov considered this sort of anticipatory salivation to be a bothersome problem. Later, he reasoned that the dog's salivation at the sight of food was also a reflex, but one that the dog had somehow ***learned.***

In a well-known experiment, Pavlov rang a bell before putting food in the dog's mouth.



Source: Adapted from Anrep, 1920

As shown in this graph, after a number of trials of hearing a bell paired with food, the dog salivated at the sound of the bell alone, a phenomenon that Pavlov called a ***conditioned reflex*** and today is called classical conditioning. Classical conditioning was an important discovery because it allowed researchers to study learning in an observable, or objective, way (Honey, 2000).

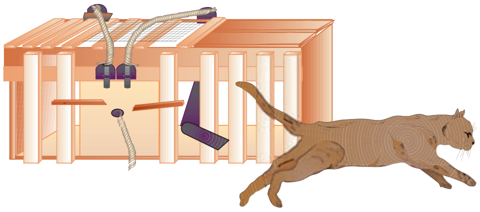
Classical conditioning **is a kind of learning in which a neutral stimulus acquires the ability to produce a response that was originally produced by a different stimulus.**

Next, we'll visit a lab in the United States and observe a different kind of learning.

Operant Conditioning

Why does the cat escape?

It is the late 1800s, and you are now working in the laboratory of the American psychologist E. L. Thorndike. Your task is to place a cat in a box with a door that can be opened from the inside by hitting a simple latch. Outside the box is a fish on a dish. You are to record the length of time it takes the cat to hit the latch, open the door, and get the fish.



Thorndike studied how a cat learned to open a cage to get nearby food.

On the first trial, the cat sniffs around the box, sticks its paw in various places, accidentally hits the latch, opens the door, and gets the fish. You place the cat back into the box for another trial. Again the cat moves around, accidentally strikes the latch, and gets the fish. After many such trials, the cat learns to spend its time around the latch and eventually to hit the latch and get the fish in a very short time.

To explain the cat's goal-directed behavior, Thorndike formulated the law of effect.

The *law of effect* says that if some random actions are followed by a pleasurable consequence or reward, such actions are strengthened and will likely occur in the future.

Thorndike's law of effect was important because it identified a learning process different from Pavlov's conditioned reflex. Today, the law of effect has become part of operant conditioning (Evans, 1999).

Operant conditioning **refers to a kind of learning in which the consequences that follow some behavior increase or decrease the likelihood of that behavior's occurrence in the future.**

We will discuss operant conditioning in Module 10. Our next lab has a big plastic doll and a bunch of kids.

Cognitive Learning

Why do they punch the doll?

It is the 1960s, and you are in Albert Bandura's laboratory, where children are watching a film of an adult who is repeatedly hitting and kicking a big plastic doll. Following this film, the children are observed during play.

Bandura found that children who had watched the film of an adult modeling aggressive behavior played more aggressively than children who had not seen the film (Bandura et al., 1963). The children's change in behavior, which was increased aggressive responses, did not seem to be based on Pavlov's conditioned reflexes or Thorndike's law of effect. Instead, the entire learning process appeared to take place in the children's minds, without their performing any observable responses or receiving any noticeable rewards. These mental learning processes are part of cognitive learning, which is a relatively new approach that began in the 1960s (Chance, 2006).

Cognitive learning **is a kind of learning that involves mental processes, such as attention and memory; may be learned through observation or imitation; and may not involve any external rewards or require the person to perform any observable behaviors.**

Bandura's study demonstrated a third principle of learning, which essentially says that we can learn through observation or imitation. ***We will discuss cognitive learning in Modules 10, 11, and 12.***

Now, let's return to Pavlov's laboratory and examine his famous discovery in greater detail.

B. Procedure: Classical Conditioning

Pavlov's Experiment

What's the procedure?

Imagine that you are an assistant in Pavlov's laboratory and your subject is a dog named Sam. You are using a procedure that will result in Sam's salivating when he hears a bell, a response that Pavlov called a ***conditioned reflex.*** Today, we call Pavlov's procedure ***classical conditioning,*** which involves the following three steps.

Step 1. Selecting Stimulus and Response

Terms. Before you begin the procedure to establish classical conditioning in Sam, you need to identify three critical terms: *neutral stimulus, unconditioned stimulus,* and *unconditioned response.*

Neutral stimulus. You need to choose a neutral stimulus.

A ***neutral stimulus*** is some stimulus that causes a sensory response, such as being seen, heard, or smelled, but does not produce the reflex being tested.

Your neutral stimulus will be a tone (bell), which Sam the dog hears but which does not normally produce the reflex of salivation.

Unconditioned stimulus. You need to choose an unconditioned stimulus, or UCS.

An ***unconditioned stimulus,*** or ***UCS,*** is some stimulus that triggers or elicits a physiological reflex, such as salivation or eye blink.

Your unconditioned stimulus will be food, which when presented to Sam will elicit the salivation reflex—that is, will make Sam salivate.

Unconditioned response. Finally, you need to select and measure an unconditioned response, or UCR.

The ***unconditioned response,*** or ***UCR,*** is an unlearned, innate, involuntary physiological reflex that is elicited by the unconditioned stimulus.

For instance, salivation is an unconditioned response that is elicited by food. In this case, the sight of food, which is the unconditioned stimulus, will elicit salivation in Sam, which is the unconditioned response.

Step 2. Establishing Classical Conditioning

Trial. A common procedure to establish classical conditioning is for you first to present the neutral stimulus and then, a short time later, to present the unconditioned stimulus. The presentation of both stimuli is called a ***trial.***

Neutral stimulus. In a typical trial, you will pair the neutral stimulus, the tone, with the unconditioned stimulus, the food. Generally, you will first present the neutral stimulus (tone) and then, a short time later, present the unconditioned stimulus (food).

+

Unconditioned stimulus (UCS). Some seconds (but less than a minute) after the tone begins, you present the unconditioned stimulus, a piece of food, which elicits salivation. This trial procedure is the one most frequently used in classical conditioning.

→

Unconditioned response (UCR). The unconditioned stimulus, food, elicits the unconditioned response, salivation, in Sam. Food and salivation are said to be unconditioned because the effect on Sam is inborn and not dependent on some prior training or learning.

Step 3. Testing for Conditioning

Only CS. After you have given Sam 10 to 100 trials, you will test for the occurrence of classical conditioning. You test by presenting the tone (conditioned stimulus) without showing Sam the food (unconditioned stimulus).

Conditioned stimulus. If Sam salivates when you present the tone alone, it means that the tone has become a conditioned stimulus.

A ***conditioned stimulus,*** or ***CS,*** is a formerly neutral stimulus that has acquired the ability to elicit a response that was previously elicited by the unconditioned stimulus.

In this example, the tone, an originally neutral stimulus, became the CS.

→

Conditioned response. When Sam salivates to the tone alone, this response is called the conditioned response.

The ***conditioned response,*** or ***CR,*** which is elicited by the conditioned stimulus, is similar to, but not identical in size or amount to, the unconditioned response.

One thing to remember is that the conditioned response is usually similar in appearance but smaller in amount or magnitude than the unconditioned response. This means that Sam's conditioned response will involve less salivation to the tone (conditioned stimulus) than to the food (unconditioned stimulus).

Predict. One question you may ask about classical conditioning is: What exactly did Sam learn during this procedure? One thing Sam learned was that the sound of a bell predicted the very likely occurrence of food (Rescorla, 1988). Classical conditioning helps animals and humans predict what's going to happen and thus provides information that may be useful for their survival (D. A. Lieberman, 2004).

Next, we'll use the concepts of classical conditioning to explain how Carla was conditioned to her dentist's aftershave.

B. Procedure: Classical Conditioning

Terms in Classical Conditioning

What happened to Carla?

After many trips to her dentist, Carla unknowingly experienced classical conditioning, which explains why she now feels anxious and tense when she smells a certain aftershave lotion. As we review the steps involved in classical conditioning, you will see how they apply to Carla's situation.

Step 1. Selecting Stimulus and Response

Terms. To explain how classical conditioning occurs, it's best to start by identifying three terms: *neutral stimulus, unconditioned stimulus,* and *unconditioned response.*

aftershave

The ***neutral stimulus*** in Carla's situation was the odor of the dentist's aftershave lotion, which she smelled while experiencing pain in the dentist's chair. The aftershave is a neutral stimulus because although it affected Carla (she smelled it), it did not initially produce feelings of anxiety. In fact, initially Carla liked the smell.

The ***unconditioned stimulus*** for Carla was one or more of several dental procedures, including injections, drillings, and fillings. These dental procedures are unconditioned stimuli (UCS) because they elicited the unconditioned response (UCR), which was feeling anxious and tense.

The ***unconditioned response*** was Carla's feeling of anxiety, which is a combination of physiological reflexes, such as increased heart rate and blood pressure and rapid breathing, as well as negative emotional reactions. Carla's unconditioned response (anxiety) was elicited by the unconditioned stimulus (painful dental procedure).

Step 2. Establishing Classical Conditioning

Trial. One procedure to establish classical conditioning is for the neutral stimulus to occur first and be followed by the unconditioned stimulus. Each presentation of both stimuli is called a ***trial.***

In Carla's case, the ***neutral stimulus*** was smelling the dentist's aftershave while she was experiencing a number of painful dental procedures.

aftershave

+

Carla's many trips to the dentist resulted in her having repeated trials that involved occurrence of the ***neutral stimulus,*** smelling the dentist's aftershave, and occurrence of the ***unconditioned stimulus,*** having painful dental procedures.

→

The painful dental procedures elicited the ***unconditioned response*** (feelings of anxiety) as well as other physiological responses, such as increases in heart rate, blood pressure, and breathing rate.

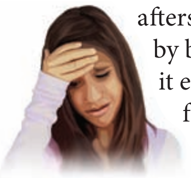
Step 3. Testing for Conditioning

Only CS. A test for classical conditioning is to observe whether the neutral stimulus, when presented alone, elicits the conditioned response.

Conditioned stimulus. When Carla smelled her boyfriend's aftershave, which was the same as the dentist's, she felt anxious. The aftershave's smell, formerly a neutral stimulus, had become a ***conditioned stimulus*** because it elicited anxiety, the conditioned response.

aftershave

→



Conditioned response. Whenever Carla smelled the aftershave (conditioned stimulus) used by both her dentist and her boyfriend, it elicited the ***conditioned response,*** feeling anxious. However, remember that the conditioned response is similar to, but of lesser intensity than, the unconditioned response. Thus, the anxiety elicited by smelling the aftershave was similar to, but not as great as, the anxiety Carla felt during painful dental procedures.

Dental fears. Through classical conditioning, Carla learned that the smell of a certain aftershave predicted the likely occurrence of pain and made her feel anxious. Researchers suggest that people who developed an extreme fear or phobia of dental procedures learned such fears through classical conditioning (Klaassen et al., 2008; Skaret & Soevdsnes, 2005). However, just as classical conditioning can elicit fears, it can also be used to treat them through an "unconditioning" procedure that we'll discuss in the Application section on page 206.

Next, we'll describe several other behaviors that are associated with classical conditioning.

C. Other Conditioning Concepts

What else happened to Carla?

Carla's experience in the dentist's office of being classically conditioned to feel anxious when she smelled a particular aftershave has some other interesting features. Carla found that similar odors also elicited anxious feelings but that other odors did not; her anxiety when smelling her boyfriend's aftershave gradually decreased, but accidentally meeting the dentist and smelling his aftershave triggered some anxiety. Pavlov found that these phenomena were associated with classical conditioning, and he named them generalization, discrimination, extinction, and spontaneous recovery.

1. Generalization

Why her shampoo?

During Carla's conditioning trials, the neutral stimulus, which was the odor of the dentist's aftershave, became the conditioned stimulus that elicited the conditioned response, anxiety. However, Carla may also feel anxiety when smelling other similar odors, such as her own hair shampoo; this phenomenon is called generalization.

Reacting to similar odors is generalization.

Generalization is the tendency for a stimulus that is similar to the original conditioned stimulus to elicit a response that is similar to the conditioned response. Usually, the more similar the new stimulus is to the original conditioned stimulus, the larger will be the conditioned response.

Pavlov suggested that generalization had an adaptive value because it allowed us to make an appropriate response to stimuli that are similar to the original one. For example, although you may never see your friend's smiling face in exactly the same situation, generalization ensures that the smiling face will usually elicit positive feelings.

2. Discrimination

Why not her nail polish?

Carla discovered that smells very different from that of the aftershave did not elicit anxiety; this phenomenon is called discrimination.

Discrimination occurs during classical conditioning when an organism learns to make a particular response to some stimuli but not to others.

For example, Carla had learned that a particular aftershave's smell predicted the likelihood of a painful dental procedure. In contrast, the smell of her nail polish, which was very different from that of the aftershave, predicted not painful dental procedures but nice-looking fingernails.

nail
polish

Not reacting to a new odor is discrimination.

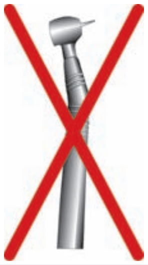
Discrimination also has an adaptive value because there are times when it is important to respond differently to related stimuli. For example, you would respond differently to the auditory stimulus of a police siren than to the auditory stimulus of a baby's cries.

3. Extinction

What about her boyfriend?

If Carla's boyfriend did not change his aftershave and she repeatedly smelled it, she would learn that it was never followed by painful dental procedures, and its smell would gradually stop making her feel anxious; this phenomenon is called extinction.

Extinction refers to a procedure in which a conditioned stimulus is repeatedly presented without the unconditioned stimulus and, as a result, the conditioned stimulus tends to no longer elicit the conditioned response.



Not reacting to a previously powerful stimulus is extinction.

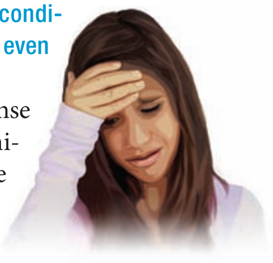
The procedure for extinguishing a conditioned response is used in therapeutic settings to reduce fears or phobias. For example, clients who had a conditioned fear of needles and receiving injections were repeatedly shown needles and given injections by qualified nurses. After exposure to the conditioned stimuli during a 3-hour period, 81% of the clients reported a significant reduction in fear of needles and receiving injections (Ost et al., 1992). This kind of exposure therapy is a practical application of Pavlov's work and will be discussed more fully in Module 22.

4. Spontaneous Recovery

Would the anxiety come back?

Suppose Carla's conditioned anxiety to the smell of the aftershave had been extinguished by having her repeatedly smell her boyfriend's lotion without experiencing any painful consequences. Some time later, when Carla happened to accidentally meet her dentist in the local supermarket, she might spontaneously show the conditioned response and feel anxiety when smelling his aftershave; this is called spontaneous recovery (D. C. Brooks, 2000).

Spontaneous recovery is the tendency for the conditioned response to reappear after being extinguished even though there have been no further conditioning trials.



Having a reaction come back is spontaneous recovery.

Spontaneous recovery of the conditioned response will not persist for long and will be of lesser magnitude than the original conditioned response. If the conditioned stimulus (smell of aftershave) is not presented again with the unconditioned stimulus (painful dental procedure), the spontaneously recovered conditioned response will again undergo extinction and cease to occur. Thus, once Carla had been classically conditioned, she would have experienced one or more of these four phenomena.

Now that you are familiar with the procedure and concepts of classical conditioning, we'll explore its widespread occurrence in the real world.

D. Adaptive Value & Uses

How useful is classical conditioning?

Pavlov believed that animals and people evolved the capacity for classical conditioning because it had an adaptive value (D. A. Lieberman, 2004).

Adaptive value refers to the usefulness of certain abilities or traits that have evolved in animals and humans and tend to increase their chances of survival, such as finding food, acquiring mates, and avoiding pain and injury.

We'll discuss several examples, such as learning to avoid certain tastes, salivating at the sight of food, and avoiding pain, that support Pavlov's view that classical conditioning is useful because it has an adaptive value.

Taste-Aversion Learning

What do you learn from getting sick?

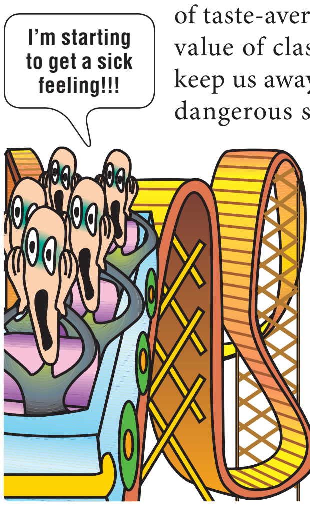
Rat exterminators have firsthand knowledge of classical conditioning's adaptive value. Exterminators find that while some rats eat enough bait poison to die, others eat only enough to get sick. Once rats get sick on a particular bait poison, they quickly learn to avoid its smell or taste, called ***bait shyness,*** and never again eat that bait poison. This kind of learning is a form of classical conditioning called taste-aversion learning (I. L. Bernstein & Koh, 2007).

Taste-aversion learning is how rats avoid poison.

Taste-aversion learning refers to associating a particular sensory cue (smell, taste, sound, or sight) with getting sick and thereafter avoiding that particular sensory cue in the future.

The adaptive value of taste-aversion learning for rats is obvious: By quickly learning to avoid the smells or taste associated with getting sick, such as eating poison bait, they are more likely to survive.

Humans. It is likely that in your lifetime, you too will experience taste-aversion learning. For example, if you have eaten something and gotten sick after taking a thrill ride, you may avoid the smell or taste of that particular food. Similarly, people who get sick from drinking too much of a particular alcoholic drink (often a sweet or distinctive-tasting drink) avoid that drink for a long period of time (Reilly & Schachtman, 2009). Taste-aversion learning may also warn us away from eating poisonous plants that cause illness or even death, such as eating certain varieties of mushrooms. All these examples of taste-aversion learning show the adaptive value of classical conditioning, which is to keep us away from potentially unpleasant or dangerous situations, such as taking thrill rides, overdrinking, or eating poisonous plants.



I'm starting to get a sick feeling!!!

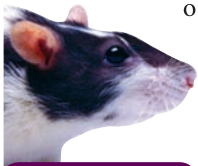
As many people have learned, taste-aversion learning can develop after a single experience and may last weeks, months, years, or forever (Reilly & Schachtman, 2009). The study of taste-aversion learning changed two long-held beliefs about classical conditioning.

Explanation

Is only one trial enough?

For a long time, psychologists believed that bait shyness was not due to classical conditioning. They were sure that classical conditioning required many trials (not a single trial of getting sick) and that the neutral stimulus (smell or taste) must be followed within seconds by the unconditioned response (nausea), and certainly not hours later (getting sick). Psychologist John Garcia thought otherwise.

One-trial learning. Garcia showed that taste-aversion learning did occur in one trial and, surprisingly, did occur even though there was an hour or more delay between the neutral stimulus (smell or taste) and the unconditioned response (sickness or vomiting). Garcia's findings proved that taste-aversion learning is a form of classical conditioning (I. L. Bernstein & Koh, 2007; Koh & Bernstein, 2005).



Taste-aversion learning occurs in one trial.

Preparedness. An interesting finding was that animals acquired taste aversion differently. For example, rats, which have poor vision but great senses of taste and olfaction (smell), acquired taste aversion easily to smell and taste cues but were rarely conditioned to light cues (Garcia et al., 1966). Similarly, quails, which have poor olfaction but great vision, acquired taste aversion more easily to visual cues (Wilcoxon et al., 1971). Garcia concluded that, depending on the animal, different stimuli or cues have different potentials for becoming conditioned stimuli. These findings challenged the long-standing belief in classical conditioning that all stimuli (smell, taste, visual, auditory) have an equal chance of becoming conditioned stimuli. Garcia's finding that some stimuli were more easily conditioned than others was called preparedness (Seligman, 1970).

Preparedness refers to the phenomenon that animals and humans are biologically prepared to associate some combinations of conditioned and unconditioned stimuli more easily than others.

The idea of preparedness means that different animals are genetically prepared to use different senses to detect stimuli that are important to their survival and adaptation. For example, John Garcia and his colleagues (1974) applied their knowledge of preparedness and taste aversion to the problem of sheep-killing by coyotes. They baited grazing areas with pieces of sheep flesh laced with a chemical that caused coyotes to become nauseated and ill. As a result, coyotes that had acquired a taste aversion showed an estimated 30–60% reduction in sheep-killing (B. Bower, 1997; Gustavson et al., 1976). Taste-aversion learning has applications for sheep ranchers and for people who get sick from overdrinking or eating before going on thrill rides (Loy & Hall, 2002; Reilly & Schachtman, 2009).

Taste-aversion learning is used to stop coyotes from eating sheep.

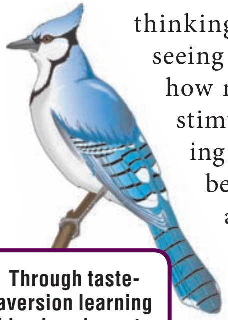
Classical Conditioning and Adaptive Value

Why do blue jays avoid monarchs?

Taste-aversion learning helps rats survive by alerting them to the smell and taste of poison, and it also warns blue jays, who feast on butterflies, not to eat monarch butterflies. Monarch butterflies, which have a distinctive coloring pattern, contain a chemical that, when eaten, will make birds sick. Through taste aversion, blue jays learn that the distinctive color pattern of monarch butterflies predicts getting sick, and so blue jays avoid eating monarch butterflies. Thus, classically conditioned taste aversion has survival value for animals. In contrast, things that taste good can produce a classically conditioned response in humans that is also adaptive.



Through taste-aversion learning blue jays learn to avoid monarchs.

Hot fudge sundaes. The next time you enter a restaurant, read the menu, think about food, and see people eating, notice that you are salivating even though you have no food in your own mouth. Just as Pavlov's dog was conditioned to salivate at the sound of a bell, we have also become conditioned to salivate when only thinking about, imagining, smelling, or seeing food. This is a clear example of how many different kinds of neutral stimuli, such as reading a menu, seeing people eat, or imagining food, can become conditioned stimuli that elicit a conditioned response—salivation.

Does thinking about food make you salivate?

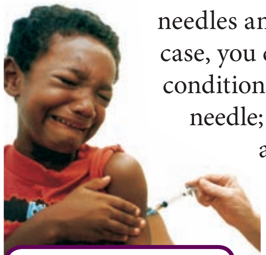
Salivation serves a useful purpose: It lubricates your mouth and throat to make chewing and swallowing food easier. Thus, being classically conditioned to salivate when reading a menu prepares your mouth for the soon-to-arrive food. Conditioned salivation and taste-aversion learning are examples of how classical conditioning has an adaptive value (Aamodt & Wang, 2008; D. A. Lieberman, 2004).

Next, we'll examine how emotional responses can be classically conditioned.

Classical Conditioning and Emotions

Why do people fear needles?

At the beginning of this module, I told a true childhood story of getting an injection that elicited such pain and fear that I fainted. Even 50 years later, I still fear injections and needles and always lie down to avoid fainting. In my case, you can easily identify each element of classical conditioning: The neutral stimulus is the sight of the needle; the unconditioned stimulus is the injection; and the unconditioned response is pain and fear. After a painful injection, the formerly neutral stimulus, the needle, becomes a conditioned stimulus and elicits the conditioned response, which is fear and even fainting. Because this situation involved the conditioning of an emotional response, my fear of injections and needles is called a conditioned emotional response (Barad et al., 2006).



This situation can condition fear of needles or injections.

A ***conditioned emotional response*** **refers to feeling some positive or negative emotion, such as happiness, fear, or anxiety, when experiencing a stimulus that initially accompanied a pleasant or painful event.**

Conditioned emotional responses can have survival value, such as learning to fear and avoid stimuli that signal dangerous situations, like the sound of a rattlesnake or wail of a siren (McNally & Westbrook, 2006). Conditioned emotional responses can also signal pleasant situations. For example, many couples have a special song that becomes emotionally associated with their relationship. When this song is heard by one in the absence of the other, it can elicit strong emotional and romantic feelings. Thus, different kinds of stimuli can be classically conditioned to elicit strong conditioned emotional responses.

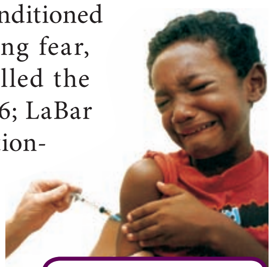
Classical Conditioning in the Brain

Where does it happen?

The man in the photo is wearing head gear that delivers a tone (conditioned stimulus) followed by a puff of air (unconditioned stimulus) that elicits his eye blink reflex (unconditioned response). With this classical conditioning procedure, individuals learn to blink about 90% of the time to the tone alone (conditioned response), before the air puff occurs. Classical conditioning of the eye blink requires the cerebellum (right figure). Lacking the cerebellum, neither humans nor animals can acquire the conditioned eye blink reflex, which is a highly specific motor response (Gerwig et al., 2003).

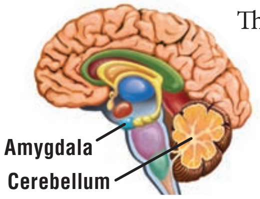
Conditioning eye blink reflex

In contrast to the classically conditioned eye blink reflex, which is a *motor response,* the young boy on the right is acquiring a classically conditioned emotional response—fear of needles and injections. Acquiring a conditioned *emotional response,* especially involving fear, involves a different brain structure called the amygdala (p. 80) (Calandreau et al., 2006; LaBar & Cabeza, 2006). Thus, classically conditioning responses involves different areas of the brain, depending on whether the responses are motor or emotional.



Conditioning emotional response

Recent research found that specialized "fear neurons" located in the amygdala fire in response to a stimulus during and after the conditioning of an emotional response. Then, when the conditioned emotional response undergoes extinction, only "extinction neurons" fire in response to the same stimulus (Herry et al., 2008).



Next, we'll examine how and why classical conditioning works.

E. Three Explanations

Theories of Classical Conditioning

Do you salivate when thinking of pizza?

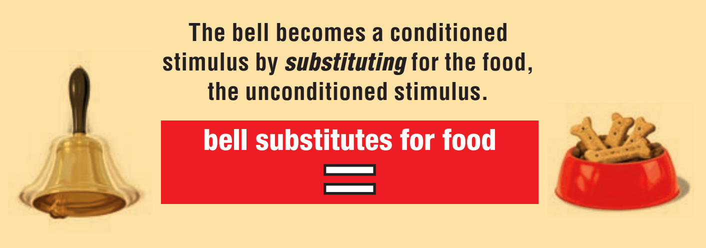
Although most of us have had the experience of salivating when thinking about or seeing a favorite food, such as a pizza, researchers have given different explanations of what is learned during conditioning. We'll discuss three theories—stimulus substitution, contiguity theory, and cognitive perspective—that offer different explanations of why nearly all of us salivate when only thinking about or seeing a delicious pizza.

Stimulus Substitution & Contiguity Theory

Does the bell substitute for food?

The first explanation of classical conditioning came from Pavlov, who said the reason a dog salivated to a tone was that the tone became a substitute for the food, a theory he called stimulus substitution.

Stimulus substitution means that a neural bond or association forms in the brain between the neutral stimulus (tone) and unconditioned stimulus (food). After repeated trials, the neutral stimulus becomes the conditioned stimulus (tone) and acts like a substitute for the unconditioned stimulus (food). Thereafter, the conditioned stimulus (tone) elicits a conditioned response (salivation) that is similar to that of the unconditioned stimulus.



The bell becomes a conditioned stimulus by *substituting* for the food, the unconditioned stimulus.
bell substitutes for food
=

According to stimulus substitution theory, you salivate when you see a pizza because the act of seeing a pizza (conditioned stimulus) becomes bonded in your nervous system to the pizza itself (unconditioned stimulus). Because of this neural bond or association, the sight of pizza substitutes for the pizza, so that just the sight of a pizza can elicit salivation (conditioned response).

However, researchers discovered that the responses elicited by the unconditioned stimulus were often slightly different from those elicited by the conditioned stimulus. For example, following the unconditioned stimulus, a dog salivated and always chewed, but, following the conditioned stimulus, it salivated but rarely chewed (Zener, 1937). As a result of this and other criticisms of Pavlov's stimulus substitution theory, researchers suggested a different explanation, the contiguity theory.

The ***contiguity theory*** says that classical conditioning occurs because two stimuli (neutral stimulus and unconditioned stimulus) are paired close together in time (are contiguous). As a result of this contiguous pairing, the neutral stimulus becomes the conditioned stimulus, which elicits the conditioned response.

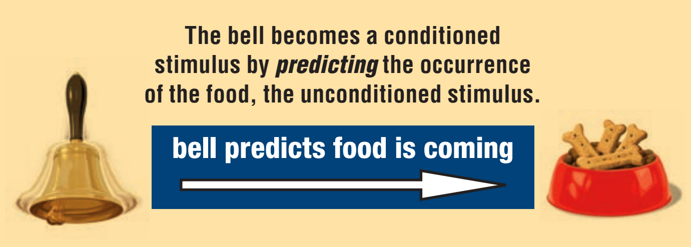
The contiguity theory says that because seeing a pizza is paired closely in time with eating it, the sight alone begins to elicit salivation. Contiguity theory was the most popular explanation of classical conditioning until the 1960s, when it was challenged by the clever research of psychologist Robert Rescorla (1966).

Cognitive Perspective

Does the bell predict food is coming?

To the surprise of many researchers, Robert Rescorla (1966, 1987, 1988) showed that an association between neutral and unconditioned stimuli did not necessarily occur when the two stimuli were closely paired in time. Instead, he found that classical conditioning occurred when a neutral stimulus contained information about what was coming next; this explanation is called the cognitive perspective.

The ***cognitive perspective*** says that an organism learns a predictable relationship between two stimuli such that the occurrence of one stimulus (neutral stimulus) predicts the occurrence of another (unconditioned stimulus). In other words, classical conditioning occurs because the organism learns what to expect.



The bell becomes a conditioned stimulus by *predicting* the occurrence of the food, the unconditioned stimulus.
bell predicts food is coming

For example, the cognitive perspective theory would explain that you salivate at the sight of pizza because you have learned a predictable relationship: Seeing a pizza (conditioned stimulus) often leads to eating one (unconditioned stimulus), and your expectation causes salivation (conditioned response).

Support for the cognitive perspective comes from a number of findings. For example, classical conditioning works best if the neutral stimulus (tone) occurs slightly before the unconditioned stimulus (food). In this sequence, the organism learns a relationship between two stimuli: Tone predicts food. However, if the sequence is reversed and the unconditioned stimulus appears before the neutral stimulus, this is called *backward conditioning* and does not usually result in classical conditioning.

The cognitive perspective would explain that backward conditioning makes it impossible to predict a relationship between the neutral and unconditioned stimuli and thus does not usually result in classical conditioning. Currently, there is widespread support for the cognitive perspective, which says that classical conditioning involves learning about predictable relationships, or learning about cause and effect (S. G. Hofmann, 2008).

After the Concept Review, we'll discuss a well-known study of classical conditioning that involves the famous "Little Albert."

Photo Credit: © PhotoDisc, Inc.

Concept Review

1. In classical conditioning, one of the stimuli that is chosen has two characteristics: The stimulus, such as a tone, must cause some reaction, such as being heard, seen, tasted, or smelled, but it must not elicit the unconditioned response. A stimulus with these two characteristics is called a ________________.

2. In classical conditioning, a second stimulus is chosen that can elicit an unlearned, involuntary physiological reflex, such as salivation. This stimulus is called an ________________.

3. In classical conditioning, the unconditioned stimulus elicits an unlearned, involuntary physiological reflex, such as salivation, which is called the ________________.

4. A typical trial in classical conditioning involves first presenting the (a) ________________ and then, a short time later, presenting the (b) ________________.

5. On the very first conditioning trial, the neutral stimulus (tone) did not itself elicit the unconditioned response (salivation). However, on the first trial, the presentation of food, which is called the (a) ________________, did elicit salivation, called the (b) ________________.

6. After a dozen trials that paired the tone with the food, you noticed that as soon as the tone was presented, the dog salivated. Because the tone itself elicited a response similar to that elicited by the unconditioned stimulus (food), the tone is called the (a) ________________. The salivation elicited by the tone itself is called the (b) ________________.

aftershave
SHAMPOO

7. During classical conditioning, there is a tendency for a stimulus similar to the original conditioned stimulus to elicit a response similar to the conditioned response. This tendency is called ________________.

8. During classical conditioning, an organism learns to make a particular response to some stimuli but not to others; this phenomenon is called ________________.

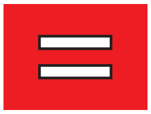
nail polish
aftershave

9. If a conditioned stimulus is repeatedly presented *without* the unconditioned stimulus, there is a tendency for the conditioned stimulus to no longer elicit the conditioned response. This phenomenon is called ________________.

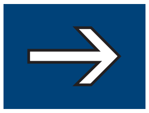
10. The tendency for the conditioned response to reappear some time later, even though there are no further conditioning trials, is called ________________.

11. The kind of learning in which the cues (smell, taste, auditory, or visual) of a particular stimulus are associated with an unpleasant response, such as nausea or vomiting, is called (a) ________________. This kind of learning can even occur after only a single (b) ________________.

12. According to Pavlov's original explanation, classical conditioning occurs because of (a) ________________, which means that the conditioned stimulus (tone) bonds to the unconditioned stimulus (food). Through this bond, or association, the conditioned stimulus (tone) elicits the conditioned response (salivation) by substituting for the (b) ________________ (food). Pavlov's explanation of classical conditioning was criticized, and researchers suggested instead that conditioning occurs because two stimuli are paired close together in time. This explanation, which is called (c) ________________ theory, has been challenged, in turn, by more recent explanations.



13. The current and widely accepted explanation of classical conditioning, which is called the (a) ________________ perspective, states that animals and humans learn a predictable relationship between stimuli. According to this explanation, a dog learns predictable relationships, such as a tone predicting the occurrence of (b) ________________.



Answers: *1. neutral stimulus; 2. unconditioned stimulus (UCS); 3. unconditioned response (UCR); 4. (a) neutral stimulus, (b) unconditioned stimulus (UCS); 5. (a) unconditioned stimulus (UCS), (b) unconditioned response (UCR); 6. (a) conditioned stimulus (CS), (b) conditioned response (CR); 7. generalization; 8. discrimination; 9. extinction; 10. spontaneous recovery; 11. (a) taste-aversion learning, (b) trial; 12. (a) stimulus substitution, (b) unconditioned stimulus, (c) contiguity; 13. (a) cognitive, (b) food*

F. Research Focus: Conditioning Little Albert

Can Emotional Responses Be Conditioned?

Why did Little Albert fear white animals?

One of the first attempts to study the development of emotional responses, such as becoming fearful, occurred in the 1920s. At this time, psychologists did not yet know if emotional responses could be conditioned. John Watson realized that he could use Pavlov's conditioning procedure to study the development of emotional behaviors in an objective way. As you may remember from Module 1, John Watson (p. 13) was a strong supporter of behaviorism, which emphasized the study of observable behaviors and the rejection of unobservable mental or cognitive events.

What follows is a first in psychology: an important classic experiment on conditioning emotions that John Watson and his student assistant, Rosalie Rayner, published in 1920.

Method: Identify Terms

Watson questioned the role that conditioning played in the development of emotional responses in children. To answer his question, Watson (photo) tried to classically condition an emotional response in a child.

Subject: Nine-month-old infant. The subject, known later as Little Albert, was described as healthy, stolid, and unemotional, since "no one had ever seen him in a state of rage and fear. The infant practically never cried" (Watson & Rayner, 1920, p. 3).

Neutral stimulus: White rat. Watson briefly confronted 9-month-old Albert with a succession of objects, including a white rat, a rabbit, and a dog. "At no time did this infant ever show fear in any situation" (Watson & Rayner, 1920, p. 2).

Rat is neutral stimulus.

Unconditioned stimulus: Noise. Standing behind Albert, the researchers hit a hammer on a metal bar, which made a loud noise and elicited startle and crying. "This is the first time an emotional situation in the laboratory has produced any fear or crying in Albert" (Watson & Rayner, 1920, p. 3).

Bang is UCS.

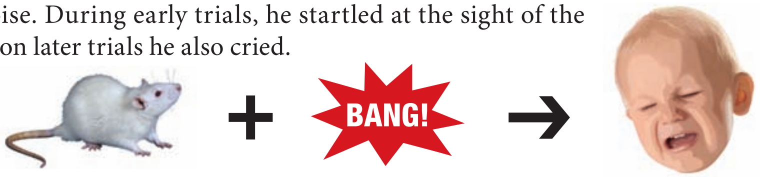
Unconditioned response: Startle/cry. Startle and crying were observable and measurable emotional responses that indicated the baby was feeling and expressing fear.

After Watson identified the three elements of classical conditioning, he and his assistant, Rayner, began the procedure for classical conditioning.

Fear is UCR.

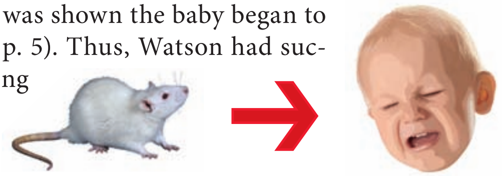
Procedure: Establish and Test for Classical Conditioning

Establish. At the age of 11 months, Albert was given repeated trials consisting of a neutral stimulus, a white rat, followed by an unconditioned stimulus, a loud noise. During early trials, he startled at the sight of the rat and on later trials he also cried.



Rat (neutral stimulus) plus loud bang (UCS) elicits fear response (UCR).

Test. When first presented with the rat alone (no noise), Albert only startled. Then he was given additional conditioning trials and retested with the rat alone (no noise). "The instant the rat was shown the baby began to cry" (Watson & Rayner, 1920, p. 5). Thus, Watson had succeeded in classically conditioning Albert's emotional response (fear).



Classical conditioning: rat (CS) alone elicits fear response (CR).

Results and Conclusions

Watson and Rayner had shown that Albert developed a conditioned emotional response of startle and crying to the sight of a rat, which lasted about a week and then diminished, or underwent ***extinction.***

After Albert was conditioned to fear a white rat, he was shown other objects to test for ***generalization.*** For example, he crawled away and cried at the sight of a rabbit, and he turned away and cried at the sight of a fur coat. But he showed no fear of blocks, paper, or Watson's hairy head, which indicates ***discrimination.***

Rabbit elicits fear (CR) is an example of generalization.

Watson's conditioning of Albert was more of a demonstration than a rigorously controlled experiment (Field & Nightingale, 2009). For example, Watson and Rayner did not use a standardized procedure for presenting stimuli, and sometimes removed Albert's thumb from his mouth, which may have made him cry. Watson was also criticized for not unconditioning Albert's fears before he left the hospital.

Although other researchers failed to replicate Watson and Rayner's results, this was the first demonstration that emotional responses could be classically conditioned in humans (Samelson, 1980). Watson's demonstration laid the groundwork for explaining how people can acquire conditioned emotional responses, such as developing a fear of needles (Field & Nightengale, 2009).

We've discussed how emotional responses can be conditioned; next, we'll show how conditioned emotional responses can influence a person's behavior.

G. Cultural Diversity: Conditioning Dental Fears

In the Dentist's Chair

What goes on at the dentist's?

As you sit in the dentist's chair, two interesting psychological factors are at work: the possibility of being classically conditioned and the possibility of perceiving more or less pain (Johnsen et al., 2003).

Earlier, we discussed the likely possibility of being classically conditioned during dental treatment. For example, in the dentist's chair you'll receive unconditioned stimuli (injection, drilling), which elicit unconditioned responses (pain, fear, and anxiety), which, in turn, can be conditioned to a variety of neutral stimuli (smells, sights, sounds, or images). At the beginning of this module we discussed how Carla's anxiety was conditioned to the smell of the dentist's aftershave lotion (see p. 198).

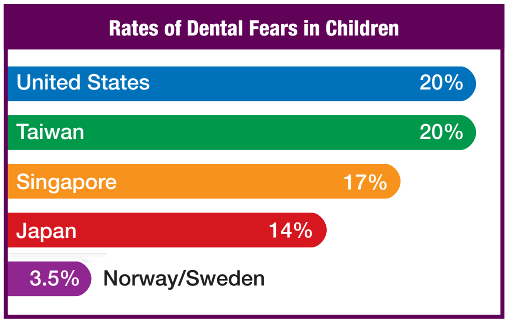
Classical conditioning: smell (CS) plus drilling (UCS) elicits pain (UCR).

As we also discussed earlier, pain is somewhat unlike other senses in that the intensity of pain can be increased or decreased by a number of psychological factors, such as your ability to relax or refocus your attention on something else (see p. 112). Now we'll discuss how cultural factors can influence the conditioning of dental fears, which in turn can increase or decrease the visits to dentists in different countries (Milgrom et al., 1994).

Cultural Practices

Which citizens have the most dental fears?

As the graph below indicates, the percentage of children reporting high levels of dental fear is greater in the United States and Asia (Taiwan, Singapore, Japan) than in Scandinavia (Norway, Sweden) (Chellappah et al., 1990; Klingberg & Hwang, 1994; C. Lee et al., 2007; Milgrom et al., 1994; Neverlien & Johnsen, 1991).



One reason for cultural differences in rates of dental fear is that the countries have different systems of dental care. In Scandinavian countries, dental care is part of a free, universal health care program available to all citizens. Because it is free and easily available, Scandinavian children tend to receive regular dental care rather than be treated only for dental emergencies. These children view dental treatment as unpleasant but necessary.

In contrast, neither America nor Japan provides free, universal dental coverage. Consequently, some children receive treatment only when there is a serious and painful dental problem. As a result, a child's first dental experience is more painful and something to be avoided. This is an example of how cultural practices influence the "painfulness" of dental treatments.

Origins

When did dental fears develop?

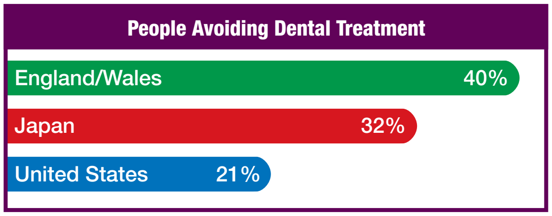
American and Asian adults who reported high rates of dental fears were asked when their fears began. About 66% replied that they acquired their dental fears in childhood or adolescence, often after a painful treatment that was necessitated by a dental emergency (Milgrom et al., 1995; Poulton et al., 1997). These fearful adults reported that the more painful their childhood dental experiences had been, the greater was their fear (Milgrom et al., 1992).

Researchers concluded that the majority of dental fears are acquired in childhood or adolescence, often through classical conditioning (Klaassen et al., 2008). In addition, these fears can keep individuals from asking for or receiving dental treatment for future but necessary dental problems (Abrahamsson et al., 2002).

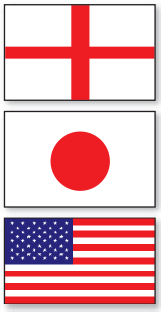
Effects of Fear

Which citizens most avoid dentists?

Once dental fears are established, about 20–40% of these individuals report avoiding regular checkups or routine dental treatment (graph below). Usually, these individuals seek dental treatment only when they have emergency problems, which tend to involve very painful procedures. As a result, painful emergency dental procedures strengthen their already high level of fears and start a new vicious circle of avoiding dental treatment until the next emergency (Armfield et al., 2008; Meng et al., 2007). From our knowledge of classical conditioning, we know that one way to reduce high levels of dental fear is to receive regular, nonpainful dental checkups and treatment, which will extinguish some of the conditioned emotional responses (Litt et al., 1999).



Based on these data, researchers concluded that cultural differences, such as the kind and frequency of dental treatment in childhood and adolescence, affect both a child's perception of pain and the occurrence of conditioned emotional responses—in this case, fear of dentists (McNeil et al., 2006; Milgrom et al., 1994).



Next, we'll examine chemotherapy treatment for cancer, which also involves classical conditioning and results in a terrible problem—conditioned nausea.

Photo Credit: © Royalty-Free/Corbis

H. Application: Conditioned Fear & Nausea

Examples of Classical Conditioning

Why do people faint from fear?

Conditioned emotional response

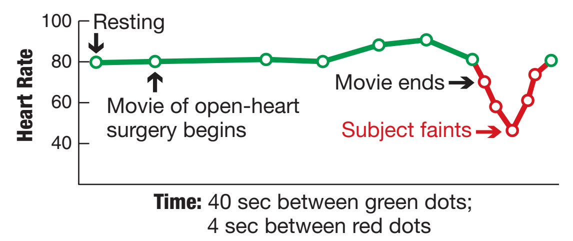
At the beginning of this module, I related my childhood experience of receiving an injection and then fainting. This one trial of classical conditioning resulted in my fear of needles, which remains with me to this present day. My experience illustrates the powerful effect that conditioned emotional responses can have on our behavior. If you still doubt that relatively nonthreatening stimuli (needle, blood) can be conditioned to elicit such a powerful physiological response as fainting, you'll be convinced by the next study (Page, 2003).

Conditioned Emotional Response

About 5–20% of adults report a fear of needles, injections, or seeing blood that often began before the age of 10 (Vogele et al., 2003). Wondering why some people feel faint at the sight of blood, researchers asked 30 such subjects to watch a movie on open-heart surgery as their heart rates were monitored. During the movie, 4 of the 30 subjects unexpectedly fainted.

For example, the graph shows that after 4 minutes of watching the open-heart surgery movie, one subject became so fearful and anxious that his body went into mild shock and he fainted. The reason this subject fainted from simply watching a movie on open-heart surgery was that he had developed a conditioned emotional response, intense fear, to the sight of blood (Steptoe & Wardle, 1988). Intense fear triggers tremendous changes in heart rate and blood pressure that can cause many physiological changes, including fainting.

Classical conditioning can also trigger nausea to a particular odor.



Source: Adapted from Steptoe & Wardle, 1988

Anticipatory Nausea

Anticipatory nausea is an example of classical conditioning.

At the beginning of this module, we told you about Michelle, who was receiving chemotherapy treatment for breast cancer. One side effect of the powerful anticancer drugs used in chemotherapy is nausea, which may be accompanied by severe vomiting that lasts 6–12 hours.

As Michelle received additional chemotherapy injections, she experienced nausea when she smelled the treatment room or smelled her dish soap, which smelled like the treatment room. Michelle's problem is called anticipatory nausea.

Anticipatory nausea refers to feelings of nausea that are elicited by stimuli associated with nausea-inducing chemotherapy treatments. Patients experience nausea after treatment but also before or in anticipation of their treatment. Researchers believe that conditioned nausea occurs through classical conditioning.

For example, by their fourth injection, 60–70% of patients who receive chemotherapy experience anticipatory nausea when they encounter smells, sounds, sights, or images related to treatment (Montgomery & Bovbjerg, 1997). Even 1 to 2 years after treatment ends, patients may continue to experience anticipatory nausea if they encounter cues associated with chemotherapy (Fredrickson et al., 1993). Conditioned nausea is especially troublesome because current medications do not always control it (Ko et al., 2008; NCI, 2008).

First we'll discuss how conditioned nausea occurs and then how it can be controlled with a nonmedical treatment.

Conditioning Anticipatory Nausea

A few weeks after beginning her chemotherapy, Michelle began to experience anticipatory nausea that was triggered by a number of different stimuli, including the smell of her dish detergent, which smelled similar to the treatment room. Now that you know her situation, perhaps you can identify the terms and explain how classical conditioning occurred.

- **Neutral stimulus** is the smell of the treatment room and her dish detergent, which initially did not cause any nausea.
- **Unconditioned stimulus** is the chemotherapy, which elicits nausea and vomiting.
- **Unconditioned responses** are the nausea and vomiting, which were elicited by chemotherapy, the unconditioned stimulus.
- **Conditioning trials** involve presenting the neutral stimulus, smell of the treatment room (same as her detergent), with the unconditioned stimulus, the chemotherapy.
- **Conditioned stimulus** (smell of the treatment room or detergent), when presented by itself, now elicits the conditioned response (nausea).

Dish soap is CS.

Once conditioning is established, anticipatory nausea can be very difficult to treat and control with drugs (Brennan, 2004). Even after chemotherapy ends, anticipatory nausea may reappear for a while, which is an example of spontaneous recovery.

However, there is a nonmedical treatment for anticipatory nausea, which is also based on classical conditioning. This treatment is called systematic desensitization, which we'll discuss next.

Photo Credit: © Digital Stock Corporation
Figure/Text Credit: Graph adapted from "Emotional Fainting and the Psychophysiologic Response to Blood and Injury: Autonomic Mechanisms and Coping Strategies," by A. Steptoe and J. Wardle, 1988, *Psychosomatic Medicine, 50*, 402–417.

Systematic Desensitization

Can you "uncondition" fearful things?

Because of repeated chemotherapy sessions, Michelle developed anticipatory nausea (right photo), which was not relieved by medication. She is now going to try a nonmedical treatment called systematic desensitization.

Systematic desensitization is a procedure based on classical conditioning, in which a person imagines or visualizes fearful or anxiety-evoking stimuli and then immediately uses deep relaxation to overcome the anxiety. Systematic desensitization is a form of counterconditioning because it replaces, or counters, fear and anxiety with relaxation.

Learning to decrease anxiety through systematic desensitization

Essentially, systematic desensitization is a procedure to "uncondition," or overcome, fearful stimuli by pairing anxiety-provoking thoughts or images with feelings of relaxation. Systematic desensitization was developed by Joseph Wolpe in the early 1950s and has become one of the most frequently used nonmedical therapies for relief of anxiety and fears in both children and adults (M. A. Williams & Gross, 1994). Just as anticipatory nausea is based on Pavlov's classical conditioning, so too is systematic desensitization (Thorpe & Sigman, 2008).

In Michelle's case, she will try to "uncondition," or override, the anxiety-producing cues of chemotherapy, such as smells and sights, with feelings of relaxation. The procedure for systematic desensitization involves the three steps described below (Wolpe & Lazarus, 1966).

Systematic Desensitization Procedure: Three Steps

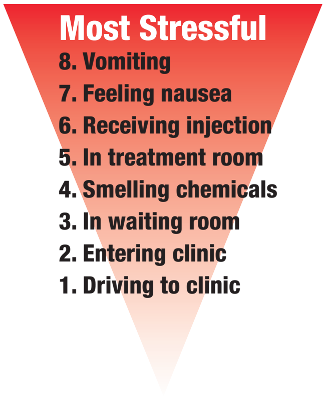
Step 1. Learning to relax

Michelle is taught to relax by tensing and relaxing sets of muscles, beginning with the muscles in her toes and continuing up to the muscles in her calves, thighs, back, arms, shoulders, neck, and finally face and forehead. She practices doing this intentional relaxation for about 15 to 20 minutes every day for several weeks.

1st step is learning to relax on cue.

After learning how to relax her body at will, she goes on to Step 2.

Step 2. Making an anxiety hierarchy



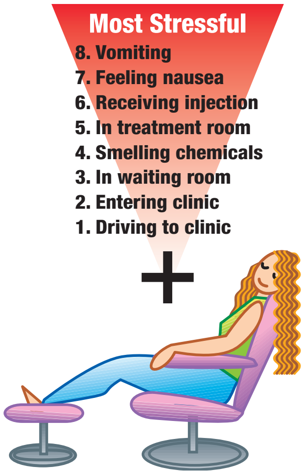
2nd step is making a list of items that elicit anxiety.

Michelle makes up a list of 7–12 stressful situations associated with chemotherapy treatment. As shown above, she arranges her list of situations in a hierarchy that goes from least to most stressful. For example, the least stressful situations are driving to and entering the clinic, and the most stressful are nausea and vomiting. Now she's ready for Step 3.

Step 3. Imagining and relaxing

Michelle ***first*** puts herself into a deeply relaxed state and then vividly imagines the least stressful situation, driving to the clinic. She is told to remain in a relaxed state while imagining this situation. If she becomes anxious or stressed, she is told to stop imagining this situation and return instead to a relaxed state. Once she is sufficiently relaxed, she again imagines driving to the clinic. If she can imagine driving to the clinic while remaining in a relaxed state, she goes to the next stressful situation.

She then imagines entering the clinic, while remaining in a relaxed state. She continues up the anxiety hierarchy, imagining in turn each of the eight stressful stimuli while keeping herself in a relaxed state. At the first sign of feeling anxious, she stops and returns to a relaxed state. After returning to a relaxed state, she continues with this procedure until she reaches the most stressful situation in her anxiety hierarchy.



3rd step is combining relaxation with items in anxiety hierarchy.

Effectiveness of Systematic Desensitization

As Michelle associates relaxation with each stressful situation in the hierarchy, she overcomes, or counterconditions, each stimulus. In other words, systematic desensitization can be thought of as using relaxation to get rid of the stressful and anxious feelings that have become associated with the stimuli that are listed in the hierarchy.

Systematic desensitization has been found to be very effective in treating a variety of fearful and anxiety-producing behaviors, including conditioned nausea and fear of blood, injections, snakes, and speaking in public (Aapro et al., 2005; Head & Gross, 2009; Spiegler & Guevremont, 2010).

We have discussed the many sides of classical conditioning, from salivation to fainting, from taste aversion to little Albert's conditioned emotional responses, from bait shyness in rats to dental fears in humans, from anticipatory nausea to systematic desensitization. It's evident that classical conditioning has a considerable influence on many of our thoughts, emotions, and behaviors.

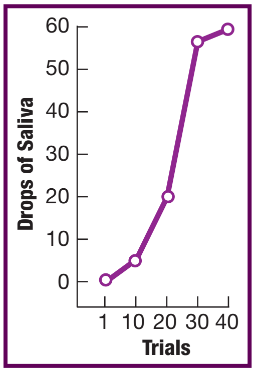
Summary Test

A. Three Kinds of Learning



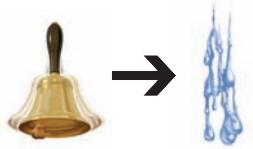
1. A relatively permanent change in behavior that involves specific stimuli and/or responses that change as a result of experience is a definition of ________________. The change in behavior includes both unobservable mental events and observable behavioral responses.

2. Psychologists have identified three different principles that are the basis for three different kinds of learning. One kind of learning can be traced to Pavlov's well-known experiment in which a bell was sounded and then food was placed in a dog's mouth. After a number of trials in which the bell and food were presented, the dog began to salivate to the bell alone. Pavlov called this kind of learning a conditioned reflex, which today is called ________________.

3. A second kind of learning grew out of Thorndike's observations of cats learning to escape from a box. To explain a cat's goal-directed behavior of hitting a latch to get food, Thorndike formulated a principle of learning called the (a) ________________. This law states that if certain random actions are followed by a pleasurable consequence or reward, such actions are strengthened and will likely occur in the future. Today, the law of effect has become part of the second kind of learning that is called (b) ________________.

4. A third kind of learning involves mental processes, such as attention and memory; may be learned through observation or imitation; and may not involve any external rewards or require the person to perform any observable behaviors. This kind of learning is called ________________.

B. Procedure: Classical Conditioning



5. Suppose you wanted to classically condition your roommate to salivate at the sight of a psychology textbook. One procedure for establishing classical conditioning would be to present two stimuli close together in time. The presentation of the two stimuli is called a trial. In our example, a typical trial would involve first presenting a psychology textbook, initially called the (a) ________________, which does not elicit salivation. A short time later, you would present a piece of brownie, called the (b) ________________ stimulus, which elicits salivation. Salivation, an innate, automatic, and involuntary physiological reflex, is called the (c) ________________.

6. After giving your roommate about a dozen trials, you observe that, as soon as you show him the psychology text, he begins to salivate. Because the sight of the psychology textbook itself elicits salivation, the psychology text has become a (a) ________________. The roommate's salivation at the sight of the psychology book, presented alone, is called the (b) ________________. You know that classical conditioning is established when the neutral stimulus becomes the (c) ________________ and elicits the (d) ________________. Compared to the unconditioned response, the conditioned response is usually similar in appearance but smaller in amount or magnitude.

C. Other Conditioning Concepts

7. The more similar the new stimulus is to the original conditioned stimulus, the stronger or larger the conditioned response will usually be. During classical conditioning, there is a tendency for a stimulus similar to the original conditioned stimulus to elicit a response similar to the conditioned response. This tendency is called ________________.

8. During classical conditioning, an organism learns to make a particular response to some stimuli but not to others; this phenomenon is called ________________.

9. If a conditioned stimulus is repeatedly presented without the unconditioned stimulus, there is a tendency for the conditioned stimulus to no longer elicit the conditioned response; this phenomenon is called (a) ________________. However, if some time later you again presented the psychology text to your roommate without giving him a brownie, he would show salivation, the conditioned response. This recurrence of the conditioned response after it has been extinguished is called (b) ________________.

D. Adaptive Value & Uses

10. After receiving an injection, people may develop fear or anxiety in the presence of stimuli associated with the treatment. If we feel fear or anxiety in the presence of some stimulus that precedes a painful or aversive event, we are experiencing a ________________.

11. A powerful form of classical conditioning occurs in real life when a neutral stimulus is paired with an unpleasant response, such as nausea or vomiting. The result of this conditioning is called ________________. This form of classical conditioning is unusual in two ways: It may be acquired in a single trial and may last a relatively long period of time; and there may be a considerable lapse of time between the presentations of the two stimuli.

12. We now know that animals and humans are biologically prepared to associate certain combinations of conditioned and unconditioned stimuli more easily than others. This phenomenon is called ________________.

13. Classical conditioning of the eye blink reflex, which is a motor response, requires a brain structure called the (a) ________. Acquiring a classically conditioned emotional response, especially involving fear, involves a different brain structure called the (b) ________.

14. The occurrence of salivation in response to the thought, sight, or smell of food is helpful to digestion and shows that classical conditioning has an ________ role or value.

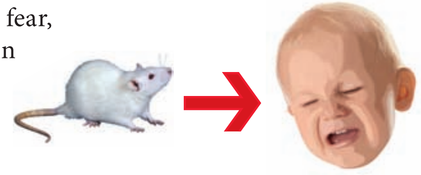
E. Three Explanations

15. According to Pavlov's explanation, classical conditioning occurs because a neural bond or association forms between the conditioned stimulus and unconditioned stimulus so that the conditioned stimulus eventually substitutes for the unconditioned stimulus. Pavlov's explanation is called ________.

16. The explanation that says that classical conditioning occurs because two stimuli (the neutral and unconditioned stimuli) are paired close together in time is called the ________ theory. However, researchers have shown that contiguity or simply pairing stimuli close together does not necessarily produce classical conditioning.

17. The explanation of classical conditioning that says that an organism learns a relationship between two stimuli such that the occurrence of one stimulus predicts the occurrence of the other is called the (a) ________. This theory is supported by the idea that classical conditioning is not usually learned if the unconditioned stimulus appears before the neutral stimulus, a procedure that is called (b) ________.

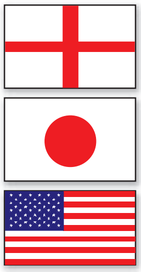
F. Research Focus: Conditioning Little Albert



18. An emotional response, fear, was classically conditioned in Little Albert by presenting a white rat, which was the (a) ________, and then making a loud noise, which was the (b) ________; in turn, the loud noise elicited crying, which was the (c) ________. Albert's conditioned emotional response, crying, also occurred in the presence of stimuli similar to the white rat, such as a rabbit; this phenomenon is called (d) ________. Albert did not cry at the sight of blocks or papers; this phenomenon is called (e) ________. Watson and Rayner were the first to demonstrate that (f) ________ responses could be classically conditioned in humans.

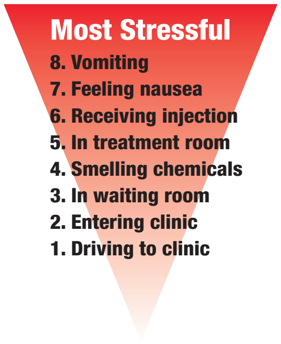
Photo Credit: (rat) © PhotoDisc, Inc.

G. Cultural Diversity: Conditioning Dental Fears



19. In the United States and Asia, the percentage of children reporting (a) ________ is considerably higher than in Scandinavia. A likely reason for this difference in dental fears is different (b) ________ practices. The majority of people with high levels of dental fears report that these fears originated in childhood, probably through the occurrence of (c) ________.

H. Application: Conditioned Fear & Nausea



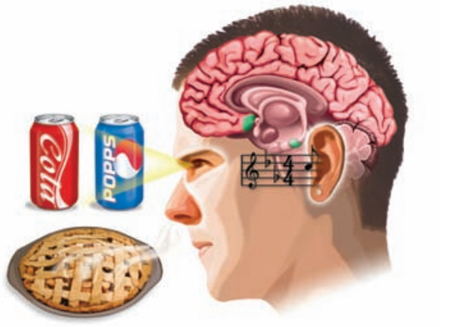
20. During chemotherapy, 60–70% of the patients develop nausea in anticipation of, or when encountering stimuli associated with, the actual treatment. This type of nausea, which is called ________, cannot always be treated with drugs and may persist long after the chemotherapy ends. Researchers believe that conditioned nausea is learned through classical conditioning.

21. A nondrug treatment for conditioned nausea involves a procedure based on classical conditioning in which a person imagines or visualizes fearful or anxiety-evoking stimuli and then immediately uses deep (a) ________ to decrease the anxiety associated with these stimuli. This procedure, which is called (b) ________, is a form of counterconditioning because it uses deep relaxation to replace or decrease the fear or anxiety with particular (c) ________ that are arranged in a hierarchy.

Answers: *1. learning; 2. classical conditioning; 3. (a) law of effect, (b) operant conditioning; 4. cognitive learning; 5. (a) neutral stimulus, (b) unconditioned stimulus, (c) unconditioned response; 6. (a) conditioned stimulus, (b) conditioned response, (c) conditioned stimulus, (d) unconditioned response; 7. generalization; 8. discrimination; 9. (a) extinction, (b) spontaneous recovery; 10. conditioned emotional response; 11. taste-aversion learning; 12. preparedness; 13. (a) cerebellum, (b) amygdala; 14. adaptive, or survival; 15. stimulus substitution; 16. contiguity; 17. (a) cognitive perspective, (b) backward conditioning; 18. (a) neutral stimulus, (b) unconditioned stimulus, (c) unconditioned response, (d) generalization, (e) discrimination, (f) conditioned emotional; 19. (a) dental fears, (b) cultural, (c) classical conditioning; 20. anticipatory nausea; 21. (a) relaxation, (b) systematic desensitization, (c) stimuli or situations*

Critical Thinking

Marketing Changes Your Brain



What guides your preference for Coke or Pepsi? McDonald's or Burger King? Can these choices be explained as a matter of taste preference, or is there something occurring in the brain that makes us choose one over the other? Neuroscientists have been discovering how marketing companies direct us to choose their products.

Take, for instance, Coke® and Pepsi®, which are almost identical chemically and physically, yet people usually have a strong preference for one over the other. In one study, researchers found that when subjects didn't know which brand of cola they were drinking, they were equally likely to choose Coke or Pepsi as their favorite. Also, the part of the brain that responds to rewards or pleasure was activated as they drank either cola. When subjects had knowledge about which cola they were drinking, subjects were more likely to prefer Coke and their brain activity explains why—not only was there increased activity in the part of the brain that responds to rewards, but memory-related brain regions involved in recalling cultural influences were also activated. The same was not true for Pepsi. These results suggest that the marketing messages about brands of cola influence our brains in a way that likely alters taste perception or preference.

We've seen how marketing influences us to purchase a particular cola, but are marketing techniques aimed to get us to quit using addictive drugs powerful enough to change our behavior? Researchers found that warning labels on cigarette packs actually stimulate the pleasure area of the brain, which brings on cigarette cravings. The warning labels are aimed to reduce smoking, but they may just increase profits for tobacco companies!

Marketing companies also take advantage of our hearing to get us to make purchases. In one study, shoppers purchased wines from different countries based on the music being played at the store. Shoppers were more likely to purchase French wine when French music was played and more likely to purchase German wine when German music was played.

And, let's not forget about smell. Smell, more than any other sense, is connected to the brain areas that process motivations and emotions. This means if businesses use attractive scents, we may make purchases based on impulse rather than rational thought. This is why supermarkets place their bakery near the entrance. The smell of fresh oven-baked bread or pies puts a big smile on our faces and activates the emotional centers in our brain. Consequently, we are likely to spend more money while shopping.

By applying neuroscience to marketing, we now better understand the complex, mostly unconscious forces that influence our preferences and purchase decisions. The question remains, however: Now that we know about these clever marketing techniques, can we resist these powerful influences, when making purchase decisions or will many of our buying decisions continue to take place deep below our conscious awareness? (Adapted from R. Baron, 2008; Herz, 2008; Lindstrom, 2008; McClure et al., 2004a, 2004b; Park, 2007)

QUESTIONS

1 Why was the part of the brain that responds to rewards activated?

2 Why were the memory-related brain regions activated when subjects knew they were drinking Coke, but not when subjects knew they were drinking Pepsi?

3 How might these results be useful to companies interested in developing a cola to compete with Coke or other products similar to those that have strong brand images?

4 Which structures make up the pleasure area of the brain?

5 How is this type of marketing strategy similar to auditory subliminal messages?

6 What can explain why the smell of fresh baked goods makes us smile?

Suggested Answers to Critical Thinking

1. The reward/pleasure center of the brain is activated when a person eats a favorite food, has sex, and does other pleasurable activities, such as drinking a sugared beverage like Coke or Pepsi. (p. 175)
2. One explanation for why memory-related brain regions involved in recalling cultural influences were activated only when subjects knew they were drinking Coke is that the brand image of Coke may be more culturally familiar than that of Pepsi.
3. Companies should be cautious about developing a cola similar to Coke or other products similar to favored brands because it will take a lot of effort and expense to have people buy a new product that competes with an existing one with a strong brand.
4. Many drugs, including nicotine in cigarettes, activate the brain's pleasure center, which includes the nucleus accumbens and ventral tegmental area. (p. 175)
5. Subliminal messages are brief auditory or visual messages that are presented in a way such that the message is unlikely to be consciously perceived. In the study with French and German music, the shoppers were probably not aware that the music influenced their purchase decision, just as people hearing auditory subliminal messages do not perceive the messages, but the messages may still influence their behaviors. (p. 135)
6. One function of olfaction or smell is to elicit strong memories, often associated with emotional feelings. For example, the smell of apple pie may remind you of a festive family gathering, making you feel happy and bringing a smile to your face.

Learning 45 Commands

How did Bart become a movie star?

It was an unusual movie for two reasons. First, there was almost no dialogue: Human actors spoke only 657 words. Second, the star of the movie was a nonspeaking, nonhuman, 12-year-old, 10-foot-tall, 1,800-pound, enormous brown Kodiak bear named Bart (shown on the left). Bart is one of the world's largest land-dwelling carnivores and can, with one swipe of his massive 12-inch paw, demolish anything in his path. Yet, in the movie, there was big bad Bart, sitting peacefully on his haunches, cradling a small bear cub in his arms. "So what?" you might say, but what you don't know is that, in the wild, a Kodiak bear normally kills and eats any cub it encounters.

Bart the bear learned to perform 45 behaviors on cue through operant conditioning.

Because Bart was found as a cub and raised by a human trainer, Bart grew to act more like an overgrown teddy bear than a natural-born killer. For his role in the movie *The Bear,* Bart learned to perform 45 behaviors on cue, such as sitting, running, standing up, roaring, and, most difficult of all, cradling a teddy bear, which is not what an adult bear does in the wild.

The training procedure seems deceptively simple: Each time Bart performed a behavior on cue, the trainer, Doug Seus, gave Bart an affectionate back scratch, an ear rub, or a juicy apple or pear. For example, when the trainer raised his arms high in the air, it was the signal for Bart to sit and hold the teddy bear. After Bart correctly performed this behavior, Doug would give him a reward. After Bart learned to perform all these behaviors with a stuffed teddy bear, a live bear cub was substituted and the scene was filmed for the movie (Cerone, 1989).

Bart learned to perform 45 behaviors on cue through a kind of learning called operant conditioning.

Operant conditioning, **also called instrumental conditioning, is a kind of learning in which an animal or human performs some behavior, and the following consequence (reward or punishment) increases or decreases the chance that an animal or human will again perform that same behavior.**

For example, if Bart performed a particular behavior, such as picking up a teddy bear, the consequence that followed—getting a rewarding apple—increased the chance that Bart would again pick up the teddy bear. Because of what Bart learned through operant conditioning, he starred in 20 movies and became the highest paid animal actor, making about $10,000 a day (Brennan, 1997). That's a salary that most of us would be very happy to bear!

Operant conditioning seems rather straightforward. You perform an action or operate on your environment, such as studying hard. The consequence of your studying, such as how well you do on exams, increases or decreases the likelihood that you will perform the same behavior—studying hard—in the future.

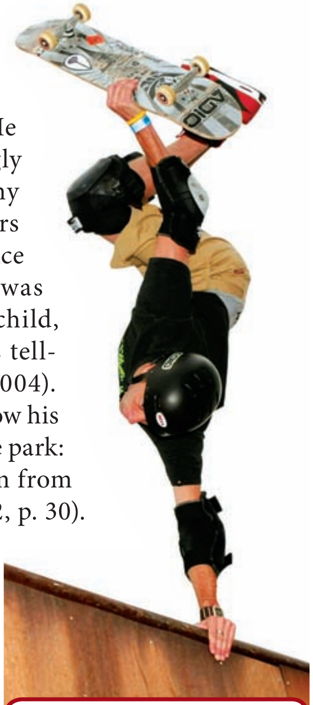
Besides learning by having your behaviors rewarded or punished, you can also learn in a very different way.

Learning to Skateboard

What did Tony Hawk learn from just watching?

In operant conditioning, the learning process is out in the open: Bart performs an observable behavior (holds a teddy bear), which is followed by an observable consequence (gets an apple). But there is another kind of learning that involves unobservable mental processes and unobservable rewards that you may give yourself. This kind of learning, called cognitive learning, is partly how Tony Hawk learned to skate.

Tony Hawk is recognized as the greatest skateboarder of all time. But Tony did not always have a talent for skating. When Tony was 9 years old, his brother gave him his old skateboard. Tony had seen his brother skate before, and he tried to skate just like him. Tony then visited a skate park, where he was awed by how quickly skaters went up, down, and around walls. He was also amazed at how they daringly spun while high up in the air. Tony wanted to be as talented as the skaters at the park, and he went on to practice every chance he had. When Tony was asked why he enjoyed skating as a child, he replied, "I liked that no one was telling me how to do it" (CBS News, 2004). Instead, Tony learned by observing how his friends and professionals skated at the park: "I would watch them and try to learn from them. I'd imitate them" (Hawk, 2002, p. 30). On his own initiative and without any special guidance, Tony learned to skate by imitating others.



Tony Hawk learned to skateboard partly from watching others.

The process Tony used to learn skateboarding is very different from the operant conditioning procedure used to teach Bart new behaviors. During operant conditioning, Bart performed observable behaviors that were influenced by observable consequences. In comparison, Tony learned how to skateboard through observation and imitation, which involved unobservable mental processes and is called cognitive learning. We'll discuss cognitive learning later in this module.

What's Coming

In the first half of this module, we'll discuss the history and procedure of operant conditioning, how operant conditioning differs from classical conditioning, how consequences or reinforcers work, and other examples of operant conditioning. In the second half of this module, we'll explain the history of cognitive learning, the theory behind observational learning, and the role of insight learning.

We'll begin with an important study that involved a cat, a puzzle box, and a smelly fish.

Photo Credits: left, © George Frey; right, © Evan Agostini/Getty Images

A. Operant Conditioning

Background: Thorndike and Skinner

How did Bart become a movie star?

We told you how a trainer used operant conditioning to teach Bart to perform 45 different behaviors on cue. Operant conditioning has now been applied to many different settings, such as training animals to perform, training children to use the potty, stopping retarded children from injuring themselves, and helping autistic children learn social behaviors. However, the discovery of operant behavior involved two different researchers who worked in two different laboratories on two different kinds of problems. So that you can appreciate the thinking that led to operant conditioning, we'll visit the laboratories of the two important researchers—E. L. Thorndike and B. F. Skinner.

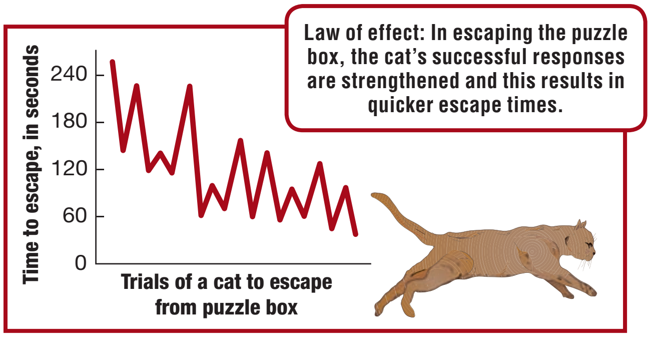
Thorndike's Law of Effect

E. L. Thorndike (1874–1949)

It's the late 1800s, and we're in the laboratory of E. L. Thorndike, who is interested in animal intelligence—specifically, in measuring their capacity for reasoning.

Unlike pet owners who assume from anecdotal observations that their animals are intelligent, Thorndike devised a simple but clever way to measure reasoning in a more objective way. He built a series of puzzle boxes from which a cat could escape by learning to make a specific response, such as pulling a string or pressing a bar. Outside the puzzle box was a reward for escaping—a piece of fish.

We watch Thorndike place a cat in the puzzle box and record its escape time. After Thorndike graphs the data (graph below), we see a gradual lessening in the time needed to escape. Notice that on the first trial the cat needed over 240 seconds to hit the escape latch, but by the last trial, the cat hits the escape latch in less than 60 seconds.



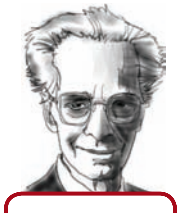
Law of effect: In escaping the puzzle box, the cat's successful responses are strengthened and this results in quicker escape times.

Thorndike explains that, with repeated trials, the cat spends more time around the latch, which increases the chances of finding and hitting the latch and more quickly escaping to get the fish. To explain why a cat's random trial-and-error behaviors gradually turned into efficient, goal-directed behaviors, Thorndike formulated the law of effect.

The ***law of effect*** states that behaviors followed by positive consequences are strengthened, while behaviors followed by negative consequences are weakened.

Thorndike's (1898) findings were significant because they suggested that the law of effect was a basic law of learning and provided an objective procedure to study it. Thorndike's emphasis on studying the consequences of goal-directed behavior was further developed and expanded by B. F. Skinner.

Skinner's Operant Conditioning



B. F. Skinner (1904–1990)

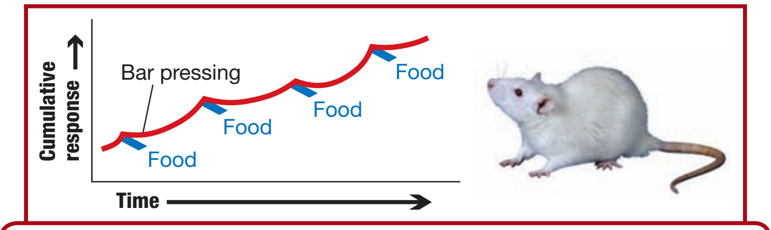
It's the 1930s, and we're in the laboratory of B. F. Skinner, who is interested in analyzing ongoing behaviors of animals. Skinner explains that Thorndike's law of effect is useful, since it describes how animals are rewarded for making particular responses. However, in order to analyze ongoing behaviors, you must have an objective way to measure them. Skinner's clever solution is a unit of behavior he calls an operant response (Skinner, 1938).

An ***operant response*** is a response that can be modified by its consequences and is a meaningful unit of ongoing behavior that can be easily measured.

For example, suppose that out of curiosity Bart picks up a teddy bear. His picking up the teddy bear is an example of an operant response because Bart is acting or operating on the environment. The consequence of his picking up the teddy bear is that he receives an apple, which is a desirable effect. This desirable effect modifies his response by increasing the chances that Bart will repeat the same response.

By measuring or recording operant responses, Skinner can analyze animals' ongoing behaviors during learning. He calls this kind of learning ***operant conditioning,*** which focuses on how consequences (rewards or punishments) affect behaviors.

A simple example of operant conditioning occurs when a rat in an experimental box accidentally presses a bar. If the bar press is followed by food, this consequence increases the chance that the rat will press the bar again. As the rat presses the bar more times, more food follows, which in turn increases the chances that the rat will continue to press the bar (indicated by the rise of the red line in the figure below).



Rat learns to press a bar, which increases the chances of getting food.

Using his newly developed procedure of operant conditioning, B. F. Skinner spent the next 50 years exploring and analyzing learning in rats, pigeons, schoolchildren, and adults.

The 1920s and 1930s gave learning a mighty jolt with the discovery of two general principles—Pavlov's classical conditioning and Skinner's operant conditioning. For the first time, psychologists had two methods to analyze learning processes in an objective way.

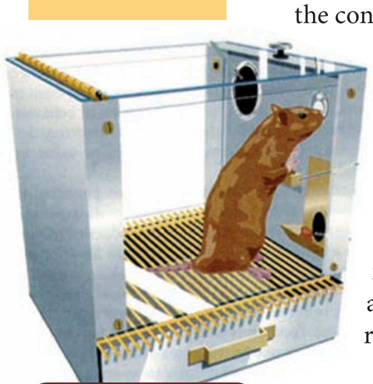
Now we'll examine Skinner's ingenious procedure for operant conditioning in more detail.

Photo Credit: (rat) © PhotoDisc, Inc.
Figure/Text Credit: Graph on right based on data from *Behavior of Organisms*, by B. F. Skinner, 1938. Appleton-Century-Crofts.

Principles and Procedures

Why does a rat press a bar?

A rat may initially press a bar out of curiosity, and whether it presses the bar again depends on the consequences. To show how consequences can affect behavior, imagine that you are looking over Skinner's shoulder as he places a rat into a box. The box is empty except for a bar jutting out from one side and an empty food cup below and to the side of the bar (above figure). This box, called a ***Skinner box,*** is automated to record the animal's bar presses and deliver food pellets. The Skinner box is an efficient way to study how an animal's ongoing behaviors may be modified by changing the consequences of what happens after a bar press.



Skinner box contains bar and food cup.

As you watch, Skinner explains that the rat is a good subject for operant conditioning because it can use its front paws to manipulate objects, such as a bar, and it has a tendency to explore its environment, which means that it will eventually find the bar, touch it, or even press it.

Skinner goes on to explain the following three factors that are involved in operantly conditioning a rat to press a bar in the Skinner box.

1 The rat has not been fed for some hours so that it will be active and more likely to eat the food reward. A hungry rat tends to roam restlessly about, sniffing at whatever it finds.

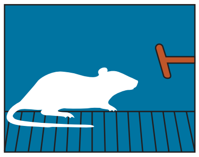
2 The goal is to condition the rat to press the bar. By pressing the bar, the rat operates on its environment; thus, this response is called an ***operant response.***

3 Skinner explains that a naive rat does not usually waltz over and press the bar. In conditioning a rat to press a bar, Skinner will use a procedure called shaping.

Shaping is a procedure in which an experimenter successively reinforces behaviors that lead up to or approximate the desired behavior.

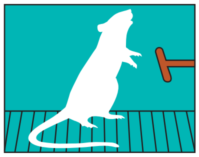
For example, if the desired behavior is pressing the bar, here's how shaping works.

Shaping: Facing the Bar



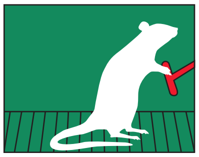
Skinner places a white rat into the (Skinner) box, closes the door, and watches the rat through a one-way mirror. At first, the rat wanders around the back of the box, but when it turns and faces the bar, Skinner releases a food pellet that makes a noise as it drops into the food cup. The rat hears the pellet drop, approaches the food cup, then sees, sniffs, and eats the pellet. After eating, the rat moves away to explore the box. But, as soon as the rat turns and faces the bar, Skinner releases another pellet. The rat hears the noise, goes to the food cup, sniffs, and eats the pellet. Shaping is going well.

Shaping: Touching the Bar



As shaping continues, Skinner decides to reinforce the rat only when it actually moves toward the bar. Skinner waits and as soon as the rat faces and then moves toward the bar, Skinner releases another pellet. After eating the pellet, the rat wanders a bit but soon returns to the bar and actually sniffs it. A fourth pellet immediately drops into the cup, and the rat eats it. When the rat places one paw on the bar, a fifth pellet drops into the cup. Notice how Skinner has shaped the rat to spend all its time near the bar.

Shaping: Pressing the Bar



As soon as the rat actually puts its paws on the bar, Skinner releases a pellet. After eating, the rat puts its paws back on the bar and gets a pellet. Now Skinner waits until the rat puts its paws on the bar and actually happens to press down, which releases another pellet. Soon, the rat is pressing the bar over and over to get pellets. Notice how Skinner reinforced the rat's behaviors that led up to or approximated the desired behavior of bar pressing.

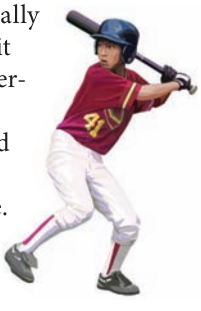
Immediate Reinforcement

Depending on the rat and the trainer's experience, it may take from minutes to an hour to shape a rat to press a bar. Skinner explains that in shaping behavior, the food pellet, or ***reinforcer,*** should follow ***immediately*** after the desired behavior. By following immediately, the reinforcer is associated with the desired behavior and not with some other behavior that just happens to occur. If the reinforcer is delayed, the animal may be reinforced for some undesired or superstitious behavior.

Superstitious behavior is a behavior that increases in frequency because its occurrence is accidentally paired with the delivery of a reinforcer.

When I (R. P.) was a graduate student, I conditioned my share of superstitious rat behaviors, such as making them turn in circles or stand up instead of pressing the bar. That's because I accidentally but immediately reinforced a rat after it performed the wrong behavior.

Humans, especially professional baseball players, report a variety of superstitious behaviors that were accidentally reinforced by getting a hit (Burger & Lynn, 2005). For example, a five-time batting champion (Wade Boggs) ate chicken every day he played, allowed no one else to touch his bats, and believed each bat had a certain number of hits. Once a batter's superstitious behaviors are reinforced, especially by getting a big hit or home run, superstitious behaviors tend to persist and can be very difficult to eliminate. You probably have some of your own!



Next, we'll discuss some interesting examples of operant conditioning in very young humans.

Figure/Text Credit: Skinner box illustration from *Introduction to Psychology,* by E. Bruce Goldstein, 1995. Brooks/Cole.

A. Operant Conditioning

Examples of Operant Conditioning

Have you been operantly conditioned?

Without realizing it, you may be performing many behaviors learned through operant conditioning. For example, operant conditioning was involved if you learned to drive through a yellow traffic light to avoid stopping, study for hours to get good grades, or give flowers to your honey to see him or her smile. And you may continually perform these behaviors because they are followed by reinforcers that increase the chances that you will perform these same behaviors again. We'll discuss how procedures and principles of operant conditioning have been used by parents to solve two relatively common problems: getting young children to use the toilet and to stop refusing to eat a wide variety of healthy foods.

Toilet Training

Imagine that you are a parent of 3-year-old Sheryl, who is physically mature enough to begin toilet training. Here's how operant conditioning techniques can be applied to teach toilet training.

1. Target behavior. The target behavior or goal is for Sheryl to urinate in the toilet.

4 steps in toilet training

2. Preparation. Before training begins, put all of Sheryl's toys away so that she will not be distracted. Then give her a large glass of apple juice, so that she will have to urinate soon.

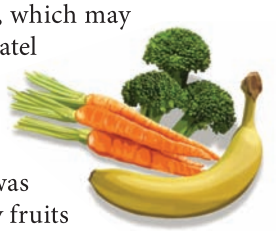
3. Reinforcers. Select reinforcers, which can be candy, verbal praise, or a hug. Each time Sheryl performs or emits a desired behavior, you immediately reinforce it. The reinforcer increases the likelihood that the behavior will be repeated.

4. Shaping. Just as Skinner used the shaping procedure in conditioning a rat to press a bar, you can use a similar shaping procedure in conditioning Sheryl to use the toilet. Each time Sheryl performs a behavior that leads to the target behavior (using the toilet), give her a treat, verbal praise, or a hug. For instance, when Sheryl says that she has to go potty, say, "That's great." When Sheryl enters the bathroom, say, "What a good girl." When she lowers her pants by herself, say, "You're doing really well." After Sheryl urinates into the toilet, give her a big hug and perhaps a treat.

Mothers who were supervised as they used this training procedure needed 4–18 hours to toilet train their 2- to 3-year-olds (Berk & Patrick, 1990; Matson & Ollendick, 1977). However, children vary in when they are ready to begin toilet training and operant conditioning. Researchers advise that "in most cases there's no clear benefit to starting training before 24 to 27 months and in fact kids who start early often take longer to finish" (N. Blum, 2003).

Another difficulty parents face is when children eat only one or two favorite foods and refuse all others.

Food Refusal



Some young children with no medical problems may develop a habit of eating only certain foods and refusing all others, which may result in having an unhealthy diet or low weight (Patel et al., 2002). Researchers taught parents how to use the principles of operant conditioning to overcome food refusal in their young children.

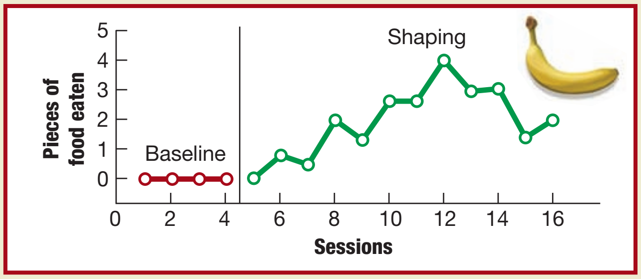
1. Target behavior. The target behavior or goal was for the child to taste, chew, and eat a food (usually fruits or vegetables) that she or he has persistently refused to eat.

2. Preparation. Researchers first showed mothers how to shape and reinforce target behaviors. Next, each mother shaped the target behavior in her child in the home setting.

3. Reinforcers. Each time the child performed or emitted a target behavior, the mother immediately reinforced the child with a positive reinforcer, such as praise, attention, or a smile.

4. Shaping. The shaping procedure consisted of having the child notice the food and let it be placed in his or her mouth, letting the child taste the food, and, finally, having the child chew and swallow the food.

The graph below explains and shows the success of using operant conditioning to overcome food refusal in young children (Werle et al., 1993).



Baseline: During these four sessions, the mother offered nonpreferred food to her child, who refused the food each time.

Shaping: During these sessions, the mother shaped the child to accept nonpreferred food by giving praise, attention, and smiles each time her child made a response that was similar to or approximated the target behavior (chewing and swallowing food). Shaping proved effective in overcoming the child's habit of food refusal. Compare the child's food refusal during baseline to that during shaping sessions.

Notice that the same principles of operant conditioning apply whether the goal is to condition a child to use the potty, to overcome food refusal, or to train Bart the bear to pick up and hold a teddy bear.

Next, we'll compare the principles of operant and classical conditioning.

Operant Versus Classical Conditioning

How are they different?

Earlier in this module, we discussed how Bart the bear was operantly conditioned to hold a teddy bear—something he would never do in the wild. As you may remember from Module 9, we discussed how Sam the dog was classically conditioned to salivate to the sound of a bell—something he would not usually do. Although both operant and classical conditioning lead to learning, they have very different procedures and principles, which may be a little confusing. We'll try to clear up any confusion by doing a side-by-side comparison of the principles and procedures of operant and classical conditioning by using the same subject, Bart, one of the world's largest subjects.

Bart—classically or operantly conditioned?

Operant Conditioning

1 Goal. The goal of operant conditioning is to ***increase or decrease the rate*** of some response, which usually involves shaping. In Bart's case, the goal was to increase his rate of holding a teddy bear.

2 Voluntary response. Bart's behavior of holding a teddy bear is a voluntary response because he can perform it at will. Bart must first perform a voluntary response before getting a reward.

3 Emitted response. Bart voluntarily performs or emits some response, which Skinner called the operant response (holding teddy bear). Skinner used the term ***emit*** to indicate that the organism acts or operates on the environment. In most cases, animals and humans are shaped to emit the desired responses.

4 Contingent on behavior. Bart's performance of the desired response depends on, or is ***contingent*** on, the consequences, or what happens next. For example, each time Bart holds the teddy bear, the consequence is that he receives an apple. The apple, which is a reward (reinforcer), increases the chances that Bart will perform the desired response in the future.

The reinforcer must occur ***immediately after*** the desired response. In Bart's case, the reinforcer (apple) would be given immediately after Bart holds the teddy bear. If the reinforcer occurs too late, the result may be the conditioning of unwanted or superstitious responses.

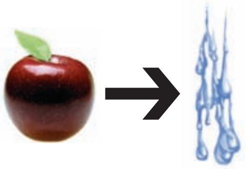
5 Consequences. An animal or human's performance of some behavior is dependent or contingent on its ***consequences***—that is, on what happens next. For example, the consequence of Bart's picking up and holding a teddy bear was to get an apple.

Thus, in operant conditioning, an animal or human learns that performing or ***emitting*** some behavior is followed by a ***consequence*** (reward or punishment), which, in turn, increases or decreases the chances of performing that behavior again.

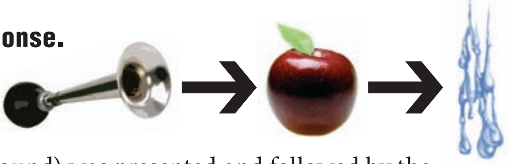
Classical Conditioning

1 Goal. The goal of classical conditioning is to create a new response to a ***neutral stimulus.*** In Bart's case, he will make a new response, salivation, to the sound of a horn, which is the neutral stimulus because it does not usually cause Bart to salivate.

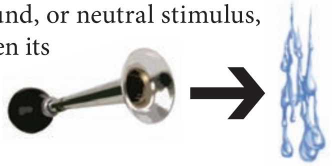
2 Involuntary response. Salivation is an example of a ***physiological reflex.*** Physiological reflexes (salivation, eye blink) are triggered or elicited by some stimulus and therefore called involuntary responses.



3 Elicited response. As Bart eats an apple, it will trigger the involuntary physiological reflex of salivation. Thus, eating the apple, which is called the ***unconditioned stimulus,*** triggers or elicits an involuntary reflex response, salivation, which is called the ***unconditioned response.***



4 Conditioned response. Bart was given repeated trials during which the neutral stimulus (horn's sound) was presented and followed by the unconditioned stimulus (apple). After repeated trials, Bart learned a relationship between the two stimuli: The horn's sound is followed by an apple. The horn's sound, or neutral stimulus, becomes the ***conditioned stimulus*** when its sound alone, before the occurrence of the apple, elicits salivation, which is the ***conditioned response.***



For best results, the neutral stimulus is presented slightly before the unconditioned stimulus. If the unconditioned stimulus is presented before the neutral stimulus, this is called ***backward conditioning*** and produces little if any conditioning.

5 Expectancy. According to the ***cognitive perspective*** of classical conditioning, an animal or human learns a predictable relationship between, or develops an expectancy about, the neutral and unconditioned stimuli. This means Bart learned to ***expect*** that the neutral stimulus (horn's sound) is always followed by the unconditioned stimulus (apple). Thus, in classical conditioning, the animal or human learns a ***predictable relationship*** between stimuli.

One major difference between operant and classical conditioning is that in operant conditioning, the performance of some response depends on its consequence (rewards or punishment). We'll discuss the effects of different kinds of consequences next.

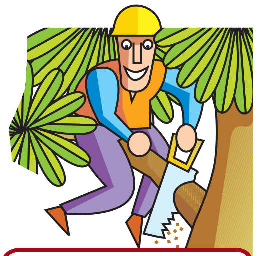
B. Reinforcers

Consequences

Why are consequences important?

Notice where the man is sitting as he saws off a tree limb. His behavior illustrates a key principle of operant conditioning, which is that ***consequences are contingent on behavior.*** In this case, the man will fall on his head (consequence) if he cuts off the tree limb (behavior). Furthermore, this consequence will make the tree trimmer think twice before repeating this stupid behavior. Thus, consequences affect behavior, and in operant conditioning, there are two kinds of consequences—reinforcement and punishment.



There are serious consequences to this man's behavior!

Reinforcement **is a consequence that occurs after a behavior and increases the chance that the behavior will occur again.**

For example, one of the main reasons you study hard for exams is to get good grades (reinforcement). The consequence of getting a good grade increases the chances that you'll study hard for future exams.

Punishment **is a consequence that occurs after a behavior and decreases the chance that the behavior will occur again.**

For example, one school used punishment to reduce students' absentee rates. Students who got more than eight unexcused absences lost desirable privileges (no football games, no prom). In this case, punishing consequences decreased from 15% to 4% the chance of students playing hooky from school (Chavez, 1994). However, other research shows when schools use physical punishment to discourage undesirable behavior, absenteeism rates increase (HRW, 2008).

Sometimes reinforcement and punishment are used together to control some behavior, as was done in treating a serious behavioral disorder called pica.

Pica **is a behavioral disorder, often seen in individuals with mental retardation, that involves eating inedible objects or unhealthy substances. This can result in serious physical problems, including lead poisoning, intestinal blockage, and parasites.**

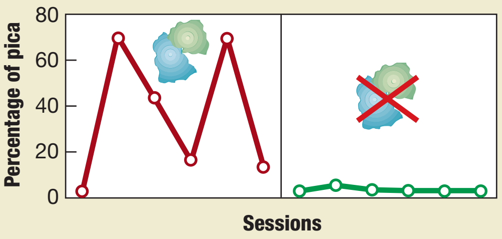
Here's an example of how reinforcement and punishment were used to treat pica.

Changing the Consequences

Walt was 15 years old and suffered from profound retardation. One of Walt's problems was pica, which included eating bits of paper and clothing, metal and plastic objects, and especially paint chips, from which he had gotten lead poisoning.

To control his pica, Walt was given a tray containing nonfood items (fake paint chips made from flour) and food items (crackers). Each time Walt chose a food item, he received a reinforcement—verbal praise. When Walt chose a paint chip, he received a mild punishment—having his face washed for 20 seconds. The graph below shows how the consequences (reinforcement or punishment) greatly modified Walt's pica behavior (C. R. Johnson et al., 1994).

Baseline: During these sessions, Walt chose the nonfood items 10–80% of the time. Compare the baseline with training sessions.



Training: During these sessions, Walt was reinforced with praise for choosing food items and punished with face washing for choosing nonfood items. These consequences greatly modified his behaviors so that he chose primarily food items.

In this study, reinforcement and punishment proved an effective combination to treat a potentially dangerous problem. Next, we'll discuss two kinds of reinforcements.

Reinforcement

How are an apple and an "F" alike?

Although getting an apple and getting a grade of "F" seem very different, they are both consequences that can increase the occurrence of certain behaviors. There are two kinds of reinforcements, or consequences—positive and negative—that increase the occurrence of behaviors.

Positive Reinforcement

Immediately after Bart the bear emitted or performed a behavior (holding a teddy bear), the trainer gave him an apple to increase the likelihood of his repeating that behavior. This situation is an example of positive reinforcement.

Positive reinforcement **refers to the presentation of a stimulus that increases the probability that a behavior will occur again.**

A ***positive reinforcer*** **is a stimulus that increases the likelihood that a response will occur again.**

For example, if you ask a friend for money and get it, the money is a positive reinforcer that will increase the chances of your asking again. There's a second kind of reinforcement, called negative reinforcement.

Negative Reinforcement

If you have a headache and take an aspirin to get rid of it, your response of taking an aspirin is an example of negative reinforcement.

Negative reinforcement **refers to an aversive (unpleasant) stimulus whose removal increases the likelihood that the preceding response will occur again.**

If taking an aspirin removes your headache (aversive or unpleasant stimulus), then your response of taking an aspirin is negatively reinforced because it removes the headache and thus increases the chances of your taking an aspirin in the future. Don't be confused by the fact that both positive and negative reinforcers ***increase*** the frequency of the responses they follow.

Besides positive and negative reinforcers, there are also primary reinforcers, such as food, and secondary reinforcers, such as money and coupons.

Photo Credit: © Corbis/SuperStock

Reinforcers

How are chocolate and a coupon alike?

A student might repeat a behavior, such as study, because the consequence is food, a primary reinforcer, or be quiet on the school bus because the consequence is a coupon, a secondary reinforcer.

Primary Reinforcers

Food: primary reinforcer

If you made yourself study for 2 hours before rewarding yourself with chocolate, you would be using a primary reinforcer.

A *primary reinforcer* is a stimulus, such as food, water, or sex, that is innately satisfying and requires no learning on the part of the subject to become pleasurable.

Primary reinforcers, such as eating, drinking, or having sex, are unlearned and innately pleasurable. Brain scans (p. 70) showed that these activities, including eating chocolate, activate the brain's built-in or inherited reward/pleasure center (Belin & Rauscent, 2006). Although brain scans were discovered after Skinner, they have proven him right: Primary reinforcers are innately satisfying and require no training because they automatically activate the brain's built-in reward/pleasure center. In our example, chocolate is a primary reinforcer for studying. However, many behaviors are aided or maintained by secondary reinforcers.

Secondary Reinforcers

A school teacher used a secondary reinforcer when she gave each child a coupon good for fun prizes if he or she ate fruits and vegetables during lunch. A coupon is an example of a secondary reinforcer.

A *secondary reinforcer* is any stimulus that has acquired its reinforcing power through experience; secondary reinforcers are learned, such as by being paired with primary reinforcers or other secondary reinforcers.

Coupons, or secondary reinforcers, encourage children's good behaviors.

Coupons, money, grades, and praise are examples of secondary reinforcers because their value is learned or acquired through experience (Delgado et al., 2006; S. B. Klein, 2009). For example, children learned that coupons were valuable because they could be redeemed for fun prizes. The coupons became secondary reinforcers that encouraged children to eat fruits and vegetables during lunch at school (Hendy et al., 2005, 2007). Many of our behaviors are increased or maintained by secondary reinforcers.

Unlike primary and secondary reinforcers, which are consequences that increase behaviors, punishment has a very different effect.

Punishment

Are there different kinds of punishment?

Although placing a child in time-out and giving a child an electric shock seem very different, they are both consequences that can decrease the occurrence of certain behaviors.

There are two kinds of punishment or consequences—positive and negative—that decrease the occurrence of behaviors. Both positive and negative punishment function as "stop signs"; they stop or decrease the occurrence of a behavior.

Positive Punishment

There is a school in Massachusetts that uses a controversial method of punishment to discourage students from engaging in dangerous behaviors. Many of the children at this school have severe behavior problems, such as hitting strangers in the face, biting others or themselves, and eye gouging.

The school requires students to wear backpacks, which contain an electric device that allows staff members to apply a shock to electrodes attached to the student's body whenever the student engages in dangerous or prohibited behaviors (L. Kaufman, 2007). The goal is to decrease the occurrence of certain behaviors, and the method used is an example of positive punishment.

***Positive punishment* refers to presenting an aversive (unpleasant) stimulus after a response. The aversive stimulus decreases the chances that the response will recur.**

The aversive stimulus in the above example is electric shock, which decreases the chances that dangerous and self-destructive behaviors will occur.

There's a second type of punishment, called negative punishment, that can also be used to decrease children's undesirable behaviors.

Negative Punishment

One kind of undesirable behavior in young children is the persistent refusal of parental requests, a problem called noncompliance.

***Noncompliance* refers to a child refusing to follow directions, carry out a request, or obey a command given by a parent or caregiver.**

One method used to decrease children's noncompliance is time-out.

***Time-out* removes reinforcing stimuli after an undesirable response. This removal decreases the chances that the undesired response will recur.**

Time-out is an example of negative punishment.

***Negative punishment* refers to removing a reinforcing stimulus (a child's allowance) after a response. This removal decreases the chances that the response will recur.**

In time-out, the reinforcing stimulus being removed is the freedom to play and the undesirable behavior being decreased is noncompliance. In the Application section of this module, we'll discuss the pros and cons of positive and negative punishment.

Although somewhat confusing, remember that positive and negative punishment ***decrease*** the likelihood of a behavior occurring again, while positive and negative reinforcement ***increase*** the likelihood of a behavior occurring again.

C. Schedules of Reinforcement

Skinner's Contributions

Why are consequences important?

On September 20, 1971, *Time* magazine recognized B. F. Skinner's influence and accomplishments in psychology and education by putting him on its cover (right photo). Just a year earlier, the *American Psychologist* rated B. F. Skinner second, after Freud, in influence on 20th-century psychology.

Skinner is perhaps best known for his discovery of operant conditioning, which is a powerful method for analyzing the individual behaviors of animals and humans. Part of his method was to study how different kinds of consequences or reinforcements affected behavior, and this led to his study of different schedules of reinforcement.

TIME
B. F. Skinner Says:
We Can't Afford Freedom

B. F. Skinner (1904–1990)

A ***schedule of reinforcement*** refers to a program or rule that determines how and when the occurrence of a response will be followed by a reinforcer.

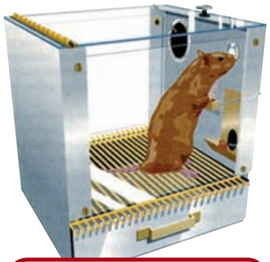
Skinner pointed out many examples of how schedules of reinforcement both maintained and controlled behaviors. For example, slot machine players don't realize that they are paid off according to a schedule of reinforcement that encourages rapid responding.

Skinner was able to study how different schedules of reinforcement affected behavior because he developed a clever method to record ongoing, individual behaviors. His method included the use of the now-famous "Skinner box" and something called the cumulative record.

Measuring Ongoing Behavior

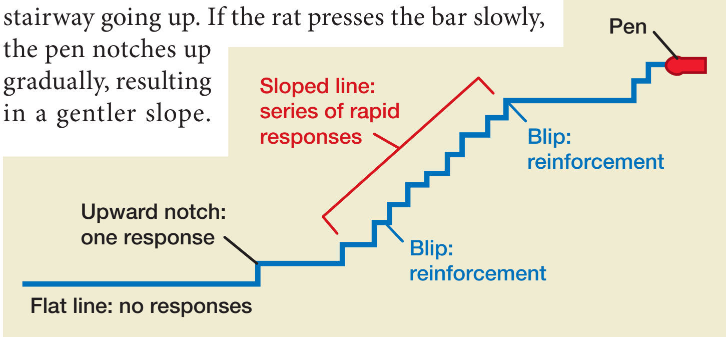
Skinner showed how different schedules of reinforcement affected an animal's or a human's ongoing behavior with something called a cumulative record.

A ***cumulative record*** is a continuous written record that shows an animal's or a human's individual responses and reinforcements.



Rat in a Skinner box

A rat in a Skinner box is shown on the left, and a cumulative record is shown below. When the rat is not pressing the bar, a pen draws a straight line on a long roll of paper that unwinds slowly and continuously to the left. When the rat presses the bar, the pen moves up a notch. When the rat makes numerous responses, the pen moves up many notches to draw a line that resembles a stairway going up. If the rat presses the bar slowly, the pen notches up gradually, resulting in a gentler slope. If the rat responds quickly, the pen notches up more quickly, resulting in a steeper slope. A downward blip indicates that the rat received a food pellet, or reinforcement (only two are shown). The cumulative record shows you an animal's ongoing responses and reinforcements across time.



Pen
Sloped line: series of rapid responses
Blip: reinforcement
Upward notch: one response
Blip: reinforcement
Flat line: no responses

We'll first look at how two general schedules of reinforcement—continuous and partial reinforcement—can greatly affect ongoing behavior.

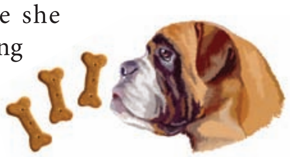
Schedules of Reinforcement

When I (H. K.) first began training my dog to "shake hands," I gave her a treat each time she responded to my command by shaking my hand. Later on, when she had mostly learned to shake hands, I gave her a treat only some of the time. These situations illustrate two general schedules of reinforcement—continuous and partial.

Continuous Reinforcement

Giving my dog a treat each time she responded to my command by shaking my hand illustrates the schedule of continuous reinforcement.

Continuous reinforcement means that every occurrence of the operant response results in delivery of the reinforcer.



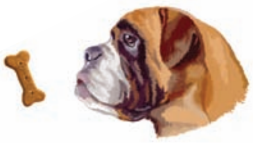
Every response is reinforced.

In the real world, relatively few of our behaviors are on a continuous reinforcement schedule because very few things or people are as reliable as my dog. Continuous reinforcement is often used in the initial stages of operant conditioning because it results in rapid learning of some behavior.

Partial Reinforcement

After my dog had mostly learned to shake hands on command, I gave her a treat about every fifth time, which illustrates the schedule of partial reinforcement.

Partial reinforcement refers to a situation in which responding is reinforced only some of the time.



Only some responses are reinforced.

In the real world, many of our behaviors are on a partial reinforcement schedule, which is very effective in maintaining behavior over the long run. My dog keeps shaking my hand on command because some of the time she gets a treat.

We'll discuss the four common schedules of partial reinforcement and show how differently they affect behavior.

Photo Credit: © 1971 *Time*, Inc./Getty Images. Reprinted by permission.
Figure/Text Credit: Reinforcement diagram from *Psychology: Themes and Variations*, by Wayne Weiten, 2nd ed., figure 6.13. Copyright © 1992 by Wadsworth, Inc. Reproduced by permission.

Partial Reinforcement Schedules

Which schedule are you on?

We'll discuss four different schedules of partial reinforcement, each of which has a different effect on controlling and maintaining animal and human behaviors.

Fixed-Ratio Schedule

If factory workers are paid after packing six boxes, they are on a fixed-ratio schedule.

Fixed-ratio schedule means that a reinforcer occurs only after a fixed number of responses are made by the subject.

A fixed-ratio schedule is often used to pay assembly-line workers because it results in fast rates of work.

Fixed-Interval Schedule

If a surfer gets a big wave to ride (the reinforcer) every 30 seconds (waves come in regular sets of big and small), he is on a fixed-interval schedule.

Fixed-interval schedule means that a reinforcer occurs following the first response that occurs after a fixed interval of time.

A fixed-interval schedule has slow responding at first, but as the time for the reinforcer nears, responses increase.

Variable-Ratio Schedule

If a slot machine pays off after an average of 25 pulls, the gambler is on a variable-ratio schedule.

Variable-ratio schedule means that a reinforcer is delivered after an average number of correct responses has occurred.

The variable-ratio schedule produces a high rate of responding because the person (gambler) doesn't know which response will finally produce the payoff.

Variable-Interval Schedule

BUS
254
257
259
260
262
263
268

If a bus arrives (the reinforcer) at your stop an average of 7 minutes late but at variable intervals, the bus rider is on a variable-interval schedule. This reinforces your arriving just a few minutes late for your bus.

Variable-interval schedule means that a reinforcer occurs following the first correct response after an average amount of time has passed.

A variable-interval schedule results in a more regular rate of responding than does a fixed-interval schedule.

In the real world, many of our behaviors are maintained on one or more of these four schedules of partial reinforcement.

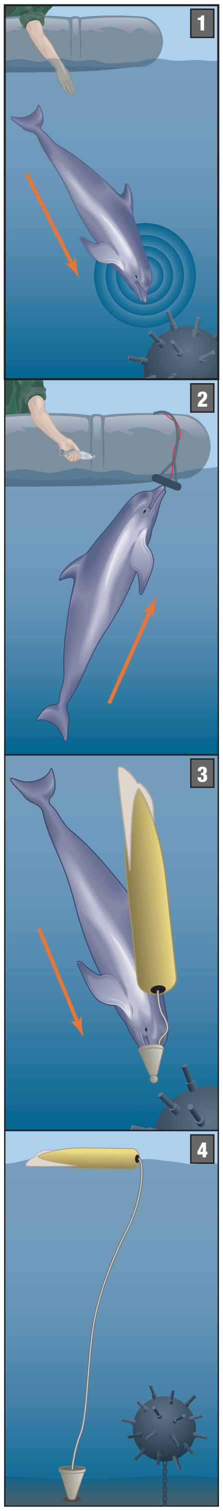
Next, we'll describe an interesting and unusual application of Skinner's principles of operant conditioning.

Applying Skinner's Principles

How smart are dolphins?

Trainer and dolphin

After the Gulf War, ships carrying food and medicine had to wait outside the ports until the many underwater mines were located. Because the water was dark and murky, human divers could not easily detect the mines, but dolphins had no difficulty, since they can "see" by using sound waves or echolocation to find objects. Dolphins are trained to detect mines similarly to how dogs are trained to detect explosives: Their trainers applied Skinner's principles of operant conditioning.



1. A dolphin has been trained to wait and circle around an inflatable boat. On the trainer's signal (discriminative stimulus), the dolphin dives and uses echolocation to find the mine in the murky water. Echolocation involves emitting sound waves (too high for humans to hear) and analyzing the waves that are reflected back from objects. The dolphin's echolocation is so sensitive that it can detect a quarter-sized metal disk 100 feet away, no matter how murky the water is.

2. After locating the mine, the dolphin returns to the surface and is trained to touch a rubber disk at the front of the boat. The trainer rewards the dolphin with a fish for this and many other behaviors.

3. The trainer places on the dolphin's nose a hollow cone attached to a plastic cylinder that rides on the dolphin's back. Again, the dolphin dives and echolocates the mine, but it has been trained not to touch the mine. When close to the mine, the dolphin is trained to release the nose cone, and the cylinder break opens and releases an anchor.

4. The anchor (sound transmitter) falls to the bottom while the cylinder rises to the surface to mark the location of the mine. Human divers use the cylinder to locate and then detonate the mine. The dolphin is always removed from the area before the mine is detonated. A Navy spokesperson says that the dolphins are well cared for and, for that reason, live in captivity as long as or longer than in the wild (Friend, 2003).

Through operant conditioning, dolphins learned to perform this complex series of behaviors. During operant conditioning, a number of other things are also happening.

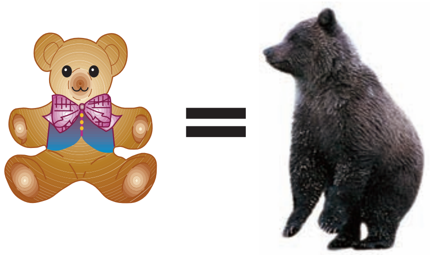
D. Other Conditioning Concepts

What else did Bart learn?

During the time that Bart was being operantly conditioned to pick up and hold a teddy bear to a hand signal, he simultaneously learned a number of other things, such as to also hold a bear cub, not to obey commands from a stranger, and to stop picking up the teddy bear if he was no longer given apples (reinforcers). You may remember these phenomena—generalization, discrimination, extinction, and spontaneous recovery—from our discussion of classical conditioning in Module 9 (see p. 199). We'll explain how the same terms also apply to operant conditioning.

Generalization

In the movie, Bart was supposed to pick up and hold a bear cub on command. However, in the wild, adult male Kodiak bears don't pick up and hold cubs; instead, they usually kill them.



Generalization: Bart transfers his response from teddy bear to live cub.

Although Bart was relatively tame, his trainer took no chances of Bart's wilder nature coming out and killing the bear cub. For this reason, the trainer started by conducting the initial conditioning with a stuffed teddy bear. Only after Bart had learned to pick up and hold the teddy bear on cue did the trainer substitute a live bear cub. As the trainer had predicted, Bart transferred his holding the teddy bear to holding the live bear cub, a phenomenon called generalization.

In operant conditioning, ***generalization*** means that an animal or person emits the same response to similar stimuli.

In classical conditioning, ***generalization*** is the tendency for a stimulus similar to the original conditioned stimulus to elicit a response similar to the conditioned response.

A common and sometimes embarrassing example of generalization occurs when a young child generalizes the word "Daddy" to other males who appear similar to the child's real father. As quickly as possible, embarrassed parents teach their child to discriminate between the real father and other adult males.

Discrimination

Since Bart had been raised and trained by a particular adult male, he had learned to obey and take cues only from his trainer and not from other males. This is an example of discrimination.

In operant conditioning, ***discrimination*** means that a response is emitted in the presence of a stimulus that is reinforced and not in the presence of unreinforced stimuli.

In classical conditioning, ***discrimination*** is the tendency for some stimuli but not others to elicit a conditioned response.

One problem with Bart was that he would repeatedly pick up and hold the teddy bear to receive an apple. To control this problem, the trainer used a cue—raising his arms in the air—to signal that only then would Bart receive an apple for his behavior. This is an example of a discriminative stimulus.

A ***discriminative stimulus*** is a cue that a behavior will be reinforced.

Discrimination: Bart obeys signals from his trainer but not from a stranger.

If you pay close attention to an animal trainer, you'll notice that discriminative stimuli, such as a hand signal or whistle, are used to signal the animal that the next behavior will be reinforced.

Young children learn to discriminate between stimuli when their parents reinforce their saying "Daddy" in the presence of their real fathers but do not reinforce their children when they call strangers "Daddy."

Extinction and Spontaneous Recovery

Even after filming ended, Bart continued to perform his trained behaviors for a while. However, after a period of time when these behaviors were no longer reinforced, they gradually diminished and ceased. This is an example of extinction.

In operant conditioning, ***extinction*** refers to the reduction in an operant response when it is no longer followed by the reinforcer.

Extinction: Bart stops behaviors if reinforcers stop. Spontaneous recovery: After extinction, Bart's behavior returns.

In classical conditioning, ***extinction*** refers to the reduction in a response when the conditioned stimulus is no longer followed by the unconditioned stimulus.

After undergoing extinction, Bart may show spontaneous recovery.

In operant conditioning, ***spontaneous recovery*** refers to a temporary recovery in the rate of responding.

In classical conditioning, ***spontaneous recovery*** refers to the temporary occurrence of the conditioned response in the presence of the conditioned stimulus.

Remember that all four phenomena—generalization, discrimination, extinction, and spontaneous recovery—occur in both operant and classical conditioning.

One distinctive characteristic of operant conditioning is that it usually has an observable response and an observable reinforcer. Next, we turn to cognitive learning, which may have neither observable response nor observable reinforcer.

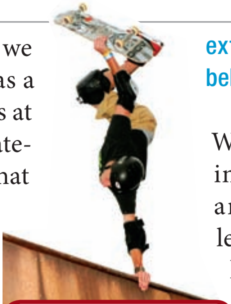
E. Cognitive Learning

Three Viewpoints of Cognitive Learning

How did Tony Hawk learn?

At the beginning of this module, we told you about Tony Hawk, who as a child loved to watch skateboarders at the park. He began to practice skateboarding every chance he had so that he could imitate what he saw. Tony learned how to skateboard not from classical or operant conditioning but from another kind of learning process called cognitive learning.

Cognitive learning, which involves mental processes such as attention and memory, says that learning can occur through observation or imitation and such learning may not involve any external rewards or require a person to perform any observable behaviors.

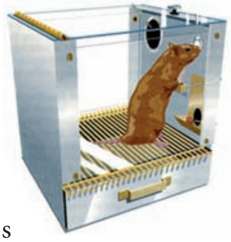


He learned by observing.

The roots of cognitive learning extend back to the work of Wilhelm Wundt in the late 1800s (p. 12) and Edward Tolman in the 1930s. It died in the 1950s, was reborn in the 1960s, and became popular in the 1990s. Currently, cognitive learning is extremely useful in explaining both animal and human behavior and was vital to the development of a new area called cognitive neuroscience (p. 71) (Bandura, 2001a). We'll begin by discussing what three famous psychologists had to say about cognitive learning.

Against: B. F. Skinner

Eight days before his death, B. F. Skinner was honored by the American Psychological Association (APA) with the first APA Citation for Outstanding Lifetime Contribution to Psychology. In his acceptance speech to over 1,000 friends and colleagues, Skinner spoke of how psychology was splitting between those who were studying feelings and cognitive processes and those who were studying observable behaviors, such as animals under controlled conditions (figure at right). In a sharp criticism of cognitive learning, Skinner said, "As far as I'm concerned, cognitive science is the creationism [downfall] of psychology" (Vargas, 1991, p. 1).



Skinner's severe criticism of studying cognitive processes caused many in the audience to gasp and only a few to applaud (Vargas, 1991).

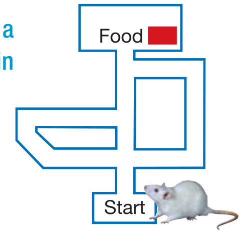
In the 1950s and 1960s, Skinner had advocated that psychology's goal should be to study primarily observable behaviors rather than cognitive processes.

However, psychologists gradually discovered that cognitive processes played a major role in human and animal activities and that such activities could not be understood or explained from observable behaviors alone. Today, the study of cognitive processes is a major goal of psychology (Bandura, 2001a).

In Favor: Edward Tolman

In the 1930s, about the same time that Skinner was emphasizing observable behaviors, Tolman was exploring hidden mental processes. For example, he would place rats individually in a maze, such as the one shown below, and allow each rat time to explore the maze with no food present. Then, with food present in the maze's food box, he would test the rat to see which path it took. The rat learned very quickly to take the shortest path. Next, Tolman blocked the shortest path to the food box. The first time the rat encountered the blocked shortest path, it selected the next shortest path to the food box. According to Tolman (1948), the rat selected the next shortest path because it had developed a cognitive map of the maze.

A ***cognitive map*** is a mental representation in the brain of the layout of an environment and its features.



Tolman showed that rats, in addition to forming a cognitive map, learned the layout of a maze without being reinforced, a position very different from Skinner's. Tolman's position is making a comeback as psychologists currently study a variety of cognitive processes in animals (Redish, 2007). Tolman's study of cognitive processes in animals laid the groundwork for the study of cognitive processes in humans, which is best shown by the current theory of Albert Bandura (2001a).

In Favor: Albert Bandura

Bandura began as a behaviorist in the Skinnerian tradition, which means focusing on observable behaviors and avoiding study of mental events. Since then he has almost entirely shifted to a cognitive approach. In many of his studies, Bandura (1986) has focused on how humans learn through observing things. For example, Bandura says that a child can learn to hate spiders simply by observing the behaviors of someone who shows a great fear of spiders. This is an example of social cognitive learning.

Social cognitive learning results from watching, imitating, and modeling and does not require the observer to perform any observable behavior or receive any observable reward.

Just as Tolman found that learning occurred while rats were exploring, Bandura found that humans learned while observing and that much (most) of human learning takes place through observation. Observational learning, which involves numerous cognitive processes, is a 180-degree change from Skinner's position, which had emphasized observable, noncognitive behaviors.

Following the death of Skinner in 1990, the study of cognitive processes has ballooned in popularity and usefulness. We'll introduce you to cognitive learning by describing one of Bandura's best-known studies, which involved a doll and a considerable amount of kicking and screaming.

E. Cognitive Learning

Observational Learning

Do children learn by watching?

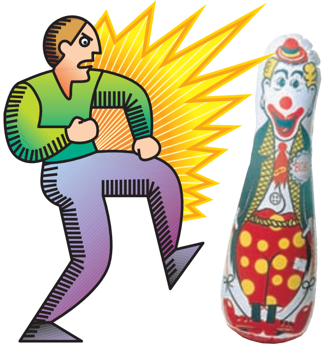
Perhaps a dozen experiments in psychology have become classics because they were the first to demonstrate some very important principles. One such classic experiment demonstrated the conditioning of emotional responses in "Little Albert" (p. 204). Another classic is Albert Bandura (1965) and his colleagues' demonstration that children learned aggressive behaviors by watching an adult's aggressive behaviors. Learning through watching is called observational learning, which is a form of cognitive learning.

Bobo Doll Experiment

Why did children kick the Bobo doll?

One reason this Bobo doll study is a classic experiment is it challenged the idea that learning occurred through classical or operant conditioning. Children learned to perform aggressive responses simply from watching.

Procedure. In one part of the room, preschool children were involved in their own art projects. In another part of the room, an adult got up and, for the next 10 minutes, kicked, hit, and yelled ("Hit him! Kick him!") at a large, inflated Bobo doll. Some children watched the model's aggressive behaviors, while other children did not.



After watching, children imitated adults kicking doll.

Each child was later subjected to a frustrating situation and then placed in a room with toys, including the Bobo doll. Without the child's knowledge, researchers observed the child's behaviors.

Results. Children who had observed the model's aggressive attacks on the Bobo doll also kicked, hit, and yelled ("Hit him! Kick him!") at the doll. Through observational learning alone, these children learned the model's aggressive behaviors and were now performing them. In comparison, children who hadn't observed the model's behaviors didn't hit or kick the Bobo doll after they had been mildly frustrated.

Conclusion. Bandura's point is that children learned to perform specific aggressive behaviors not by practicing or being reinforced but simply by watching a live model perform behaviors. Observational learning is called modeling because it involves watching a model and imitating the behavior.

It turns out that observational learning may have a biological foundation. Recent research on mirror neurons (see p. 6) shows that they become activated when we observe others perform behaviors, which suggests we are biologically programmed to learn through observation (Iacoboni, 2008a; Lepage & Théoret, 2007).

Another finding of the Bobo doll study is that a child may learn by observing but then not perform the behavior. This is called the ***learning–performance distinction.***

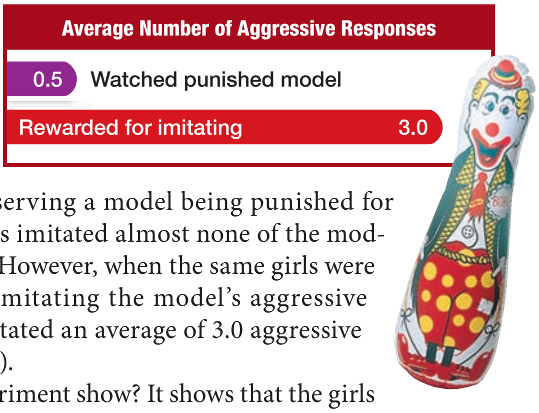
Learning Versus Performance

Do you learn but not show it?

Is it possible that people learn by observing but not necessarily perform what they have learned? To answer this question, Bandura and colleagues asked children to watch a movie in which someone hit and kicked a Bobo doll. However, after hitting and kicking the doll, the person in the film was punished by being criticized and spanked. Next, each child was left alone in a room filled with toys, including a Bobo doll.

As the experimenters watched each child through a one-way mirror, they found that more boys than girls imitated the model and performed aggressive behaviors on Bobo. But not all the children imitated the model's aggressive behaviors. Next, each child who had not imitated the model's aggressive behaviors on Bobo was offered a reward (a sticker or some fruit juice) to imitate the model's behavior. With the promise of a reward, all of the children imitated the model's aggressive behaviors. We'll examine in more detail the girls' imitated aggressive behaviors, which were similar to the boys' but more dramatic.

As the graph below shows, girls imitated an average of 0.5 aggressive behaviors after watching a film of a model who performed aggressive behaviors on Bobo and then was punished for being aggressive. In other words, after observing a model being punished for aggressive behaviors, girls imitated almost none of the model's aggressive behaviors. However, when the same girls were promised a reward for imitating the model's aggressive behaviors, these girls imitated an average of 3.0 aggressive behaviors (Bandura, 1965).



So what does this experiment show? It shows that the girls had actually ***learned*** the model's aggressive behaviors through observation but that some did not ***perform*** these behaviors until they were rewarded for doing so (Bandura, 1965). This is an example of the learning–performance distinction.

The *learning–performance distinction* means learning may occur but may not always be measured by, or immediately evident in, performance.

Child imitates adult's speech.

The learning–performance distinction may be demonstrated by young children, often to the embarrassment of their parents. For instance, a young child may overhear a "dirty" word but not repeat the word until out in public. Repeating a "dirty" word shows that the child had learned the word through observation but waited until later to imitate the parent and actually say (perform) the "dirty" word.

Based on the Bobo doll study and others, Bandura developed a theory of cognitive learning that we'll examine next.

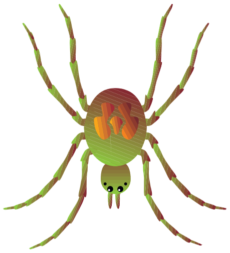
Bandura's Social Cognitive Theory

Would you hold this spider?

The idea that humans gather information about their environments and the behaviors of others through observation is a key part of Bandura's (2001a) social cognitive theory of learning.

Social cognitive theory **emphasizes the importance of observation, imitation, and self-reward in the development and learning of social skills, personal interactions, and many other behaviors.**



Unlike operant and classical conditioning, this theory says that it is not necessary to perform any observable behaviors or receive any external rewards to learn.

Bandura believes that four processes—attention, memory, imitation, and motivation—operate during social cognitive learning. We'll explain how these processes operate in decreasing fear of spiders and snakes.

Social Cognitive Learning: Four Processes

1 Attention

The observer must pay attention to what the model says or does. In the photo at right, a nonfrightened person (model) holds a huge spider while a woman (observer) looks on in fear.

2 Memory

The observer must store or remember the information so that it can be retrieved and used later. The observer in the photo will store the image of seeing a nonfrightened person (model) holding a spider.

3 Imitation

The observer must be able to use the remembered information to guide his or her own actions and thus imitate the model's behavior. The observer in the photo will later try to imitate the model's calm behavior when holding a spider.

After observing the fearless model, the woman may learn not to fear spiders.

4 Motivation

The observer must have some reason or incentive to imitate the model's behavior. The observer in the photo is motivated to overcome her fear of spiders because she wants to go on camping trips.

If this observer can successfully imitate the model's calm behavior, then she will overcome her fear of spiders and be able to go camping with her friends. This example shows how Bandura's four mental processes operate during social cognitive learning.

The next study by Bandura shows how social cognitive learning, which usually takes some time and effort, decreased fear of snakes.

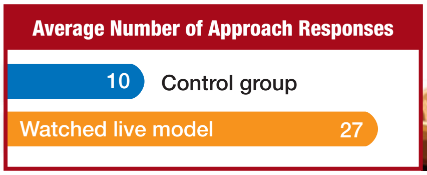
Social Cognitive Learning Applied to Fear of Snakes

Background. Although most people are wary of snakes, some develop an intense fear of them. Bandura and colleagues recruited subjects who had developed such an intense fear of snakes that they avoided many normal outdoor activities, such as hiking or gardening (Bandura et al., 1969). The subjects' fear of snakes was objectively measured by noting how many of 29 steps of increasingly frightening actions they would perform. For example, step 1 was approaching a glass cage containing a snake; step 29 was putting the snake in their laps and letting it crawl around while holding their hands at their sides.

Treatment. One group of subjects watched as a model handled a live, 4-foot, harmless king snake. After watching for 15 minutes, subjects were invited to gradually move closer to the snake. Then the model demonstrated touching the snake and asked the subjects to imitate her actions. As the model held the snake, subjects were encouraged to touch the snake with a gloved hand. Another group of subjects, who also reported an intense fear of snakes, received no treatment (control group).

Social cognitive learning helped this woman overcome her fear of snakes.

Results and conclusion. As the graph below shows, subjects who watched a live model handle a snake and who imitated some of the model's behaviors scored an average of 27 on the 29-step approach scale.



In contrast, control subjects scored an average of only 10 approach behaviors on the 29-step scale. This study clearly showed that behavior can be greatly changed through social cognitive learning, which emphasizes observation and imitation.

Bandura believes that humans acquire a great amount of information about fears, social roles, discrimination, and personal interactions through social cognitive learning. We'll discuss other aspects of cognitive learning and memory in Modules 11 and 12.

Next, we'll describe another kind of cognitive learning that involves what is often described as the "ah-ha!" feeling.

E. Cognitive Learning

Insight Learning

What's the "ah-ha!" feeling?

Earlier we told you that Thorndike studied how cats learned to escape from a puzzle box to get a piece of fish. Thorndike concluded that learning occurred through a process of trial and error as cats gradually formed associations between moving the latch and opening the door. None of the cats showed any evidence of suddenly discovering the solution of how to escape the box.

About the same time that Thorndike in America was studying the trial-and-error learning of cats escaping from a puzzle box, Wolfgang Köhler in Germany was studying how chimpanzees learned to obtain bananas that were out of reach. Köhler challenged Thorndike's conclusion that animals learned only through trial and error. Köhler suggested instead that cats and other animals that were observed under the proper circumstances could solve a problem in a sudden flash, known as insight or "ah-ha!" (G. Cook, 2002).

Flash of insight

Insight **is a mental process marked by the sudden and unexpected solution to a problem: a phenomenon often called the "ah-ha!" experience.**

Here's an example of Köhler's chimp, Sultan, who showed insight in getting a banana that was hanging out of reach.

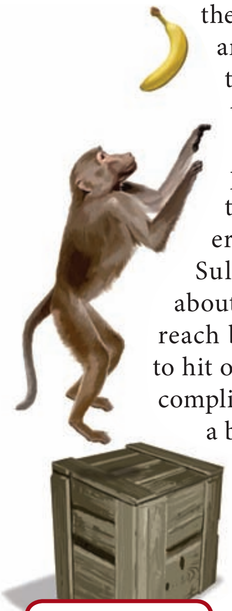
Insight in Animals

How did the chimp get the banana?

This classic experiment in psychology suggested a new kind of learning.

What Köhler (1925) did was to hang a banana from the ceiling in a room that had a box placed off to one side. The banana was too high for Sultan the chimp to grab by reaching or jumping. When Sultan first entered the room, he paced restlessly for about 5 minutes. Then he got the box, moved it toward the banana, climbed onto the box, jumped up, and seized the banana. On his second try, Sultan quickly moved the box directly beneath the banana and jumped up to get it.

What intrigued Köhler about Sultan's problem-solving behavior was that it seemed to differ greatly from the random trial-and-error behavior of Thorndike's cats. Before Sultan arrived at a solution, he might pace about, sit quietly, or vainly grasp at the out-of-reach banana. Then, all of a sudden, he seemed to hit on the solution and immediately executed a complicated set of behaviors, such as standing on a box, to get the banana. Köhler believed that Sultan's sudden solution to a problem was an example of ***insight,*** a mental process quite different from what Thorndike had observed in the random trial-and-error learning of cats.



Chimp stood on a box and jumped up to reach the banana.

However, critics of Köhler's insight studies pointed out that he did not explain how chimps solved problems; rather, he simply described the process. Köhler replied that his studies on insight were more a way to study problem solving than an explanation of what was happening in the chimp's head. The significance of Köhler's work was that it represented a method for studying learning that was different from either classical conditioning or random trial-and-error learning (Pierce, 1999). Since the early 1990s, there has been a renewed interest in studying the workings of the animal mind, which is currently called animal cognition (Pearce, 2008; Wynne, 2001).

Let's look at an example of insight learning in humans.

Insight in Humans

Can you solve this puzzle?

Just as Sultan the chimp seemed to suddenly arrive at a solution to a problem, humans also report the experience of suddenly and unexpectedly solving a challenging or difficult problem. We call this phenomenon the "ah-ha!" experience or a flash of insight (G. Cook, 2002). You may have an "ah-ha!" experience if you can figure out what critical piece of information is needed to make the following story make sense.

A man walks into a bar and asks for a glass of water. The bartender points a gun at the man. The man says "Thank you" and walks out.

If you solved this puzzle, you had an insight!

Obviously, something critical happened between two events: ". . . asks for a glass of water" and "The bartender points a gun at the man." Some subjects solved this problem relatively quickly, while others couldn't solve this problem in the 2-hour time limit.

Neither one of us could solve the problem until we read the hint: The man has hiccups. Think about cures for hiccups and you may have an "ah-ha!" experience (answer at bottom of page). There was a difference between nonsolvers and solvers in the cognitive strategy they used. The nonsolvers focused on the obvious elements, such as man, bartender, gun, and glass of water, and not on new concepts (hiccups, cure) that lead to a solution. In comparison, the solvers spent more time on bringing in new information, and when they finally found the missing piece of information (cure for hiccups), the solution arrived suddenly, like the "ah-ha!" experience Köhler defined as insight (Durso et al., 1994).

Researchers are examining the association between brain activity and "ah-ha!" experiences and have found that a unique pattern of electrical activity occurs immediately before insightful moments (B. Bower, 2008a).

We have discussed three examples of cognitive learning: Tolman's idea of cognitive maps, Bandura's theory of social cognitive learning, and Köhler's study of insightful problem solving. After the Concept Review, we'll explain why biological factors make some things easier and some things harder to learn.

Answer: The man drank the water, but it didn't cure his hiccups. The bartender thought a surprise or fright might do the trick. He points a gun at the man, who is frightened, and so his hiccups stop. The man says "Thank you" and walks out.

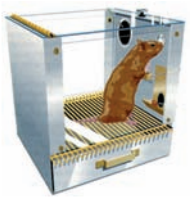
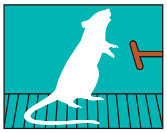
Concept Review



1. The kind of learning in which the consequences that follow some behavior increase or decrease the likelihood that the behavior will occur in the future is called ________________.

2. In operant conditioning, the organism voluntarily performs or (a) ________________ a behavior. Immediately following an emitted behavior, the occurrence of a (b) ________________ increases the likelihood that the behavior will occur again.



3. Because an organism may not immediately emit the desired behavior, a procedure is used to reinforce behaviors that lead to or approximate the final target behavior. This procedure is called ________________.

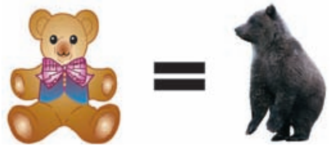
4. In operant conditioning, the term *consequences* refers to either (a) ________________, which increases the likelihood that a behavior will occur again, or (b) ________________, which decreases the likelihood that a behavior will occur again.

5. If the occurrence of some response is increased because it is followed by a pleasant stimulus, the stimulus is called a (a) ________________. An increase in the occurrence of some response because it is followed either by the removal of an unpleasant stimulus or by avoiding the stimulus is called (b) ________________.

6. A stimulus, such as food, water, or sex, that is innately satisfying and requires no learning to become pleasurable is a (a) ________________. A stimulus, such as grades or praise, that has acquired its reinforcing power through experience and learning is a (b) ________________.

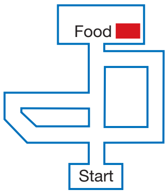
7. The various ways that reinforcers occur after a behavior has been emitted are referred to as (a) ________________ of reinforcement. For example, if each and every target behavior is reinforced, it is called a (b) ________________ schedule of reinforcement. If behaviors are not reinforced each time they occur, it is called a (c) ________________ schedule of reinforcement.

8. When an organism emits the same response to similar stimuli, it is called (a) ________________. When a response is emitted in the presence of a stimulus that is reinforced and not in the presence of unreinforced stimuli, it is called (b) ________________. A decrease in emitting a behavior because it is no longer reinforced is called (c) ________________. If an organism performs a behavior without its being reinforced, it is called (d) ________________.



9. A kind of learning that involves mental processes, that may be learned through observation and imitation, and that may not require any external rewards or the performance of any observable behaviors is referred to as ________________.

10. Tolman studied the behavior of rats that were allowed to explore a maze without any reward given. When food was present, rats quickly learned to select the next shortest path if a previously taken path was blocked. Tolman said that rats had developed a mental representation of the layout, which he called a ________________.



11. Although an organism may learn a behavior through observation or exploration, the organism may not immediately demonstrate or perform the newly learned behavior. This phenomenon is known as the ________________ distinction.

12. According to Bandura, one form of learning that develops through watching and imitation and that does not require the observer to perform any observable behavior or receive a reinforcer is called (a) ________________ learning. Bandura believes that humans gather much information from their (b) ________________ through social cognitive learning.

13. Bandura's theory of social cognitive learning involves four mental processes. The observer must pay (a) ________________ to what the model says or does. The observer must then code the information and be able to retrieve it from (b) ________________ for use at a later time. The observer must be able to use the coded information to guide his or her (c) ________________ in performing and imitating the model's behavior. Finally, the observer must be (d) ________________ to perform the behavior, which involves some reason, reinforcement, or incentive.

14. In Köhler's study of problem solving in chimps, he identified a mental process marked by the sudden occurrence of a solution, which he termed (a) ________________. This phenomenon is another example of (b) ________________ learning.

Answers: *1. operant conditioning; 2. (a) emits, (b) reinforcement or reinforcer; 3. shaping; 4. (a) reinforcement, (b) punishment; 5. (a) positive reinforcer, (b) negative reinforcement; 6. (a) primary reinforcer, (b) secondary inforcer; 7. (a) schedules, (b) continuous, (c) partial; 8. (a) generalization, (b) discrimination, (c) extinction, (d) spontaneous recovery; 9. cognitive learning; 10. cognitive map; 11. learning–performance; 12. (a) social cognitive, (b) environments; 13. (a) attention, (b) memory, (c) motor control, (d) motivated; 14. (a) insight, (b) cognitive*

F. Biological Factors

Definition

Why would a monkey make a snowball?

You may remember having difficulty learning to read, write, ride a bike, drive a car, put on makeup, or shave. But do you remember having problems learning to play? For a young child, playing just seems to come naturally. Just as children engage in play behavior with little or no encouragement, reward, or learning, so too do monkeys. For example, young monkeys learn to roll snowballs and carry them around for apparently no other reason than for play (right photo). In fact, most young mammals engage in various play behaviors, which are not easily explained by the three traditional learning procedures—classical conditioning, operant conditioning, and cognitive learning (S. Brownlee, 1997). Observations of animals and humans indicate that some behaviors, such as play, are easily and effortlessly learned partly because of innate biological factors.

Animals have innate tendencies, such as playing with objects.

Biological factors refer to innate tendencies or predispositions that may either facilitate or inhibit certain kinds of learning.

Researchers suggest that animals and humans may have evolved biological predispositions to learn play behaviors because they have adaptive functions—for example, developing social relationships among peers and learning behaviors useful for adult roles (Bekoff, 2001; Dugatkin & Bekoff, 2003). This means that animals and humans have innate biological factors or predispositions that make certain kinds of learning, such as play behavior, very easy and effortless.

Besides play behavior, we'll discuss two other examples of learning—imprinting and preparedness—that are learned early and easily because of biological factors.

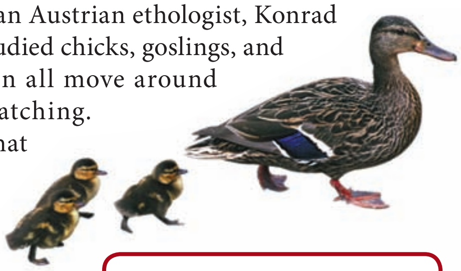
Imprinting

Why do young chicks follow their mother?

Soon after they hatch and without any apparent learning, baby chicks follow their mother hen. This following behavior was not explained by any of the principles of learning identified by Pavlov (classical conditioning), Thorndike (trial-and-error learning), or Skinner (operant conditioning). The baby chick's seemingly unlearned behavior of following its mother was a different kind of learning that was first identified by ethologists.

Ethologists are behavioral biologists who observe and study animal behavior in the animal's natural environment or under relatively naturalistic conditions.

For example, an Austrian ethologist, Konrad Lorenz (1952), studied chicks, goslings, and ducks, which can all move around minutes after hatching. He discovered that these baby animals followed the first moving object they saw, which was usually their mother. This following behavior is an example of imprinting.



Baby ducks automatically follow first moving object.

Imprinting refers to inherited tendencies or responses that are displayed by newborn animals when they encounter certain stimuli in their environment.

Imprinting is an unlearned behavior that is based on biological factors and that has great survival value: It increases the chances that newly hatched birds will remain with and follow their parent instead of wandering off into the waiting jaws of predators. Besides being unlearned, Lorenz noted two other major differences between imprinting and other kinds of learning.

Sensitive period. Unlike classical conditioning, operant conditioning, and cognitive learning, which occur throughout an animal's life, imprinting occurs best during the first few hours after hatching. This brief time period is called the critical, or sensitive, period.

The ***critical,*** or ***sensitive, period*** refers to a relatively brief time during which learning is most likely to occur.

Normally, the first object that newly hatched ducks see is their parent, upon whom they imprint. Thus, imprinting is a way for newly hatched animals to establish social attachments to members of their species. Although newly hatched birds will imprint on almost any moving object that they first see, including a human, a colored ball, or a glove, they imprint more strongly on moving objects that look or sound like their parent. Only birds that can walk immediately after hatching show imprinting, which promotes their survival (Bateson, 1991).

Irreversible. Unlike classical conditioning, operant conditioning, and cognitive learning, whose effects are usually reversible, imprinting is essentially irreversible. Most likely, imprinting evolved to be irreversible so that a young duck would not imprint on its mother one week and then imprint on a sly fox the next week.

In a program to prevent the California condor from becoming extinct, condor chicks are hatched at the San Diego Zoo and raised by humans. Because imprinting occurs very early and is irreversible, special precautions are taken so that the condor will not imprint on humans.

For example, the young condor chick shown on the right is being fed by a puppet that resembles an adult condor's head rather than a human's hand. The "puppet mother" helps the young condor imprint on real condor characteristics. When this condor grows up and is introduced into the wild, it will establish social relationships with, and attempt to mate with, its own species.

"Puppet mother" feeds baby condor.

Another example of how biological factors increase the ease and speed of learning is evident in something called prepared learning.

Photo Credits: top, © Mitsuaki Iwago/Minden Pictures; left, © PhotoDisc, Inc.; right, © Zoological Society of San Diego

Prepared Learning

Why was learning to talk so easy?

You easily learned to talk but probably had trouble learning to read because of how your brain is organized, which illustrates the importance of biological factors. We'll discuss how biological factors help humans learn to speak different languages and birds learn to remember thousands of places where they hid food.

Incredible Memory

How do birds remember?

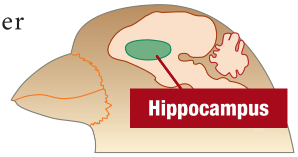
There are small birds, called Clark's nutcrackers, that live in an area where almost no food is available in the winter. During autumn, nutcrackers hide stores of food in underground places in perhaps as many as 2,500 to 6,000 different locations. During winter, nutcrackers survive by finding and digging up their hidden stores of food. How do nutcrackers locate their thousands of hidden stores? One explanation is preparedness, which we discussed earlier (see p. 200).

Remembers thousands of hidden food places

Preparedness,* or *prepared learning, refers to the innate or biological tendency of animals to recognize, attend to, and store certain cues over others, as well as to associate some combinations of conditioned and unconditioned stimuli more easily than others.

Under seminatural conditions, researchers observed the amazing ability of nutcrackers to hide and find hundreds of hidden stores of food. Researchers found that nutcrackers use natural landmarks (trees, stones, bushes) to form cognitive maps that help them remember the locations of their hidden stores (B. M. Gibson & Kamil, 2001; Kamil & Cheng, 2001).

One reason nutcrackers have such phenomenal memories is that the areas of their brains involved in memory are larger than the same areas in birds that do not store food. Specifically, the hippocampus, which is involved in transferring short-term memories into long-term memories, is larger in nutcrackers than in nonstoring birds (S. D. Healy et al., 2005). Thus, the nutcracker is biologically prepared for surviving winters by having a larger hippocampus (right figure), which helps it better remember the locations of thousands of food stores.



Just as some birds are biologically prepared to remember the locations of critical hidden stores, humans are biologically prepared to make sounds and speak at least one of 6,800 different languages.

Incredible Sounds

How do infants make "word" sounds?

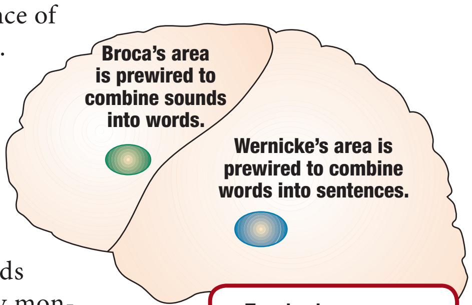
In the late 1940s, two psychologists raised a chimp in their home, along with their own child, because they wanted to know if this "speaking" environment would help a chimp learn to speak. However, after 6 years of trying, the chimp had learned to say a grand total of three words: "mama," "papa," and "cup" (Hayes & Hayes, 1951). At that time, these two psychologists did not know that the chimp's vocal apparatus and brain were not biologically prepared to produce sounds and words necessary for human speech (see the discussion of animal language on pp. 322–323).

Chimp does not have vocal structures to speak.

The reason humans but not chimps or other animals learn to speak so easily is that humans' vocal apparatus and brains are biologically prepared, or innately wired, for speaking (Pinker, 1994).

Infant's brain is prewired for speaking.

For example, the brain of a newborn infant is biologically prepared to recognize the difference between human speech sounds. Researchers discovered this ability by playing speech sounds to infants whose rate of sucking on a nipple was being recorded. After newborns heard the sound "ba" over and over, their rate of sucking slowed, indicating that they were paying little attention to the sound. But, as soon as researchers played the sound "pa," the infants' rate of sucking increased, indicating that they had noticed the relatively small change between the sounds "ba" and "pa." This study showed that infants' brains are prewired or biologically prepared (below figure) to recognize and discriminate among sounds that are essential for learning speech (Buonomano & Merzenich, 1995). In fact, infants all around the world make similar babbling sounds, which indicates the influence and importance of biological factors in learning to speak.



Broca's area is prewired to combine sounds into words.
Wernicke's area is prewired to combine words into sentences.

Two brain areas are prewired for speaking.

Conclusion. The learning principles of Pavlov, Thorndike, and Skinner do not, by themselves, explain how rats form cognitive maps, how infants easily produce and discriminate among human speech sounds, how nutcrackers remember thousands of hiding places for stored food, why monkeys spend time making and rolling snowballs, and why newborn chicks follow the first moving object. All these examples indicate how innate biological factors, such as differences in size or organization of brain structures, play a major role in preparing and helping animals and humans learn certain kinds of behaviors that are useful for maintenance and survival.

Next, we'll return to operant conditioning and discuss how its learning principles helped parents manage childhood problems.

G. Research Focus: Viewing Aggression

Relational and Physical Aggression in the Media

Can watching meanness make you aggressive?

Earlier in this module, we discussed observational learning, which is when an individual learns specific behaviors simply by watching someone engage in the behaviors. For instance, in the Bobo doll study, we saw how children can learn to perform specific aggressive behaviors simply by watching a live model perform these behaviors.

Researchers have long been interested in whether watching aggression or violence in the media (television, movies) makes people more aggressive. Numerous studies have found that watching physical aggression in the media does in fact increase physical aggression in viewers. However, physical aggression is not the only type of violence portrayed in the media. For example, relational aggression, such as verbal bullying, ostracizing peers, and spreading rumors, is also frequently portrayed. Is it possible that viewing relational aggression, such as meanness, can increase people's relational aggression behaviors or even their physical aggression behaviors? Researchers recently explored this very question (S. M. Coyne et al., 2008).

Observing physical aggression in the media increases physically aggressive behaviors in viewers.

Study: Effects of Viewing Physical and Relational Aggression in the Media

Participants. They were 53 female university students with an average age of 23.

Procedure. The women were randomly assigned to one of three groups, each to watch a different video. One video featured physical aggression (a knife fight from *Kill Bill*), another featured relational aggression (a collection of scenes from *Mean Girls*), and a third featured no aggression (a scene from *What Lies Beneath* showing people engaging in a ritual to communicate with spirits).

After watching the videos, all participants completed a questionnaire about their past aggressive behaviors. As the women left the room to go home, another researcher asked if they would participate in a second study (it's actually part of the original study). The women were told this second study would examine their reaction times in completing puzzle tasks. Once participants said yes and began working on the puzzles, the researcher intentionally behaved in a very rude manner by telling them to hurry, pacing with a stopwatch, and sighing loudly. When the participants later expressed low confidence about their performance, the researcher blamed them for ruining her study. She was doing a great job of acting rude!

Participants were then asked to engage in a competitive reaction time test (pushing buttons really fast) and to choose from ten noise levels to be administered to their opponent each time they lose the button-pushing contest. At the very end, participants completed evaluation forms for the rude experimenter.

Results. Participants who viewed the movie clips featuring physical and relational aggression reacted in aggressive ways. When instructed to administer a loud, sharp noise to their opponent, these women administered a louder noise than women who watched a clip with no aggression (example of physical aggression). On an important questionnaire to be used supposedly to help decide whether the rude researcher should be hired, these women rated the rude researcher lower than the women who did not watch aggression (example of relational aggression) (S. M. Coyne et al., 2008; Toppo, 2008).

Physical Aggression **Relational Aggression**

Participants who viewed either physical or relational aggression were more likely to subsequently engage in physical and relational aggression than participants who didn't view any aggression.

Conclusion. Viewing either physical or relational aggression in the media leads to an increased likelihood of people subsequently exhibiting physical and relational aggression. Also, watching one form of aggression can influence the occurrence of other forms of aggression. For example, observing relational aggression can make it more likely for someone to subsequently engage in physical aggression. Parents, teachers, media watchdogs, and politicians should focus not only on the effects of viewing physical aggression in the media but also on the effects of viewing relational aggression.

Learning to behave in aggressive ways by watching aggression in the media is one example of how learning principles can be applied to human behavior. Another example involves learning how to play the violin.

Photo Credits: top, © Edouard Berne/Getty Images; bottom left, © Radius Images/Photolibrary; bottom right, © SW Productions/Getty Images

What's the Suzuki method?

In the 1940s, a violin player and teacher from Japan, Shinichi Suzuki, developed a remarkably successful method for teaching violin playing to very young children (Suzuki, 1998). His method, called the ***Suzuki method,*** was brought to the United States in the mid-1960s and has generated incredible enthusiasm among children, parents, and music teachers ever since (Gokturk, 2008).

It's interesting to learn that the basic principles of the Suzuki method for teaching young children to play the violin are very similar to Bandura's four mental processes for social cognitive learning. What's different is that Suzuki developed his learning principles after years of actually teaching young children to play the violin, while Bandura developed his four mental processes of observational learning after years of research with young children. We'll discuss how even though Suzuki the teacher and Bandura the researcher lived in very different cultures thousands of miles apart, their experiences led them to very similar conclusions about how children learn.

Suzuki's method of teaching young children to play musical instruments has many similarities with Bandura's principles of social cognitive learning.

Different Cultures but Similar Learning Principles

1 Attention

Bandura states that the observer must pay attention to what the model says and does.

Similarly, Suzuki advises parents to teach violin information only when the child is actually looking at and watching the parent. Parents are told to stop teaching and wait if the child rolls on the floor, jumps up and down, walks backward, or talks about unrelated things.

The recommended age for starting a child with the Suzuki method is 3 for girls and 4 for boys. Parents are cautioned, however, that the attention span of the 3- to 4-year-old child is extremely limited, usually from 30 seconds to at most several minutes at a time.

2 Memory

Bandura says that the observer must code the information in such a way that it can be retrieved and used later.

Similarly, Suzuki tells parents that they should present information in ways that a young child can understand (Bandura would say code). Because a 3- to 4-year-old child does not have fully developed verbal skills or memory, little time is spent giving verbal instructions. Instead, the young child is given violin information through games and exercises. For example, children are taught how to hold the violin, use the bow, and press the strings by first playing games with their hands. Children are taught how to read music (notes) only when they are older and have gained some technical skill at playing the violin.

3 Imitation

Bandura says the observer must be able to use the information to guide his or her own actions and thus imitate the model's behavior.

Similarly, Suzuki suggests that children start at about 3 or 4 years old, the earliest age when they can physically perform the required movements and imitate their parents and teachers. Girls can start earlier than boys because girls physically mature earlier. For other instruments, the starting times are different—piano, 4–5 years; cello, 5 years; flute, 9 years—because these instruments require more physical dexterity. As you have probably guessed, 3- and 4-year-olds start with miniature violins and move up to bigger ones as they develop.

4 Motivation

Bandura says that the observer must have some reason, reinforcement, or incentive to perform the model's behaviors.

Similarly, Suzuki emphasizes that the most important role of the parent is to constantly reward and reinforce the child for observing and "doing what Mommy or Daddy is doing." Suzuki recommends several ways to keep motivation high in young children: Be an active and interested model for the child, play violin games that are fun for the child, avoid games or lessons that involve competition, and never push the child beyond the level that he or she is capable of reaching (Slone, 1985).

Social cognitive learning involves attention, memory, imitation, and motivation.

Conclusion. Parents and teachers who have used the Suzuki method report great success (Lamb, 1990). As you can judge, the basic principles of the Suzuki method for teaching violin are quite similar to Bandura's four mental processes for social cognitive learning. Both Suzuki and Bandura recognized the importance of observational learning and how much information children can learn from watching and imitating models. Suzuki's successful method of teaching violin to young children provides support for Bandura's four mental processes that he believes are involved in social cognitive learning.

Next, we'll discuss how operant learning principles were used to develop a method for teaching autistic children.

Photo Credit: top and right, © Hiroji Kubota/Magnum Photos

I. Application: Behavior Modification

Definitions

What is behavior mod?

In this module, we have discussed how operant conditioning principles are used to decrease food refusal in young children, to toilet train children (p. 216), to prevent eating paint chips (p. 218), and to stop children from engaging in dangerous behaviors (p. 219). These are all examples of behavior modification (Miltenberger, 2007).

Behavior modification **is a treatment or therapy that changes or modifies problems or undesirable behaviors by using principles of learning based on operant conditioning, classical conditioning, and social cognitive learning.**

For over 35 years, psychologist and researcher Ivar Lovaas of the University of California at Los Angeles has used behavior modification or, more colloquially, behavior mod to treat autism.

Autism **is marked by poor development in social relationships, such as not wanting to be touched, not making eye contact, and hiding to avoid people (see drawing); great difficulty developing language and communicating; very few activities and interests; and long periods of time spent repeating the same behaviors or motor patterns, or following rituals that interfere with more normal functioning. Symptoms range from mild to severe and usually appear when a child is about 2 to 3 years old (American Psychiatric Association, 2000).** (We discussed the symptoms and causes of autism more thoroughly in Module 1.)

Parents, doctors, and policy makers all agree that the best method to address the above symptoms, especially deficits in forming relationships and communicating, in autistic children is to enroll them in intensive behavioral treatment (between 20 and 40 hours a week) as early as possible. There is no evidence that any treatment leads to a complete recovery, but without treatment, many autistics will remain socially unresponsive (Carey, 2004; Kabot et al., 2003). We'll discuss the behavior mod treatment developed by Ivar Lovaas, who combined principles of operant conditioning and social cognitive learning (Lovaas & Buch, 1997).

Behavior mod is used to treat autism.

Behavior Modification and Autism

What kind of training?

Lovaas's program at UCLA, which is called the Young Autism Project, treats 2- to 3-year-old autistic children with a 40-hour-per-week program that runs for 2 to 3 years. Here's part of the program.

Program. Lovaas's training program actually consists of hundreds of separate teaching programs, many of them using principles of operant conditioning: Select a specific ***target behavior, shape the behavior,*** and use ***positive reinforcers*** of praise and food that are given immediately after the child emits the desired behavior. For example, here's a program to increase making eye contact.

Target behavior is getting the child to make eye contact following the command "Look at me."

Shaping the behavior involves two steps.

Step 1. Have the child sit in a chair facing you. Give the command "Look at me" every 5–10 seconds. When the child makes a correct response of looking at you, say "Good looking" and simultaneously reward the child with food.

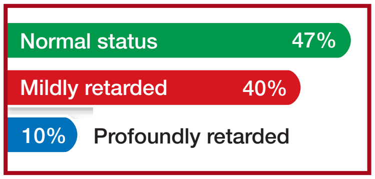
Step 2. Continue until the child repeatedly obeys the command "Look at me." Then gradually increase the duration of the child's eye contact from 1 second to periods of 2 to 3 seconds.

Using this behavior mod program, therapists and parents have had success in teaching autistic children to make eye contact, to stop constant rocking, to respond to verbal requests such as "Wash your hands," to interact with peers, to speak, and to engage in school tasks such as reading and writing (Lovaas, 1993).

47% reach normal status.

Results. Lovaas and his colleagues did a long-term study of 19 children diagnosed as autistic. Behavior modification training went on for at least 40 hours per week for 2 years or more. The graph above shows that, at the end of training, 47% (9/19) of the autistic children reached normal status (Lovaas, 1987). These children acquired sufficient language, social, and self-help behaviors to enter preschool and successfully complete first grade in public school. Many of the children did so well the teachers didn't know they were autistic.

However, even with intensive training, 40% of autistic children remained mildly retarded, and 10% remained profoundly retarded. In comparison, in a control group of autistic children who received only minimal treatment, only 2% achieved normal intellectual and educational functioning, while 45% remained mildly retarded and 53% remained severely retarded (Eikeseth, 2001; Lovaas & Buch, 1997; McEachin et al., 1993). Lovaas and colleagues concluded that without intensive behavior modification treatment, autistic children will continue to show severe behavioral deficits.



Follow-up. A six-year follow-up study of the nine children who had reached normal status found that they had kept their gains and were still functioning normally (Lovaas, 1999). A later follow-up study of the same nine children, then 20 to 30 years old, showed that eight appeared normal—that is, did not score differently from other normal adults on a variety of tests—while one had personality problems but would not be classified as autistic (Lovaas, 1999).

Recent research indicates that Lovaas's behavior mod is best suited to help those with less severe symptoms and it may not lead to improvement in those with more severe symptoms (Carey, 2004).

Health care specialists concluded that autism therapy can be effective provided it begins early (child 2–3 years old) and includes one-on-one training for a minimum of 25 hours a week, 12 months a year for several years (Tarkan, 2002). However, such therapy is so costly ($72,000 a year) that fewer than 10% of autistic children are receiving the recommended level of treatment (Lord, 2002; Wallis, 2006). It can cost over $3 million to take care of a person with autism over his or her lifetime, and the societal costs for caring for people with autism exceeds $35 billion a year (HSPH, 2006).

Biofeedback

How can we reduce tension?

Many people develop a variety of psychosomatic problems, which result from stressful or disturbing thoughts that lead to real aches and pains in the body. For example, psychosomatic problems include back pain, muscle tension, high blood pressure, stomach distress, and headaches. One procedure to reduce psychosomatic problems using behavioral modification is based on operant conditioning and is called biofeedback.

Stress may cause a buildup of muscle tension.

Biofeedback is a training procedure through which a person is made aware of his or her physiological responses, such as muscle activity, heart rate, blood pressure, or temperature. After becoming aware of these physiological responses, a person tries to control them to decrease psychosomatic problems.

For example, headaches may be caused or worsened by muscle tension, of which the sufferer may be totally unaware. The left figure shows that the forehead and neck have wide bands of muscles where tension can lead to pain and discomfort. Through video or audio (bio)feedback, a person can be made aware of muscle tension and learn how to reduce it.

Biofeedback helps in learning to control physiological responses.

As shown in the photo below, small sensors attached to the client's head detect activity in the muscles that stretch across the top front part of the head and along the jaw. The man is trying to relax his forehead muscle by imagining relaxing scenes, thinking relaxing thoughts, or actually tensing and relaxing the muscle itself. The target behavior is a decrease in facial muscle tension. To reach this target behavior, the client practices thinking about or imagining relaxing scenes that result in a decrease in muscle tension. A decrease in muscle tension is signaled by a decrease in an audio signal, which acts as a reinforcer. After a number of these sessions, the client learns to decrease muscle tension with the goal of staying relaxed the next time he gets upset.

Biofeedback is often used in conjunction with other forms of medical treatment or psychotherapy and can help a person reduce blood pressure, decrease headaches, and reduce anxiety (deCharms et al., 2005; Schwartz & Andrasik, 2005). We'll discuss other methods of reducing stress and associated psychosomatic problems in Module 21.

Our last example deals with concerns about using punishment to decrease undesirable behaviors.

Pros and Cons of Punishment

Should it be used?

About 61% of parents believe spanking is an acceptable form of discipline for young children, and 94% of 3- and 4-year-olds have been spanked during the past year (O'Callaghan, 2006). Since spanking may immediately stop undesirable behaviors, it has been and remains a popular form of discipline. But spanking is surrounded with controversy because it is associated with numerous negative side effects and may be a less desirable form of punishment (discipline) than the time-out procedure (Benjet & Kazdin, 2003). We'll discuss the pros and cons of each.

Effects of punishment depend on its usage.

Spanking: Positive Punishment

Since spanking involves the presentation of an aversive stimulus (pain), it is an example of positive punishment. Researchers disagree on the use of spanking. Some argue that all spanking is bad because it is associated with numerous short- and long-term negative side effects, such as the child imitating and modeling aggressive behavior and developing other conduct problems (Gershoff, 2002). Others agree that severe spanking administered by harsh parents is always bad but mild to moderate spanking used as one form of discipline by loving parents does not necessarily have undesirable or negative side effects (Baumrind et al., 2002).

Some of the undesirable effects of positive punishment can be reduced if it is given immediately after the behavior, if it is just severe enough to be effective, if it is delivered consistently, if the child is told the reason for the punishment, and, perhaps most important, if punishment is used in combination with positively reinforcing a desirable behavior (Benjet & Kazdin, 2003). One disadvantage of positive punishment is that it points out only what the child should not do, while positive reinforcers have the advantage of encouraging the child to engage in desirable behaviors.

Time-Out: Negative Punishment

Time-out has fewer undesirable side effects than spanking.

Another form of discipline is time-out, which was discussed earlier (see p. 219). Time-out is an example of negative punishment because it involves the removal of a reinforcing stimulus (desirable reward) so that some undesirable response will not recur. For example, after misbehaving, a child is given a time-out period (stays in a corner without games, books, or toys). Time-out is most effective when used consistently and combined with teaching the child alternative desired behaviors using positive reinforcers (J. Taylor & Miller, 1997).

Compared to spanking, time-out has fewer undesirable side effects; it does not provide a model of aggression and does not elicit severe negative emotional reactions. Thus, when it is necessary to discipline a child, care should be taken in choosing between positive punishment (spanking) and negative punishment (time-out). Although both kinds of punishment stop or suppress undesirable behaviors, spanking has more negative side effects than time-out, and time-out has been shown to be effective in eliminating undesirable behaviors. Both kinds of punishment are best used in combination with positive reinforcers so the child also learns to perform desirable behaviors (Nichols, 2004).

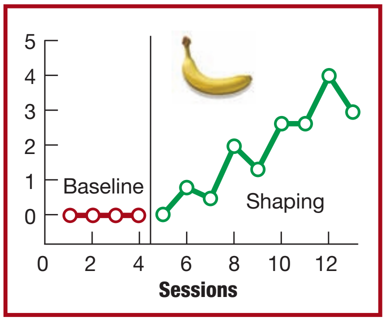
Summary Test

A. Operant Conditioning



1. A kind of learning in which the consequences that follow some behavior increase or decrease the likelihood that the behavior will occur again is called _______________.

2. To explain how random trial-and-error behaviors of cats became goal-directed behaviors, Thorndike formulated the _______________, which says that behaviors are strengthened by positive consequences and weakened by negative consequences.

3. Skinner used the term *operant* (a) _______________ to describe something that can be modified by its consequences. Operant responses provide one way to separate ongoing behaviors into units that can be observed and measured. Skinner believed that Pavlov's conditioning, which involves physiological (b) _______________, was not very useful in understanding other forms of ongoing behaviors.

4. Suppose you wished to operantly condition your dog, Bingo, to sit up. The procedure would be as follows. You would give Bingo a treat, which is called a (a) _______________, after he emits a desired behavior. Because it is unlikely that Bingo will initially sit up, you will use a procedure called (b) _______________, which is a process of reinforcing those behaviors that lead up to or approximate the final desired behavior—sitting up. Immediately after Bingo emitted a desired behavior, you would give him a (c) _______________.

5. Any behavior that increases in frequency because of an accidental pairing of a reinforcer and that behavior is called a _______________ behavior.

6. The essence of operant conditioning can be summed up as follows: Consequences or reinforcers are contingent on _______________.

7. If you compare classical and operant conditioning, you will find the following differences. In classical conditioning, the response is an involuntary (a) _______________ that is elicited by the (b) _______________. In operant conditioning, the response is a voluntary (c) _______________ that is performed or (d) _______________ by the organism. In classical conditioning, the unconditioned stimulus is presented at the beginning of a trial and elicits the (e) _______________. In operant conditioning, the organism emits a behavior that is immediately followed by a (f) _______________.

B. Reinforcers

8. In operant conditioning, the term *consequences* refers to what happens after the occurrence of a behavior. If a consequence increases the likelihood that a behavior will occur again, it is called a (a) _______________. If a consequence decreases the likelihood that a behavior will occur again, it is called a (b) _______________.

9. If a stimulus increases the chances that a response will occur again, that stimulus is called a (a) _______________. If the removal of an aversive stimulus increases the chances that a response will occur again, that aversive stimulus is called a (b) _______________. Both positive and negative reinforcements (c) _______________ the frequency of the response they follow. In contrast, punishment is a consequence that (d) _______________ the likelihood that a behavior will occur again.

10. The stimuli of food, water, and sex, which are innately satisfying and require no learning to become pleasurable, are called (a) _______________. The stimuli of praise, money, and good grades have acquired their reinforcing properties through experience; these stimuli are called (b) _______________.

C. Schedules of Reinforcement

11. A program or rule that determines how and when the occurrence of a response will be followed by a reinforcer is called a _______________.

12. If you received reinforcement every time you performed a good deed, you would be on a (a) _______________ schedule. This schedule is often used at the beginning of operant conditioning because it results in a rapid rate of learning. If your good deeds were not reinforced every time, you would be on a (b) _______________ schedule. This schedule is more effective in maintaining the target behavior in the long run. There are four kinds of partial reinforcement schedules.

D. Other Conditioning Concepts

13. The phenomenon in which an organism emits the same response to similar stimuli is called (a) _______________. If a response is emitted in the presence of a reinforced stimulus but not in the presence of unreinforced stimuli, the organism is exhibiting (b) _______________. If an organism's response is no longer reinforced, it will stop emitting this behavior, which is an example of (c) _______________. However, even without reinforcement, an organism may perform the behavior, which is an example of (d) _______________.

Figure/Text Credit: (#1 graph) Adapted from "Treating Chronic Food Refusal in Young Children: Home-Based Parent Training," by M. A. Werle, T. B. Murphy & K. S. Budd, 1993, *Journal of Applied Behavior Analysis, 26*, 421–433.

E. Cognitive Learning

14. The kind of learning that involves mental processes such as attention and memory, that may be learned through observation and imitation, and that may not involve any external rewards or require the person to perform any observable behaviors is called (a) ______________. According to Tolman, rats developed a mental representation of the layout of their environment, which he called a (b) ______________.

15. If an observer learns a behavior through observation but does not immediately perform the behavior, this is an example of the ______________ distinction.

16. During his studies of problem solving in chimpanzees, Köhler used the term ______________ to describe a mental process marked by the sudden occurrence of a solution.

17. Köhler's study of insightful problem solving, Bandura's theory of observational learning, and Tolman's idea of cognitive maps represent three kinds of ______________ learning.

F. Biological Factors

18. Innate tendencies or predispositions that may either facilitate or inhibit learning are referred to as ______________.

19. The innate tendency of newborn birds to follow the first moving object that they encounter soon after birth is called (a) ______________. This kind of learning occurs best during a critical or sensitive period and is essentially (b) ______________. One function of imprinting is to form social attachments between members of a species.

20. The innate tendency of animals to recognize, attend to, and store certain cues over others and associate some combinations of conditioned and unconditioned stimuli is referred to as ______________. An example of this tendency is observed in Clark's nutcrackers, which are preprogrammed to bury and remember thousands of hidden stores of food.

G. Research Focus: Viewing Aggression

21. Verbal bullying, ostracizing peers, and spreading rumors are all examples of ______________.

22. Female university students who viewed either physical or relational aggression were ______________ to subsequently engage in physical and relational aggression than women who did not view any aggression.

H. Cultural Diversity: East Meets West

23. Suzuki's method and Bandura's theory both emphasize observation, modeling, and imitation. Specifically, both Suzuki and Bandura focus on four concepts: paying (a) ______________ to the model, placing the information in (b) ______________, using the information to (c) ______________ the model's actions, and having (d) ______________ to perform the behavior.

I. Application: Behavior Modification

24. Using principles of operant conditioning to change human behavior is referred to as (a) ______________. Using these same principles to help individuals learn to control (increase or decrease) some physiological response, such as muscle activity or temperature, is called (b) ______________.

25. If an aversive stimulus is presented immediately after a particular response, the response will be suppressed; this procedure is called (a) ______________. If a reinforcing stimulus is removed immediately after a particular response, the response will be suppressed; this procedure is called (b) ______________. A poorly chosen form of punishment, such as spanking, may have undesirable side effects, such as developing (c) ______________ problems and serving as a model for future (d) ______________ behaviors.

Answers: *1. operant conditioning; 2. law of effect; 3. (a) response, (b) reflexes; 4. (a) reinforcer, (b) shaping, (c) reinforcer; 5. superstitious; 6. behavior; 7. (a) reflex, (b) unconditioned stimulus, (c) behavior, (d) emitted, (e) unconditioned response, (f) reinforcer; 8. (a) reinforcer, (b) punishment; 9. (a) positive reinforcer, (b) negative reinforcer, (c) increase, (d) decreases; 10. (a) primary reinforcers, (b) secondary reinforcers; 11. schedule of reinforcement; 12. (a) continuous reinforcement, (b) partial reinforcement; 13. (a) generalization, (b) discrimination, (c) extinction, (d) spontaneous recovery; 14. (a) social cognitive learning, (b) cognitive map; 15. learning–performance; 16. insight; 17. cognitive; 18. biological factors; 19. (a) imprinting, (b) irreversible; 20. preparedness, or prepared learning; 21. relational aggression; 22. more likely; 23. (a) attention, (b) memory, (c) imitate, (d) motivation; 24. (a) behavior modification, (b) biofeedback; 25. (a) positive punishment, (b) negative punishment, (c) conduct, (d) aggressive*

Critical Thinking

How Do You Train a Killer Whale?

If you have ever been to a marine park, then you most certainly have been entertained by watching the marvelous marine animal performances. In just one show an enormous killer whale jumps through a ring suspended in air, waves to audience members with its fins, swims backward while standing up on its tail, and gently kisses a brave volunteer. Whales are taught to perform these impressive behaviors with the use of operant and classical conditioning techniques.

Operant conditioning is used to train whales because when the consequences of performing a specific behavior are reinforcing, the whale will likely repeat the behavior. Positive reinforcers for whales may include food, toys, back scratches, being sprayed with a hose, or another favorite activity. Giving the whale positive reinforcers immediately after it performs a specific behavior makes it likely that the behavior will increase in frequency, duration, and intensity in a similar situation.

QUESTIONS

1 How do we know what a reinforcer is for a whale?

2 Why isn't punishment used to train a whale to perform behaviors?

The use of classical conditioning is also necessary to teach a whale to perform complex behaviors. Because it is not always possible to reinforce the whale immediately after it performs a specific behavior, trainers must use a signal (whistle) to provide the whale with immediate feedback that it has correctly performed the desired behavior. A whale learns the meaning of the whistle by the trainer whistling before giving the whale food. Over the course of several trials, the whale comes to associate the whistle with receiving food and the whale performs the behavior to get the reinforcement.

3 Why is it important to reinforce the whale *immediately* after it performs a desired behavior?

4 In this training example, what is the neutral stimulus? Unconditioned stimulus? Conditioned stimulus?

Once the association between the whistle and the reinforcer is established, whales can be taught to perform complex behaviors. First, the whale is taught to follow a target, such as a long stick with a ball at the end. The target guides the whale in a direction, and when the target touches the whale, the trainer blows the whistle and reinforces the whale. After this is done several times, the target is moved farther away and the trainer waits for the whale to touch it before providing reinforcement. The whale learns that making contact with the target results in being reinforced. Now, when the whale performs a behavior that is close to the desired behavior, the trainer whistles and the whale approaches the trainer to receive a positive reinforce.

5 What should a trainer do if a whale performs a behavior incorrectly?

Teaching whales to perform behaviors may appear like a relatively easy task while watching the trainers and whales interact on stage, but the truth is training whales to perform is very challenging work. Trainers need to be committed, patient, and friendly to earn the whale's trust, and even then it can take months or even years to teach a whale a complex set of behaviors. (Adapted from Animal training at SeaWorld, 2002; Aqua facts: Training marine mammals, 2006)

6 Can whales learn to do tricks by just watching other whales perform?

Study Guide and WebTutor

Work through the corresponding module in your Study Guide for tips on how to study effectively and for help learning the material covered in the book. WebTutor (an online Study Tool accessed through your eResources account) provides an interactive version of the Study Guide.

Suggested Answers to Critical Thinking

1. Whales cannot tell us what they like and don't like, and not all whales have the same preferences. Thus, trainers examine the frequency of the behavior after providing a reinforcer. If the frequency increases, the consequence was a reinforcer. If the frequency decreases, the trainer will use other consequences until one increases the frequency of the desired behavior.
2. Punishment only points out what the whale should not do, while reinforcers point out what the whale should do. Also, punishment can increase aggressive behaviors in some whales.
3. When a reinforcer immediately follows a desired behavior, the whale associates the reinforcer with the desired behavior and not some other behavior that just happens to occur. If the reinforcer is delayed even for a few seconds, the whale may be reinforced for an undesired or superstitious behavior.
4. The whale learns to associate the sound of a whistle with receiving food. The neutral stimulus is the whistle sound, and the unconditioned stimulus is food. After repeated pairing of the whistle sound with receiving food, the whale learns to associate the whistle sound with food, and the conditioned stimulus is the sound of the whistle.
5. If a whale performs a behavior incorrectly, the trainer must be sure to avoid giving any reinforcement. In such a case, the trainer should remain motionless and silent for a few seconds, making sure there is no possibility the whale will think its behavior earned approval.
6. Yes. Whales can learn to imitate some behaviors just by watching other whales, a process known as observational learning. Also, whales that are trained with experienced whales may learn to perform behaviors at a faster rate.

Incredible Memory

What's a super memory?

Daniel Tammet stood before the packed house at the Museum of History and Science in Oxford. He recited, from memory, the first 22,514 digits of pi, which is often rounded off to two decimal places, or 3.14. He completed this amazing feat in 5 hours and 9 minutes and made no mistakes.

Scientists describe Daniel's memory as nothing less than extraordinary. In fact, Daniel is one of only a half-dozen people worldwide with such gargantuan memory powers. He currently holds the European record for reciting digits of pi, but people elsewhere have broken his record. For instance, Akira Haraguchi correctly repeated the first 100,000 digits of pi (Associated Press, 2006e). Later in the module, we'll learn about the memory technique Daniel uses to remember so many digits.

Daniel recited 22,514 digits of pi in exact order.

Despite Daniel's unbelievable ability to memorize numbers, he faces a number of life challenges. He can't drive, doesn't tolerate shopping well, and avoids the beach because of his compulsion to count every grain of sand. As a child, he struggled to learn spelling and even simple mathematics because the techniques being taught didn't match his unique way of thinking (Schorn, 2007; Tammet, 2007, 2009).

Few people have such incredible memories and, unfortunately, many others have memory problems. Next, we'll learn about a man who has very serious problems with his memory.

Memory Problem

How important is memory?

Imagine what life would be like without memory. For Clive Wearing, that's a grim reality.

At age 40, Clive Wearing, a musician, got a disease that caused brain damage resulting in severe memory impairment. For instance, despite having written a book on a classical composer, he cannot remember any information about the composer. Clive can no longer enjoy reading books or watching movies because he is unable to follow the plot. Each time Clive sees his wife, he excitedly greets her as if he has not seen her in years, even though she may have left the room for only a moment. He cannot recall his wedding day or the names of his children.

The disease did spare Clive some of his memory. Even though Clive cannot remember being educated in music, he remembers how to play the piano, conduct an orchestra, and sing.

Clive has very serious memory problems caused by a disease that damaged his brain.

When Clive tells others about his life, he says it is "precisely like death. I'd like to be alive" (J. Goodwin, 2006, p. 125). He does not feel alive because for the past 25 years, his memory problems have robbed him of a past and future. Clive lives in a never-ending present. His wife describes his memory by explaining, "It's as if Clive's every conscious moment is like waking up for the first time" (J. Goodwin, 2006, p. 126). Clive's problems with memory really affect his quality of life and demonstrate the importance of memory (Baddeley, 2009d; Sacks, 2008).

Definitions

What are the three processes?

Daniel's amazing ability to recall thousands of digits and Clive's very serious memory problems involve three different memory processes.

Memory **is the ability to retain information over time through three processes: encoding (forming), storing, and retrieving. Memories are not copies but representations of the world that vary in accuracy and are subject to error and bias.**

We'll briefly define each of the three memory processes because they are the keys to understanding the interesting and complex process of how we remember and thus create the world we live in.

1 Encoding

Daniel developed a method or code to form memories for digits, a process called encoding.

Encoding **refers to making mental representations of information so that it can be placed into our memories.**

For example, Daniel encodes numbers by visualizing each number as having a different shape, color, and texture. Such a vivid mental representation helps to store numbers in his memory.

2 Storing

Daniel used associations to encode information because associations are also useful for storing information.

Storing **is the process of placing encoded information into relatively permanent mental storage for later recall.**

New information that is stored by making associations with old or familiar information is much easier to remember, or retrieve.

3 Retrieving

Daniel was able to recall, or retrieve, 22,514 digits in order.

Retrieving **is the process of getting or recalling information that has been placed into short-term or long-term storage.**

Only a half-dozen people in the entire world can match Daniel's feat of encoding, storing, and retrieving thousands of digits in order. Most people vary in their accuracy to recall information. For example, adolescents were questioned about dating, their families, and general activities. When asked the same questions 30 years later, they made many errors in recalling the same information (Offer et al., 2000).

We'll discuss three kinds of memory, how memories are encoded, why emotional memories are long-lasting, the issue of repressed memories, and some unusual memory abilities. We'll start with an overview of the three kinds of memory.

Photo Credit: © Colin McPherson/Corbis

A. Three Types of Memory

What are the three types?

We often talk about memory as though it were a single process. In fact, a popular model of memory divides it into three different processes: sensory, short-term, and long-term memory (Baddeley, 2006). To illustrate each of these processes, we'll examine what happens as you walk through a big-city mall.

Sensory Memory

As you walk through a busy mall, you are bombarded by hundreds of sights, smells, and sounds, including the music of a lone guitarist playing for spare change. Many of these stimuli reach your sensory memory.

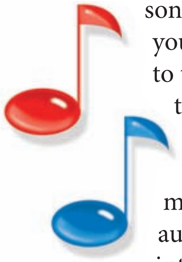
Sensory memory **refers to an initial process that receives and holds environmental information in its raw form for a brief period of time, from an instant to several seconds.**

For example, after reaching your ears, the guitarist's sounds are held in sensory memory for a second or two. What you do next will determine what happens to the guitarist's sounds that are in your sensory memory.

If you pay no more attention to these sounds in sensory memory, they automatically ***disappear*** without a trace.

However, if you pay attention to the guitarist's music, the auditory information in sensory memory is transferred into another memory process called short-term memory (Baddeley, 2009c).

Short-Term Memory



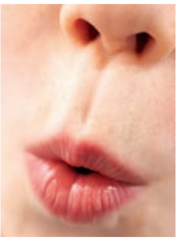
Because a few notes of the guitarist's song sounded interesting, you shifted your attention to that particular information in sensory memory. Paying attention to information in sensory memory causes it to be automatically transferred into short-term memory.

Short-term memory, **also called** ***working memory,*** **refers to another process that can hold only a limited amount of information—an average of seven items—for only a short period of time—2 to 30 seconds.**

Once a limited amount of information is transferred into short-term, or working, memory, it will remain there for up to 30 seconds. If during this time you become more involved in the information, such as humming to the music, the information will remain in short-term memory for a longer period of time.

However, the music will ***disappear*** after a short time unless it is transferred into permanent storage, called long-term memory (Squire & Kandel, 2009).

Long-Term Memory



If you become mentally engaged in whistling along or wondering why the guitarist's music sounds familiar, there is a good chance that this mental activity will transfer the music from short-term into long-term memory.

Long-term memory **refers to the process of storing almost unlimited amounts of information over long periods of time.**

For example, you have stored hundreds of songs, terms, faces, and conversations in your long-term memory—information that is potentially available for retrieval. However, from personal experience, you know that you cannot always retrieve things you learned and know you know. In Module 12, we'll discuss reasons for forgetting information stored in long-term memory.

Now that you know what the three memory processes are, we'll explain how they work together.

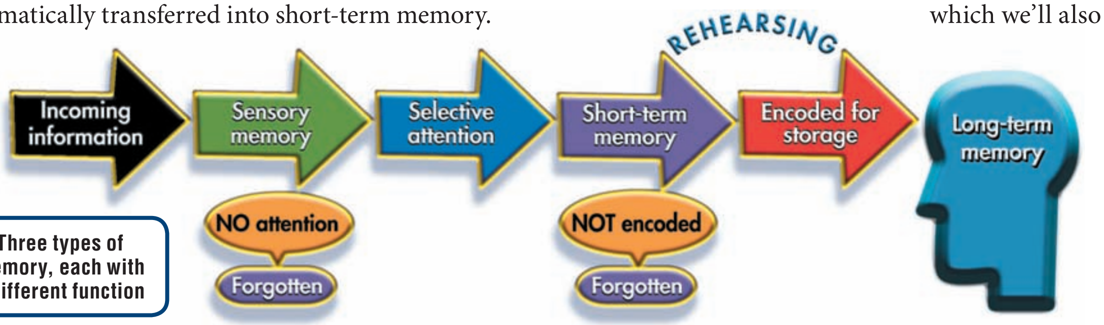
Memory Processes

1 Sensory memory. We'll explain how the three types of memory described above work and how paying or not paying attention to something determines what is remembered and what is forgotten.

Imagine listening to a lecture. All the information that enters your sensory memory remains for seconds or less. If you ***do not pay attention*** to information in sensory memory, it is forgotten. If you ***do pay attention*** to particular information, such as the instructor's words, this information is automatically transferred into short-term memory.

2 Short-term memory. If you ***do not pay attention*** to information in short-term memory, it is not encoded and is forgotten. If you ***do pay attention*** by rehearsing the information, such as taking notes, the information will be encoded for storage in long-term memory. That's why it helps to take lecture notes.

3 Long-term memory. Information that is encoded for storage in long-term memory will remain there on a ***relatively permanent basis.*** Whether or not you can recall the instructor's words from long-term memory depends partly on how they are encoded, which we'll discuss later. This means that poor class notes may result in poor encoding and poor recall on exams. The secret to great encoding and great recall is to associate new information with old, which we'll also discuss later.



Three types of memory, each with a different function

Now that we have given you an overview of memory, we'll discuss each of the three types of memory in more detail.

B. Sensory Memory: Recording

Do you have a mental video recorder?

Your brain has a mental video-audio recorder that automatically receives and holds incoming sensory information for only seconds or less. This brief period provides just enough time for you to decide whether some particular incoming sensory information is important or interesting and therefore demands your further attention. We'll examine two different kinds of sensory memory: visual sensory memory, called iconic memory, and auditory sensory memory, called echoic memory.

Iconic Memory

What happens when you blink?

About 14,000 times a waking day, your eyes blink and you are totally blind during the blinks (Casselman, 2006; Garbarini, 2005). However, the world doesn't disappear during the eye blinks because of a special sensory memory, which is called iconic *(eye-CON-ick)* memory.

Iconic memory **is a form of sensory memory that automatically holds visual information for about a quarter of a second or more; as soon as you shift your attention, the information disappears. (The word *icon* means "image.")**

You don't "go blind" when both eyes close completely during a blink (about one-third of a second) because the visual scene is briefly held in iconic memory (O'Regan et al., 2000). When your eyes reopen, you don't realize that your eyes were completely closed during the blink because "you kept seeing" the visual information that was briefly stored in iconic memory. Without iconic memory, your world would disappear into darkness during each eye blink.

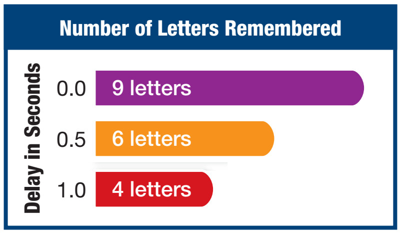
Iconic memory briefly holds visual information during eye blink.

Identifying Iconic Memory

Here's the first study that showed the existence and length of iconic memory.

Procedure. Individual subjects sat in front of a screen upon which 12 letters (three rows of four letters) appeared for a very brief period of time (50 milliseconds, or 50/1,000 of a second). After each presentation, subjects were asked to recall a particular row of letters.

Results and conclusion. As shown in the graph below, if subjects responded immediately (0.0-second delay) after seeing the letters, they remembered an average of nine letters. However, a delay of merely 0.5 second reduced memory to an average of six letters, and a delay of 1.0 second reduced memory to an average of only four letters (Sperling, 1960). Notice that an increased delay in responding resulted in subjects' remembering fewer letters, which indicated the brief duration of iconic memory—seconds or less.



This study demonstrated a sensory memory for visual information, which was called iconic memory. The sensory memory for auditory information is called echoic memory.

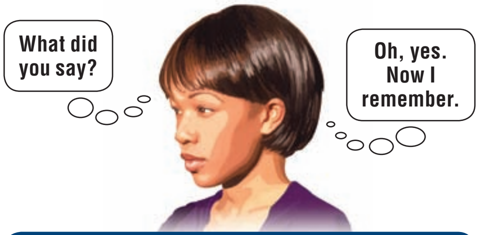
Echoic Memory

What did you hear?

Without realizing, you have already experienced auditory sensory memory, which is called echoic *(eh-KO-ick)* memory.

Echoic memory **is a form of sensory memory that holds auditory information for 1 or 2 seconds.**

For instance, suppose you are absorbed in reading a novel and a friend asks you a question. You stop reading and ask, "What did you say?" As soon as those words are out of your mouth, you realize that you can recall, or play back, your friend's exact words. You can play back these words because they are still in echoic memory, which may last as long as 2 seconds. In addition to letting you play back things you thought you did not hear, echoic memory lets you hold speech sounds long enough to know that sequences of certain sounds form words (Norman, 1982). Researchers discovered that the length of echoic memory increases as children grow into adults (Gomes et al., 1999).



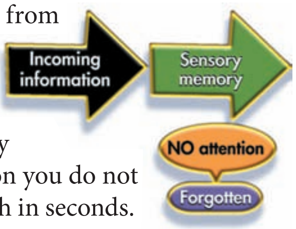
What did you say?
Oh, yes. Now I remember.

Echoic memory briefly holds sounds.

Here's a quick review of the functions of iconic and echoic memories.

Functions of Sensory Memory

1 Prevents being overwhelmed. Sensory memory keeps you from being overwhelmed by too many incoming stimuli because any sensory information you do not attend to will vanish in seconds.



2 Gives decision time. Sensory memory gives you a few seconds to decide whether some incoming sensory information is interesting or important. Information you pay attention to will automatically be transferred to short-term memory.

3 Provides stability, playback, and recognition. Iconic memory makes things in your visual world appear smooth and continuous, such as "seeing" even during blinking. Echoic memory lets you play back auditory information, such as holding separate sounds so that you can recognize them as words.

If you attend to information in sensory memory, it goes into short-term memory, the next topic.

Photo Credit: (eyes) © PhotoDisc, Inc.

C. Short-Term Memory: Working

Definition

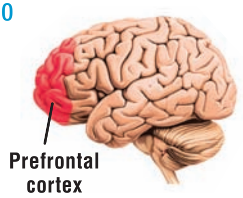
What was that phone number?

You have just looked up a phone number, which you keep repeating as you dial to order a pizza. After giving your order and hanging up, you can't remember the number. This example shows two characteristics of short-term memory.

Short-term memory, more recently called ***working memory,*** refers to a process that can hold a limited amount of information—an average of seven items—for a limited period of time—2 to 30 seconds. However, the relatively short duration can be lengthened by repeating or rehearsing the information.

For good reason, telephone numbers and postal ZIP codes are seven numbers or fewer because that is about the limit of short-term memory.

Clive Wearing's prefrontal cortex is damaged.



Recent studies found that when you are paying attention and using working memory to perform a variety of cognitive tasks, such as looking for a face in a crowd, maximum neural activity occurs in various areas of the prefrontal cortex (Pessoa & Ungerleider, 2004). The prefrontal cortex of Clive Wearing, discussed in the beginning of this module, is damaged and he can remember certain types of information for only 7 seconds. Thus, his working memory is impaired and he cannot remember a phone number for longer than a few seconds.

Although extremely useful, working or short-term memory has the two characteristics of limited duration and limited capacity.

Two Features

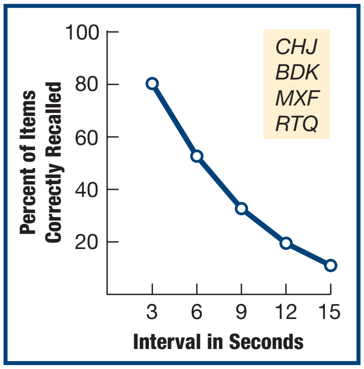
Limited Duration

The new telephone number that you looked up will remain in short-term memory for a brief time, usually from 2 to 30 seconds, and then disappear. However, you can keep information longer in short-term memory by using maintenance rehearsal.

Short-term memory holds items for 2–30 seconds.
H
C

Maintenance rehearsal refers to the practice of intentionally repeating or rehearsing information so that it remains longer in short-term memory.

Researchers studied how long information is remembered without practice or rehearsal by asking participants to remember a series of consonants composed of three meaningless letters, such as CHJ. Participants were prevented from rehearsing, or repeating, these consonants by having them count backward immediately after seeing the groups of three letters. As the graph below shows, 80% of the participants recalled the groups of three letters after 3 seconds. However, only 10% of the participants recalled the groups of three letters after 15 seconds (L. R. Peterson & Peterson, 1950). Since almost all the participants had forgotten the groups of three letters after 15 seconds (if they were prevented from rehearsing), this study clearly showed that information disappears from your short-term memory within seconds unless you continually repeat or rehearse the information.



You can increase the time that information remains in short-term memory by using maintenance rehearsal. However, during maintenance rehearsal, which involves repeating the same thing over and over, new information cannot enter short-term memory.

Not only does short-term or working memory have a limited duration, it also has a limited capacity.

Limited Capacity

In previous modules, we pointed out several studies that are considered classic because they challenged old concepts or identified significant new information. One such classic study is that of George Miller (1956), who was the first to discover that short-term memory can hold only about seven items or bits, plus or minus two. Although this seems like too small a number, researchers have repeatedly confirmed Miller's original finding (Baddeley, 2004). Thus, one reason telephone numbers worldwide are generally limited to seven digits is that seven matches the capacity of short-term memory.

Short-term memory holds about 7 items.

It is easy to confirm Miller's finding with a ***memory span test,*** which measures the total number of digits that we can repeat back in the correct order after a single hearing. For example, students make few errors when they are asked to repeat seven or eight digits, make some errors with a list of eight or nine digits, and make many errors when they repeat a list that is longer than nine digits. One of the main reasons information disappears from short-term memory is interference (M. C. Anderson, 2009a).

Interference results when new information enters short-term memory and overwrites or pushes out information that is already there.

For example, if you are trying to remember a phone number and someone asks you a question, the question interferes with or wipes away the phone number. One way to prevent interference is through rehearsal. However, once we stop rehearsing, the information in short-term memory may disappear.

Although short-term memory has limited capacity and duration, it is possible to increase both. For example, we use a classroom demonstration in which we guarantee that any student can learn to memorize a list of 23 digits, in exact order, in just 25 seconds. This impressive memory demonstration, which always works, is accomplished by knowing how to use something called chunking.

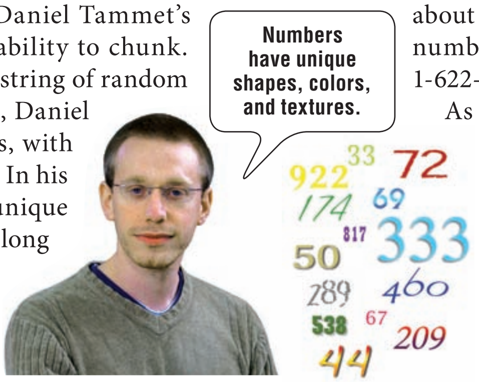
Photo Credit: (prefrontal cortex) From "A Head for Figures," by Brian Butterworth, *Science, 284,* p. 928. By permission of B. Butterworth.

Chunking

How does Daniel remember thousands of numbers?

Although short-term memory briefly holds an average of about seven items, it is possible to increase the length of each item by using a process called chunking (Baddeley, 2009c).

Chunking is combining separate items of information into a larger unit, or chunk, and then remembering chunks of information rather than individual items.



Numbers have unique shapes, colors, and textures.

538
67
209
44

One of the interesting things about Daniel Tammet's prodigious memory for numbers is his ability to chunk. Whereas most of us would see an endless string of random numbers when looking at the digits in pi, Daniel is able to chunk the numbers into groups, with each represented by a unique visual image. In his mind, every number up to 10,000 has a unique shape, color, and texture. When he sees a long sequence of numbers, as in pi, he effortlessly sees a "landscape of colorful shapes." Daniel describes some numbers as being beautiful (such as 333) and others as quite ugly (such as 289). He has a condition called synesthesia, which we discussed in Module 6 (see p. 144). Synesthesia is when people's senses become intertwined. For example, they may hear colors, see music, or taste shapes. Synesthesia has been shown to activate more areas of people's brain, which in turn may improve their memory (Foer, 2006; Schorn, 2007; Tammet, 2007, 2009).

The ability to use chunking is not limited to people with super memories. We all use chunking at times without thinking about it. For example, to remember the 11-digit phone number 16228759211, we break it into four chunks: 1-622-875-9211.

As first suggested by George Miller (1956), chunking is a powerful memory tool that greatly increases the amount of information that you can hold in short-term memory. Daniel's ability to chunk numbers helped him develop an incredible memory, and the use of chunking can improve your memory, too.

Next, we'll review three important functions of short-term memory.

Functions of Short-Term Memory

Why is it also called working memory?

Short-term memory is like having a mental computer screen that stores a limited amount of information that is automatically erased after a brief period of time and replaced by new information, and so the cycle continues. ***Short-term memory*** is also called ***working memory*** to indicate that it's an active process. Using brain scans, researchers found that short-term memory involves the front part of the brain, especially the prefrontal area (Pessoa & Ungerleider, 2004).

There are three important points to remember about short-term memory: 1st—paying attention transfers information into short-term memory; 2nd—after a short time, information disappears unless it is rehearsed; and 3rd—some information is eventually transferred from short-term memory into permanent storage.

1 Attending

Imagine driving along with your radio on while a friend in the passenger seat is talking about the weekend. A tremendous amount of information is entering your sensory memory, but you avoid stimulus overload because incoming information automatically vanishes in seconds unless you pay attention to it.

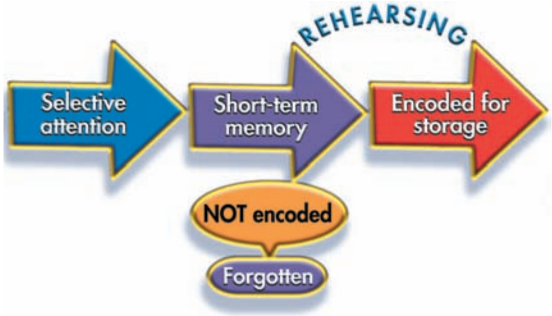
The moment you pay attention to information in sensory memory, that information enters short-term memory for further processing. For example, while your friend is talking, you don't pay attention to the radio until your favorite song comes on and enters sensory memory. As you pay attention, you hear the radio, even though it has been playing the whole time. One function of short-term memory is that it allows us ***to selectively attend to information that is relevant and disregard everything else.***

Once information enters short-term, or working, memory, several things may happen.

2 Rehearsing

Once information enters short-term memory, it usually remains for only seconds unless you rehearse it. For example, the announcer on the car radio gives a phone number to call for free movie tickets. But unless you rehearse or repeat the number over and over, it will probably disappear from your short-term memory because of interference from newly arriving information. Another function of short-term memory is that it allows you ***to hold information for a short period of time until you decide what to do with it.***

If you rehearse the information in short-term memory, you increase the chances of storing it.



3 Storing

Rehearsing information not only holds that information in short-term memory but also helps ***to store or encode information in long-term memory.*** Later, we'll discuss two different kinds of rehearsing (see p. 249) and explain why one kind of rehearsing is better than the other for storing or encoding information in long-term memory.

Next, we'll describe the steps in the memory process and why some things are stored in long-term memory.

Photo Credit: © Colin McPherson/Corbis

D. Long-Term Memory: Storing

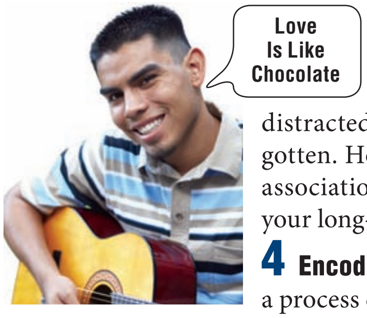
Putting Information into Long-Term Memory

Is it a thing or a process?

Don't think of sensory memory, short-term memory, and long-term memory as *things* or *places* but rather as ongoing and interacting *processes*. To show how these different memory processes interact, we'll describe what happens as you hear a new song on the car radio or iPod and try to remember the song's title.

1 Sensory memory. As you drive down the highway, you're half listening to the car radio. Among the incoming information, which is held for seconds or less in sensory memory, are the words, "Remember this song, 'Love Is Like Chocolate,' and win two movie tickets."

2 Attention. If you do NOT pay attention to information about winning tickets, it will disappear from sensory memory. If the chance to win tickets gets your attention, information about the song title, "Love Is Like Chocolate," is automatically transferred into short-term memory.



3 Short-term memory. Once the song title is in short-term memory, you have a short time (2–30 seconds) for further processing. If you lose interest in the title or are distracted by traffic, the title will most likely disappear and be forgotten. However, if you rehearse the title or, better yet, form a new association, the title will likely be transferred into and encoded in your long-term memory.

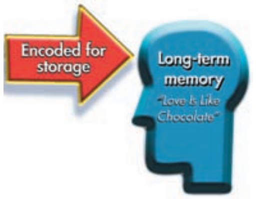
4 Encoding. You place information in long-term memory through a process called encoding.

Encoding **is the process of transferring information from short-term to long-term memory by paying attention to it, repeating or rehearsing it, or forming new associations.**

For example, if you simply repeat the title or don't make any new associations, the title may not be encoded at all or may be poorly encoded and thus difficult to recall from long-term memory. However, if you find the title, "Love Is Like Chocolate," to be catchy or unusual, or you form a new association, such as thinking of a heart-shaped chocolate, you will be successful in encoding this title into long-term memory.

We'll discuss ways to improve encoding information and thus improve recalling information later in this module.

5 Long-term memory. Once the song title is encoded in long-term memory, it has the potential to remain there for your lifetime.



Long-term memory **refers to the process of storing almost unlimited amounts of information over long periods of time with the potential of retrieving, or remembering, such information in the future.**

For example, later you may try to recall the song title from long-term memory by placing it back into short-term memory. How easily and accurately you can recall or retrieve information depends on many factors (M. C. Anderson, 2009c).

6 Retrieving. When people talk about remembering something, they usually mean retrieving or recalling information from long-term memory.

Love Is Like ________?

Retrieving **is the process of selecting information from long-term memory and transferring it back into short-term memory.**

There are several reasons you can't remember or retrieve the song's title. You may not have effectively encoded the title into long-term memory because you got distracted or neglected to form a new association (chocolate heart). The key to successfully retrieving information from long-term memory is to effectively encode information, usually by making associations between new and old information, which we'll soon discuss.

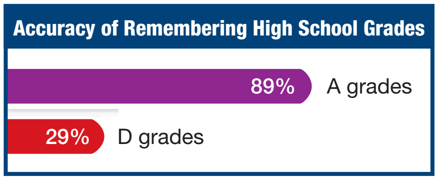
Features of Long-Term Memory

How big and how accurate?

Capacity and permanency. Long-term memory has an almost unlimited capacity to store information. Anything stored has the potential to last a lifetime, provided drugs or disease do not damage the brain's memory circuits (Bahrick, 2000).

Chances of retrieval. Although all information in long-term memory has the potential to be retrieved, how much you can actually retrieve depends on a number of factors, including how it was encoded and the amount of interference from related information. The next question is: How accurate are your long-term memories?

Accuracy of long-term memory. Researchers found that the content and accuracy of long-term memories may undergo change and distortion across time and not always be as accurate as people think. For example, college freshmen were asked to recall grades from all four years of high school. As the graph below shows, students accurately recalled 89% of grades of A but only 29% of grades of D. Thus, students were much more accurate recalling positive events, grades of A, than they were recalling negative events, grades of D (Bahrick et al., 1996).



Accuracy of Remembering High School Grades

This and other studies show we don't recall all events with the same accuracy, sometimes inflating positive events and eliminating negative ones, and this tendency becomes stronger as we age (M. C. Anderson, 2009b; Mather & Carstensen, 2005). The reasons we may change, distort, or forget information will be discussed in Module 12.

Next, we'll explain how psychologists demonstrated the existence of two separate memory processes: a short-term and a long-term memory process.

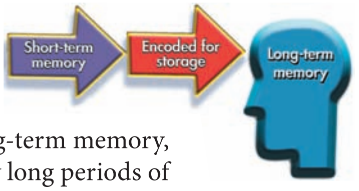
Separate Memory Systems

What is the evidence?

Most researchers agree that there are two memory systems (Neath & Surprenant, 2003). One system involves short-term memory, which stores limited information for a brief period of time and then the information disappears. For example, a stranger tells you his or her name, but a few minutes later you have totally forgotten the name because it disappeared from short-term memory. A second system involves long-term memory, which stores large amounts of information for very long periods of time. For example, you can recall in great detail many childhood memories that years ago were stored in long-term memory. Other evidence for two memory systems comes from findings that brain damage can wipe out long-term memory while completely sparing short-term memory. Still other evidence for two memory systems comes from research on how you remember items in a relatively long list. We'll give you a chance to memorize a list of items, which will show that you have two separate memory systems—short- and long-term memory.



Primacy Versus Recency

Can you remember this list?

Please read the following list only once and try to remember the animals' names:

bear, giraffe, wolf, fly, deer,
elk, gorilla, elephant, frog, snail,
turtle, shark, ant, owl

Immediately after reading this list, write down (in any order) as many of the animals' names as you can remember.

If you examine the list of names that you wrote down, you'll discover a definite pattern to the order of the names that you remembered. For example, here's the order in which names in the above list would most likely be remembered.

First items: Primacy effect. In studies using similar lists, subjects more easily recalled the ***first*** four or five items (bear, giraffe, wolf, fly) because subjects had more time to rehearse the first words presented. As a result of rehearsing, these first names were transferred to and stored in long-term memory, from which they were recalled. This phenomenon is called the primacy effect.

The ***primacy effect*** refers to better recall, or improvement in retention, of information presented at the beginning of a task.

Middle items. Subjects did not recall many items from the ***middle*** of the list (gorilla, elephant, frog) because they did not have much time to rehearse them. When they tried to remember items from the middle of the list, their attention and time were split between trying to remember the previous terms and trying to rehearse new ones. Less rehearsal meant that fewer middle names were stored in long-term memory; more interference meant that fewer names remained in short-term memory.

Last items: Recency effect. Subjects more easily recalled the ***last*** four or five items (turtle, shark, ant, owl) because they were still available in short-term memory and could be read off a mental list. This phenomenon is called the recency effect.

The ***recency effect*** refers to better recall, or improvement in retention, of information presented at the end of a task.

Together, these two effects are called the primacy-recency effect.

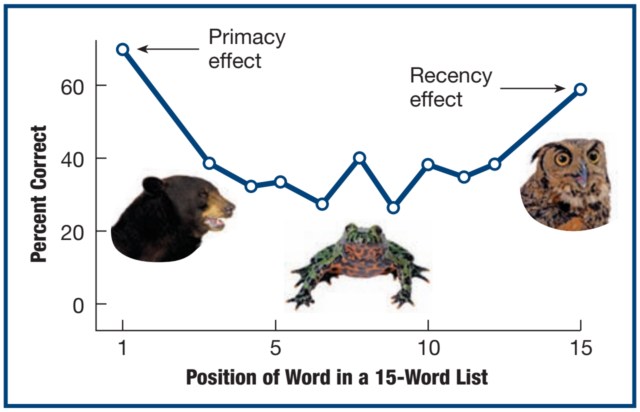
The ***primacy-recency effect*** refers to better recall of information presented at the beginning and end of a task.

As we'll explain next, the primacy-recency effect is evidence that short- and long-term memory are two separate processes.

Short-Term Versus Long-Term Memory

Why didn't you remember "elephant"?

One reason you probably didn't remember the name "elephant" is that it came from the middle of the list. The middle section of a list is usually least remembered because that information may no longer be retained in short-term memory and may not have been encoded in long-term memory. Evidence for the primacy-recency effect is shown in the graph below (Glanzer & Cunitz, 1966).



For example, subjects showed better recall (70%) for the first items presented, which is the primacy effect. The primacy effect occurs because subjects have more time to rehearse the first items, which increases the chances of transferring these items into long-term memory. Remember that rehearsal has two functions: keeping information longer in short-term memory and promoting encoding—the transfer of information into long-term memory.

In addition, subjects showed better recall (60%) for the last items presented, which is the recency effect. Sometimes subjects say that they can still "hear these words" and usually report these items first. The recency effect occurs because the last items are still in short-term memory, from which they are recalled (Glanzer & Cunitz, 1966).

The occurrence of the primacy-recency effect suggested the existence of two separate kinds of memory processes, which we now call short-term and long-term memory (R. C. Atkinson & Shiffrin, 1968; Baddeley, 2009c).

Next, you'll discover that instead of one, there are several different kinds of long-term memory.

D. Long-Term Memory: Storing

Declarative Versus Procedural or Nondeclarative

Why does Clive play the piano but forget names?

After brain damage, Clive Wearing (picture below) remembered how to play the piano but forgot the names of his children and had no memory of his wedding. Clive retained some memory abilities while losing others because different types of memory are stored differently in the brain. For instance, the ability to play the piano uses one type of long-term memory, and remembering names and personal experiences uses a second type of long-term memory. The discovery that there are two kinds of long-term memory is a relatively new finding, and like many discoveries in science, it was found quite by accident.

Researchers were testing a patient, well known in memory circles as H. M., who suffered severe memory loss because of an earlier brain operation to reduce his seizures. H. M.'s task seemed simple: draw a star by guiding your hand while looking into a mirror. However, this mirror-drawing test is relatively difficult because looking into a mirror reverses all hand movements: up is down and down is up. As H. M. did this task each day, his drawing improved, indicating that he was learning and remembering the necessary motor skills. But here's the strange part. Each and every day, H. M. would insist that he had never seen or done mirror-drawing before (N. J. Cohen, 1984).

How could H. M. have no memory of mirror-drawing, yet show a steady improvement in his performance as he practiced it each day? Based on H. M.'s mirror-drawing, as well as data from other patients and numerous animal studies, researchers discovered there are two different kinds of long-term memory, each involving different areas of the brain (Nyberg & Cabeza, 2005; Squire & Kandel, 2009).

You'll understand why H. M. could improve at mirror-drawing but not remember doing it after you learn about the two kinds of long-term memory—declarative and procedural.

Declarative Memory

Which bird cannot fly?

What did you eat for breakfast?

You would recall or retrieve answers to these questions from one particular kind of long-term memory called declarative memory.

Declarative memory **involves memories for facts or events, such as scenes, stories, words, conversations, faces, or daily events. We are aware of and can recall, or retrieve, these kinds of memories.**

There are two kinds of declarative memory—semantic and episodic (Eichenbaum, 2004).

Semantic memory

"Which bird cannot fly?" asks you to remember a fact, which involves semantic *(sah-MAN-tick)* memory.

Semantic memory **is a type of declarative memory and involves knowledge of facts, concepts, words, definitions, and language rules.**

Most of what you ***learn*** in classes (facts, terms, definitions) goes into semantic memory (Eysenck, 2009).

Episodic memory

"What did you eat for breakfast?" asks you to remember an event, which involves episodic *(ep-ih-SAW-dick)* memory.

Episodic memory **is a type of declarative memory and involves knowledge of specific events, personal experiences (episodes), or activities, such as naming or describing favorite restaurants, movies, songs, habits, or hobbies.**

Most of your college activities and experiences go into episodic memory (Baddeley, 2009a).

Since his brain operation, H. M. cannot remember new facts (semantic memory) or events (episodic memory). Thus, H. M. has lost declarative memory, which explains why he does not remember events, such as doing mirror-drawing (Squire et al., 2004).

However, H. M.'s motor skills improved during mirror-drawing, which indicates another kind of long-term memory.

Procedural or Nondeclarative Memory

How did you learn to play tennis?

Why are you afraid of spiders?

Even though you can play tennis and are afraid of spiders, you can't explain how you control your muscles to play tennis or why you're so terrified of such a tiny (usually harmless) bug. That's because motor skills and emotional feelings are stored in procedural memory.

Procedural memory, **also called** ***nondeclarative memory,*** **involves memories for motor skills (playing tennis), some cognitive skills (learning to read), and emotional behaviors learned through classical conditioning (fear of spiders). We cannot recall or retrieve procedural memories.**

Even if you have not played tennis for years, you can pick up a racket and still remember how to serve because that information is stored in procedural memory. But you cannot describe the sequence of movements needed to serve a ball because these skills are stored in procedural memory. Similarly, if you learned to fear spiders through classical conditioning, you cannot explain why you're afraid because the reasons are stored in procedural memory. Although procedural memories greatly influence our behavior, we have neither awareness of nor ability to recall these memories (Baddeley, 2009b).

Now we can explain H. M.'s strange behavior. He was able to improve at mirror-drawing because it involved learning a motor skill that was stored in procedural memory. But he could not talk about the skill because no one is aware of or can recall procedural memories. Although H. M. gradually improved at mirror-drawing, he could not remember the event of sitting down and drawing because that involves declarative (episodic) memories, which were damaged in his brain surgery (Hilts, 1995). The study of H. M. is a classic study because it first demonstrated the existence of two kinds of long-term memory: declarative memory and procedural memory. We'll discuss the brain systems underlying these types of long-term memory in Module 12.

E. Research Focus: Do Emotions Affect Memories?

Hormones and Memories

Do hormones affect memories?

Many of us have vivid memories that involve highly charged emotional situations (Goldstein, 2008). For example, imagine the emotional excitement Halle Berry (right photo) felt when she became the first African American woman to win an Oscar for Best Actress. During her acceptance speech, Halle said, “This moment is so much bigger than me” (Berry, 2002). Halle was so overwhelmed by the experience she could hardly contain her tears of joy. She will remember this event the rest of her life because something happens during strong emotions that increases the chances of remembering the particular situation, person, or event.

Excitatory hormones can “stamp in” memories.

What actually happens to improve memory during an emotional event was studied in a long-term research program that began in animals. In Module 2 we explained that researchers may use an animal model (p. 34) to answer questions that for safety, moral, or ethical reasons cannot be studied in humans. Because of safety concerns, neuropsychologist James McGaugh (1999) began using an animal model to study how hormones produced during emotional states affect memory. He found that certain drugs or hormones associated with emotional experiences could either increase or decrease the recall of long-term memories. For example, if rats were given an injection of a hormone (epinephrine) that is normally produced by the body during emotional or stressful states, rats remembered better what they had just learned (McGaugh, 1990). This was a new and interesting finding and made him wonder why emotional experiences improve long-term memories for related events.

After McGaugh found that the “emotional” hormones and drugs could be safely used in animals, he began his work with human subjects. His study on animals and humans of why emotional events seemed to “stamp in” memories spanned 40 years of research. Here’s one of his interesting studies.

Memories of Emotional Events

Can drugs block emotional memories?

After almost 20 years of research using an animal model, McGaugh found a way to safely study this phenomenon in humans.

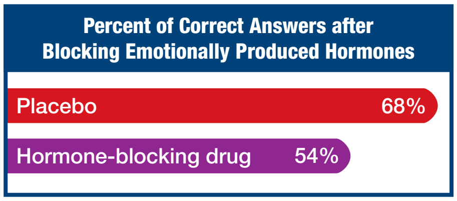
Subjects. Those in the experimental group received a drug (propranolol) that decreases or blocks the effects of hormones (epinephrine and norepinephrine) that are normally produced during emotional states. After taking this drug, experimental subjects would still feel emotions, but the drug would block the secretion of those emotionally produced hormones that had been shown to increase memory in animals. Subjects in the control group received a placebo, but because of the double-blind procedure, no subjects knew whether they were given a drug or a placebo.

Procedure. So that the drugs would have time to act, subjects were given either a placebo or the drug 1 hour before seeing a series of slides. To prevent their expectations from biasing the results, subjects did not know whether they got a drug or a placebo.

Each subject watched a series of 12 slides and heard an accompanying story. The beginning of the slide story was emotionally neutral and simply described a mother leaving home with her son to visit her husband’s workplace. The middle of the slide story was emotionally charged and described the son having a terrible accident in which his feet were severed and his skull was damaged. The end of the slide story was emotionally neutral and described the mother leaving the hospital to pick up her other child from preschool. Subjects were tested for retention of the slide story a week later.

Hypothesis. Based on their results from the animal model, McGaugh and his colleagues guessed that if a drug blocked the effects of memory-enhancing hormones normally produced during emotional situations, subjects who took the drug should show poor retention for emotional events.

Results and conclusion. Researchers found that both drug and placebo subjects remembered about the same number of neutral events. However, the graph below shows that, compared to subjects in the placebo group, subjects given a drug that blocked “emotional” hormones remembered fewer emotionally charged events (Cahill et al., 1994). Other studies on humans found that intense feelings triggered by emotional or stressful situations are encoded, or “carved in stone,” by hormones released during emotionally charged situations and that these memories are better remembered (McGaugh, 1999). Until recently, scientists haven’t understood how these hormones boost memory formation. Researchers have now discovered that these hormones cause tiny molecular changes that help brain cells form memories (Hu et al., 2007). McGaugh’s research is a good example of using an animal model to lay the basis for similar studies in humans. But of what use is it to animals or humans for emotional memories to be better remembered?



Based on years of research, McGaugh believes that one reason emotions seem to “stamp in” memories is to help a species survive. For instance, if emotions stamped in memories of dramatic or life-threatening situations, our early ancestors would better pay attention to and remember to avoid these dangers and thus increase their chances of survival (R. J. Dolan, 2002). An important clinical application of McGaugh’s research is that it explains why bad emotional memories, such as those formed after witnessing or being in a terrible accident or suffering physical or sexual abuse, are stamped in and thus become so powerful and so difficult to treat and overcome.

While McGaugh’s research shows that emotional feelings are easily encoded, you’ll see next that nonemotional information, such as learning terms and definitions, can be encoded only with hard work.

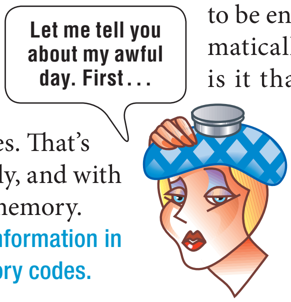
F. Encoding: Transferring

Two Kinds of Encoding

How do we store memories?

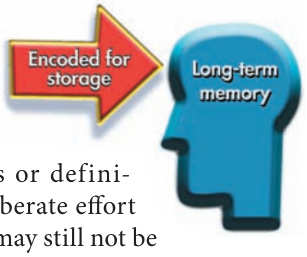
It's very common for someone to say, "Let me tell you about my day," and then proceed to describe in great detail a long list of mostly bad things, including long, word-for-word conversations. You can easily recall these detailed personal experiences, even though you took no notes. That's because many personal experiences are automatically, and with no effort on your part, encoded in your long-term memory.

Encoding refers to acquiring information or storing information in memory by changing this information into neural or memory codes.



Let me tell you about my awful day. First . . .

Why is it that detailed personal experiences and conversation seem to be encoded effortlessly and automatically and easily recalled? Why is it that much of book learning, such as memorizing terms or definitions, usually requires deliberate effort and considerable time and may still not be easily recalled when taking exams? The answer is that there are two different kinds of encoding: automatic and effortful encoding.



Automatic Encoding

Why are some things easy to encode?

Just as most of us can easily and in great detail recall all the annoying things that happened today, the person below is recalling a long list of very detailed personal activities that were automatically encoded into his long-term memory. In fact, many personal events (often unpleasant ones), as well as things we're interested in (movies, music, sports) and a wide range of skills (riding a bike) and habits, are automatically encoded (Dere et al., 2008).

Automatic encoding is the transfer of information from short-term into long-term memory without any effort and usually without any awareness.

Personal events. One reason many of your personal experiences and conversations are automatically encoded is that they hold your interest and attention and easily fit together with hundreds of previous associations. Because personal experiences, which are examples of ***episodic information,*** are encoded automatically into long-term memory, you can easily recall lengthy conversations, facts about movies and sports figures, television shows, clothes you bought, or food you ate.

I bought this hat at a second-hand store for a quarter, and then I bought these shoes from a guy who said that he makes them from old tires . . .

Interesting facts. You may know avid sports fans or watchers of popular TV programs who remember an amazing number of facts and details, seemingly without effort. Because these kinds of facts ***(semantic information)*** are personally interesting and fit with previous associations, they are automatically and easily encoded into declarative long-term memory.

Skills and habits. Learning how to perform various motor skills, such as playing tennis or riding a bike, and developing habits, such as brushing your teeth, are examples of ***procedural information,*** which is also encoded automatically. For example, H. M. learned and remembered how to mirror-draw because mirror-drawing is a motor skill that is automatically encoded into procedural long-term memory.

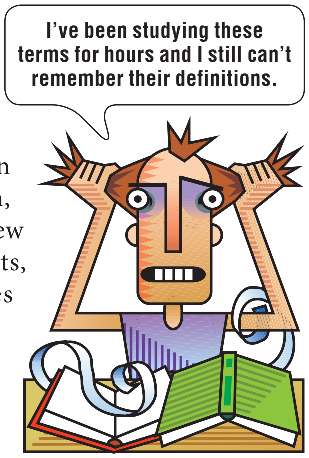
On the other hand, factual or technical information from textbooks is usually not encoded automatically but rather requires deliberate, or effortful, encoding, which we'll discuss next.

Effortful Encoding

Why are some things hard to encode?

The person below is pulling his hair because learning unfamiliar or complicated material almost always involves ***semantic information,*** such as complex terms, which is difficult to encode because such information is often uninteresting, complicated, or requires making new or difficult associations. For all these reasons, semantic information, such as terms, can be encoded only with considerable concentration and effort (Squire & Kandel, 2009).

Effortful encoding involves the transfer of information from short-term into long-term memory either by working hard to repeat or rehearse the information or, especially, by making associations between new and old information.



I've been studying these terms for hours and I still can't remember their definitions.

You already know that some information, such as learning a skill, habit, or interesting personal event, is often encoded effortlessly and automatically. In contrast, semantic information, such as learning hundreds of new or difficult terms, facts, concepts, or equations, usually requires effortful encoding because you must form hundreds of new associations. Forming new associations is often just plain hard work and is made even more difficult if you are simultaneously taking two or three difficult classes or have limited time because of other responsibilities, such as a part-time job.

Although there are two methods of effortful encoding—rehearsing and forming associations—the most effective method involves forming associations between the new information that you are trying to learn and the old information that you have already stored in long-term memory. The better the effortful encoding, the better the recall on exams. We'll explain the two methods of effortful encoding, rehearsing and forming associations, and why the second method is more effective and results in better recall.

Rehearsing and Encoding

How much do you remember?

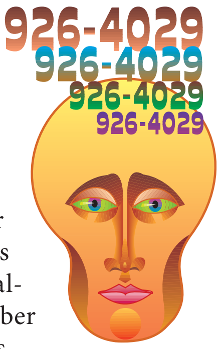
Think of encoding information in your brain as similar to saving information on a gigantic computer hard drive. Unless you have a very good system for labeling and filing the hundreds of computer files, you will have great difficulty finding or retrieving a particular file from the hard drive. Similarly, how easily you can remember or retrieve a particular memory from your brain depends on how much effort you used to encode the information. There are two kinds of effortful encoding: maintenance rehearsal and elaborative rehearsal (Baddeley, 2009a; S. C. Brown & Craik, 2005).

Maintenance Rehearsal

The easiest way to remember information for only a short period of time, such as a new phone number, for example, 926-4029, is to simply repeat or rehearse it. This kind of effortful encoding is called maintenance rehearsal.

Maintenance rehearsal refers to simply repeating or rehearsing the information rather than forming any new associations.

Maintenance rehearsal works best for maintaining or keeping information longer in ***short-term memory,*** such as remembering a phone number for a few seconds while dialing it. However, if you want to remember the phone number later, maintenance rehearsal is not a good encoding process because it does not include a system for keeping track of how and where that particular phone number will be stored. If you need to remember a phone number for a long period of time and avoid having to keep looking it up, you'll need to use another form of effortful encoding called elaborative rehearsal.



Maintenance rehearsal is not a very effective encoding process.

Elaborative Rehearsal

There are some phone numbers and much information from lectures and textbooks that you want to encode so that you remember the information for long periods of time. To have the greatest chance for remembering something, it's best to encode information using elaborative rehearsal.

Elaborative rehearsal involves using effort to actively make meaningful associations between new information that you wish to remember and old or familiar information that is already stored in long-term memory.

For example, using elaborative rehearsal, you could associate this phone number, 926-4029, with age: An old person is "926," I'm not "40," but I wish I were "29." To recall this number, you think of the different age associations and those associations lead to the phone number.

To test the usefulness of elaborative rehearsal, students were asked to remember many groups of three words each, such as *dog, bike,* and *street.* Students who encoded the words with maintenance rehearsal (repeating words) did poorly on recall. In comparison, students who encoded the words using elaborative rehearsal—that is, taking the effort to make associations among the three words (dog rides a bike down the street)—had significantly better recall (McDaniel & Einstein, 1986).

Elaborative rehearsal is a very effective encoding process.

Effectiveness. Elaborative rehearsal is such an effective system of encoding because by making associations between new and old information, you create cues for locating or retrieving the new information from long-term memory. For example, thinking of the association (dog rides a bike down the street) helps you remember the three words (dog, bike, street).

Levels of Processing

How important are associations?

The poorest system for encoding information is to simply repeat the information, which is maintenance rehearsal. The best encoding system is to make associations, which is elaborative rehearsal. How much effort and time you put into encoding information is the basis for the levels-of-processing theory (Craik & Lockhart, 1972).

The ***levels-of-processing theory*** says that remembering depends on how information is encoded. If you encode by paying attention only to basic features (length of phone number), information is encoded at a shallow level and results in poor recall. If you encode by making new associations, this information will be encoded at a deeper level, which results in better recall.

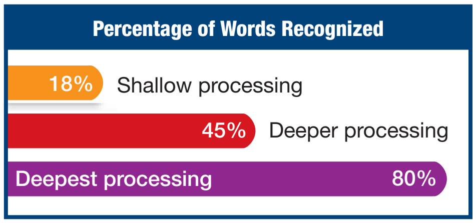
For example, students were shown a series of words and asked a question after each one. The questions were of three types, designed to trigger three different levels of processing.

1. Shallow processing question:
"Is the word printed in capital letters?" Asks about one physical feature of the word.

2. Deeper processing question:
"Does the word rhyme with *rain?*" Asks about sound properties of the word.

3. Deepest processing question:
"Does the word fit into the sentence 'She was late for the ____________'?" Asks about the meaning of the word.

After students answered these questions, they were tested to see how many of the original words they recognized.



As shown in the graph above, students recognized the lowest percentage of words after shallow processing and the highest percentage after the deepest processing (Craik & Tulving, 1975).

This study clearly demonstrates that the system you use to process or encode information has a great effect on how easily you can remember or retrieve the information (M. C. Anderson, 2009a). As we'll discuss in Module 12, a major reason for forgetting is poor encoding (S. C. Brown & Craik, 2005).

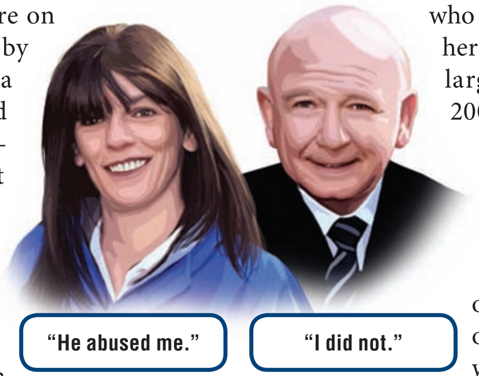
Next, we'll discuss a kind of memory that has resulted in great controversy because of the difficulties in determining whether the event ever happened.

G. Repressed Memories

Recovered Memories

Who's to blame?

The man in the picture on the right was accused by his daughter, Katrina (left picture), of allegedly molesting her as a child and being a murderer. Katrina's childhood memories first surfaced during psychiatric treatment many years later, when she was 25. She never made these accusations in a conscious state, but only while under the influence of psychiatric medication and controversial treatment methods, such as writing out her dreams using her nondominant hand (believed to prevent lying, but no scientific evidence supports this).



"He abused me."
"I did not."

It was quickly discovered that the horrors Katrina was describing couldn't possibly be true, and she later withdrew the allegations. Fortunately, Katrina and her father have mended their relationship and are now closer than ever before. Katrina sued the psychiatrist who almost ruined her life by making her believe her so-called "repressed memories" and won a large settlement (BBC News, 2007; Madeley, 2007).

Katrina's case illustrates one of the more explosive issues in psychology: the problem of repressed and recovered memories.

Psychiatrist Harold Lief, one of the first to question the accuracy of repressed memories, said, "We don't know what percent of these recovered memories are real and what percent are pseudomemories (false).... But we do know there are hundreds, maybe thousands of cases of pseudomemories and that many families have been destroyed by them" (J. E. Brody, 2000a, p. D8).

We'll discuss four issues about repressed and recovered memories.

Definition of Repressed Memories

What's different about a repressed memory?

The idea of repressed memories is based on Sigmund Freud's theory of repression, which underlies much of his psychoanalytic theory of personality (discussed in Module 19).

Repression **is the process by which the mind pushes a memory of some threatening or traumatic event deep into the unconscious. Once in the unconscious, the repressed memory cannot be retrieved at will and may remain there until something releases it and the person remembers it.**

Some therapists believe that children who are sexually abused cope with such traumatic situations and their feelings of guilt by repressing the memories. For example, a client may enter therapy with sexual problems or a mood disorder and later in therapy uncover repressed memories, such as being sexually abused as a child, as the cause of her current problems. Clients usually have total amnesia (loss of memory) for the traumatic experience, their recovery of repressed memories usually occurs in the first 12 months of therapy, and recovered memories usually involve specific incidents (Andrews et al., 2000).

Repressed memories are difficult to recover.

Many therapists believe repressed memories of sexual abuse do occur. However, a prominent memory researcher disagrees: "The idea that forgetting in abuse survivors is caused by a special repression mechanism—something more powerful than conscious suppression—is still without a scientific basis" (Schacter, 1996, p. 264). Thus, the controversy over repressed memories continues (Loftus & Davis, 2006).

Researcher Elizabeth Loftus (1997b, 2005a) partly blames increased reports of recovered memories on some therapeutic practices.

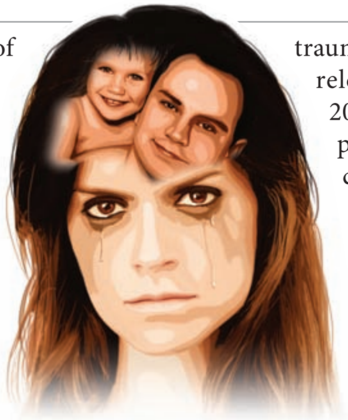
Therapist's Role in Recovered Memories

How does a therapist know?

Some therapists who treat survivors of incest and other traumatic situations maintain that repressed memories are so completely blocked that it may take deliberate suggestion and effort to release them, sometimes using images, hypnosis, or so-called truth serum, sodium amytal.

For example, in one case a client recalls that her therapist insisted that she showed signs of having been sexually abused during childhood and probably had terrible memories buried in her unconscious. The client was dubious at first but, wanting to please her therapist, finally admitted to being raped at the age of 4. However, after leaving the hospital and enlisting help from new therapists, she concluded that the sexual assaults had never happened (B. Bower, 1993).

Whatever the therapists' good intentions, Loftus (1993, 1997b) and others wonder if some therapists are suggesting or implanting traumatic memories in their clients rather than releasing repressed ones (Loftus & Davis, 2006). Loftus and others suggest that therapists not assume the cause of psychological problems must be an earlier traumatic experience and caution against aggressive efforts to recover traumatic memories (Geraerts et al., 2007; Loftus, 2003b). Thus, therapists are in the difficult position of distinguishing accurate accounts of repressed memories from those that may have been shaped or reinforced by the suggestions or expectations of the therapist (Baddeley, 2004).



The therapist may have suggested traumatic memories.

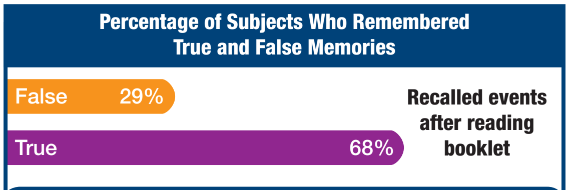
Questions about whether suggestions can influence repressed memories raise the issue of whether false memories can be implanted.

Implanting False Memories

Do people believe "fake" memories?

Because, in some cases, it appears that therapists' suggestions may have contributed to implanting false memories, researchers studied whether fake memories could in fact be implanted and later recalled as being "true."

Researchers gave 24 adults a booklet that contained descriptions of three events that occurred when each adult was 5 years old (Loftus, 1997a). Two of the childhood events had ***really happened*** because they were obtained from parents or relatives. One childhood event of being lost in a shopping mall, crying, being comforted by an elderly woman, and finally getting reunited with the family had ***not happened,*** according to parents and relatives. After reading the three events described in the booklet, the adults (aged 18–53) were asked to write what they remembered of the event or, if they did not remember, to write "I do not remember this."



About 29% of subjects said that they remembered a childhood event that never happened (false) and 68% remembered childhood events that did happen (true).

The graph above shows that 68% of subjects remembered some or most of the two ***true events*** from their childhood. However, about 29% also said they remembered having experienced the one ***false event*** of being lost in the mall at age 5 (Loftus, 1997a).

Researchers concluded that although the memory of being lost in a mall is neither as terrible nor as terrifying as the memory of being abused, this study does show that false memories can be implanted through suggestion alone. Even on a follow-up interview, subjects continued to insist that they remembered the false event.

There are now hundreds of studies reporting false memories can be implanted in children and adults (Loftus, 2003a, 2005b). However, the fact that false memories can be implanted and later recalled as true does not disprove the occurrence of repressed memories. Rather, these studies simply show that a false suggestion can grow into a vivid, detailed, and believable personal memory (Loftus, 2000, 2005b). Brain imaging is now being used to examine the biological mechanisms that lead to impaired memory after exposure to misinformation (Okado & Stark, 2005).

The repeated finding that false memories can be implanted and later remembered as "true" raises a question about the accuracy of repressed memories that are later recovered and believed to be true.

Accuracy of Recovered Memories

How accurate are repressed memories?

Some individuals may initially enter therapy for help with mood disorders or eating problems, but during the course of therapy, they recover memories, apparently repressed, of childhood sexual abuse. Since researchers have shown that "false" memories can be implanted through suggestion and believed to be "true" memories, some question the accuracy of a client's recovered memories.

In a recent study, researchers examined the accuracy of recovered memories of childhood sexual abuse in 128 individuals. Over a six-month period, researchers searched for corroborating evidence for the reported recovered memories. They found corroborating evidence for 37% of memories recovered *outside* of therapy, which almost matches the corroboration rate for childhood memories we all have (45%). However, none of the memories recovered *inside* of therapy could be corroborated. These results do not necessarily indicate that memories recovered in therapy are always false, but it does suggest there is reason for some skepticism (Geraerts, 2007; Geraerts et al., 2007).

As the study above suggests, the accuracy of recovered memories often cannot be established because there is no corroborating evidence of the client's report that the traumatic event really did occur 20–30 years earlier (Roediger & McDermott, 2005). Also, there is reason to question the accuracy of recovered memories because people usually do not recall the memories on their own, but often do so with the help of therapists or support groups (Roediger & McDermott, 2005). Additionally, if the memories were obtained under hypnosis or "truth serum" (sodium amytal), they may not be accurate, since people often become more open to suggestion and may later recall events that had been suggested during hypnosis as being true (Lynn et al., 2003).

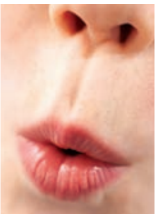
Some question the accuracy of repressed memories.

Another reason to question the accuracy of recovered memories is reports of hundreds of clients who later retracted charges of childhood sexual abuse based on memories recovered in therapy (de Rivera, 1997; Loftus & Davis, 2006). In over a dozen other cases, including the case of Katrina (discussed on the preceding page), clients have successfully sued and won large monetary awards from their therapists for implanting false memories of child abuse (Loftus, 1999; Madeley, 2007). All these examples question the accuracy of some recovered memories.

Conclusions. Memory researcher Elizabeth Loftus (1997a, 2003a) states there are examples of recovered memories that are accurate. However, she questions the accuracy of recovered memories for three reasons: Research has shown that memories that are very detailed but later proven false can be implanted in both children and adults; some clients later retracted their recovered memories; and memories might have been implanted by therapists' suggestions and/or the clients needed and used these memories to explain their current psychological problems. For these reasons, new guidelines caution therapists against using forceful or persuasive suggestions that might elicit memories from their clients (J.E. Brody, 2000a).

The debate over repressed and recovered memories, which reached its peak in the mid-1990s, has recently decreased because some therapists have been sued by their patients over the accuracy of recovered memories and researchers have showed that false memories could be implanted in both children and adults (Lynn et al., 2003).

Concept Review



1. Three processes are involved in memory: The process in which information is placed or stored in memory by making mental representations is called (a) _______________; the process of placing encoded information into a permanent mental state is called (b) _______________; the process of getting information out of short-term or permanent storage is called (c) _______________.

2. The initial step in memory is a process that holds visual and auditory information in its raw form for a very brief period of time, from an instant to several seconds; this process is called _______________.

What did you say?
Oh, yes. Now I remember.

3. Memory that holds raw visual information for up to a quarter of a second is called (a) _______________. Memory that holds raw auditory information for up to several seconds is called (b) _______________. The process for controlling the transfer of information from sensory memory to the next memory process is (c) _______________.

4. The kind of memory that has a limited capacity of about seven items (plus or minus two) and a short duration (2–30 seconds) for unrehearsed information is called either (a) _______________ or _______________. One way to increase this memory capacity is by combining separate pieces of information into larger units, which is called (b) _______________. One way to increase the duration of this memory is by repeating the information, which is called (c) _______________.

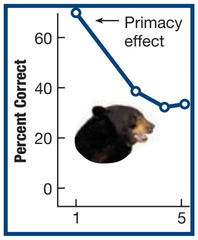
5. The kind of memory that can store almost unlimited amounts of information over a long period of time is _______________, whose accuracy may undergo change and distortion across time.

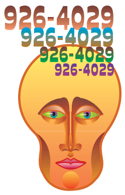
6. The process for controlling the transfer of information from short-term memory into long-term memory is called _______________, which may be automatic or may involve deliberate effort.

Love Is Like Chocolate.

7. The process for selecting information from long-term memory and transferring it back into short-term memory is _______________.

8. The better recall of items at the beginning of a list is called the (a) _______________ effect. The better recall of items at the end of a list is called the (b) _______________ effect. Evidence that there are two kinds of memory, short- and long-term, comes from the (c) _______________ effect.





9. There are two kinds of encoding. Simply repeating or rehearsing the information is called (a) _______________. Actively making associations between new and old information already stored is called (b) _______________.

10. One kind of long-term memory that involves memories for facts or events, such as scenes, stories, words, conversations, faces, or daily events, is called (a) _______________ memory. We can retrieve these memories and are conscious of them. One kind of declarative memory that involves events or personal experiences is called (b) _______________ memory. A second kind of declarative memory that involves general knowledge, facts, or definitions of words is called (c) _______________ memory.

11. A second kind of long-term memory that involves performing motor or perceptual tasks, carrying out habits, and responding to stimuli because of classical conditioning is called _______________ memory. We cannot retrieve these memories and are not conscious of them.

12. Something happens that is so threatening, shocking, or traumatic that our mind pushes that memory into the unconscious, from which it cannot be retrieved at will. This phenomenon is called _______________.

13. During very emotional or stressful situations, the body secretes chemicals called (a) _______________ that act to make encoding very effective, and this results in vivid, long-term memories. Researchers believe that this hormonal encoding system for stressful or emotional events has helped our species (b) _______________.

Answers: *1. (a) encoding, (b) storage, (c) retrieval; 2. sensory memory; 3. (a) iconic memory, (b) echoic memory, (c) attention; 4. (a) short-term, or working, memory, (b) chunking, (c) rehearsal, or maintenance rehearsal; 5. long-term memory; 6. encoding; 7. retrieval; 8. (a) primacy, (b) recency, (c) primacy-recency; 9. (a) maintenance rehearsal, (b) elaborative rehearsal; 10. (a) declarative, (b) episodic, (c) semantic; 11. procedural or nondeclarative; 12. repression, or repressed memory; 13. (a) hormones, (b) survive*

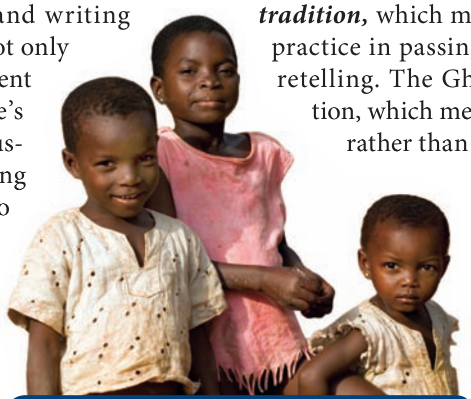
H. Cultural Diversity: Oral Versus Written

United States Versus Africa

What do you remember best?

If you went to grade school in the United States, you spent considerable time in your first 8 years learning to read and write. In the U.S. culture, reading and writing skills are viewed as being not only very important for personal growth and development but also necessary for achieving success in one's career. For similar reasons, the schools of many industrialized cultures place heavy emphasis on teaching reading and writing, which allow individuals to encode great amounts of information in long-term memory. In addition, reading and writing skills are necessary for being admitted to and doing well in college.

In contrast, if you went to grade school in the more rural countries of Africa, you would have spent your first 8 or so years learning primarily through the spoken word rather than the written word. In the less industrialized countries of Africa, such as Ghana, there are fewer public or private schools, fewer textbooks and libraries. As a result, these cultures are said to have a strong ***oral tradition,*** which means that these people have considerable practice in passing on information through speaking and retelling. The Ghana culture emphasizes the oral tradition, which means encoding information after hearing it rather than after reading it.



In more rural parts of Africa (Ghana), children must rely more on oral than written information.

With Ghana's emphasis on oral tradition, we would expect that African people would better encode and remember information that was spoken. In comparison, with the United States' emphasis on ***written tradition,*** we would expect that American people would better encode and remember information that was read rather than spoken. Let's see if this hypothesis has been supported.

Remembering Spoken Information

War of the Ghosts

One night, two young men from Egulac went down to the river to hunt seals, and while they were there it became foggy and calm. Then they heard war cries, and they thought: "Maybe this is a war party." They escaped to the shore and hid behind a log. Now canoes came up, and they heard the noise of paddles and saw one canoe coming up to them. There were five men in the canoe, and they said:

"What do you think? We wish to take you along. We are going up the river to make war on the people."

One of the young men said: "I have no arrows."

"Arrows are in the canoe," they said.

"I will not go along. I might be killed. My relatives do not know where I have gone. But you," he said, turning to the other, "may go with them."

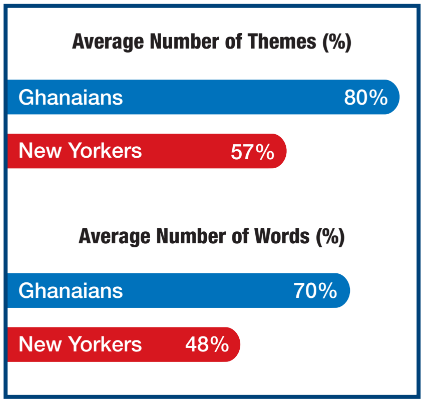
So one of the young men went, but the other returned home.

And the warriors went up the river to a town on the other side of Kalama. The people came down to the water, and they began to fight, and many were killed (story continues but is too long for full reprint).

Who best remembers what they heard?

On the left is part of a story called "War of the Ghosts," which was read aloud in English to college students at Winneba Training College in Ghana and at New York University. Each group of students heard the story twice and were told to just listen to the story so that they would not take notes on their own. They were not told that they would be tested on its content.

Although English was not the native language of the Ghanaian students, they had learned English in previous schooling, and English was used exclusively in their Training College. Sixteen days after hearing "War of the Ghosts," students were asked to write down as much of the text as they could remember. Researchers scored the amount and accuracy of recalled information by counting the number of ideas or themes and the total number of words (330). The "War of the Ghosts" story has been used frequently in memory research because it can be broken down into 21 themes, or ideas, and easily scored. For example, two of the 21 themes or ideas are (1) two young men went to hunt seals and (2) they heard war cries.



As the graph on the right shows, Ghanaian students remembered a significantly higher percentage of themes and a larger number of words than did American students. The Ghanaian students' superior performance was even more remarkable since they were tested by having to write the themes or ideas in English, which was their second language.

These results support the idea that the Ghanaian students showed superior recall of spoken information because of their long oral tradition, which involves practicing encoding information through hearing rather than reading (B. M. Ross & Millsom, 1970). This study indicates that a culture's emphasis on how information is presented or taught can influence how information or events are encoded and how easily they can be recalled.

Next, we'll examine some unusual cases of encoding and retrieving information.

She could perfectly visualize her class notes so didn't have to study for exams.

One kind of unusual memory that many of us wish we had is the ability to remember everything with little or no difficulty. Such an amazing memory is commonly called a photographic memory.

Photographic memory, which occurs in adults, is the ability to form sharp, detailed visual images after examining a picture or page for a short period of time and to recall the entire image at a later date.

There are no reports of someone developing a photographic memory and only one or two reports of adults who had a truly photographic memory (Stromeyer, 1970). Sometimes people with exceptional memories are mislabeled as having photographic memories (Adams, 2006; Higbee, 2001).

At a national memory contest (U.S. Memoriad), Tatiana Cooley (photo above) came in first by doing incredible memory feats, such as pairing 70 names and faces after studying a stack of 100 faces for just 20 minutes. As a child, Tatiana's mother would read to her, and when Tatiana was 2½ years old, she read one of the books back to her mother. In college, Tatiana says, "I remember visualizing the notes that I had taken in class and being able to recall them verbatim for tests so I didn't have to study" (P. Rogers & Morehouse, 1999, p. 90). To keep her memory sharp, she spends 45 minutes each day memorizing the order in which cards appear in a freshly shuffled deck. Wow! Tatiana's ability to visually remember her notes during exams comes close to satisfying the definition for having a photographic memory.

Although there are few examples of adults with photographic memories, a very small percentage of children do have photographic memories.

Extraordinary Episodic Memory

What did you eat for lunch when you were 14 years and 126 days old?

Jill Price effortlessly remembers life events with remarkable detail.

What would it be like to vividly remember everything you have ever experienced in your life? Jill Price, now in her forties, is known to have super-memory abilities. Interestingly, Jill doesn't have any special abilities to remember words, numbers, or factual information (types of ***semantic memory;*** p. 246), but she has an unsurpassed, unimaginable ability to remember her life events since the age of 14 (***episodic memory;*** p. 246).

Name any date and Jill can without hesitation tell you what she did on that day, such as what she had for lunch, where she went, and whom she spoke with, as well as any significant news or world events that took place on that day (provided she heard about it, of course). Jill remembers all of her life experiences in vivid detail without effort—now, that's beyond impressive!

As amazing as Jill's memory abilities are, she is constantly tormented by her memory. She describes feeling powerless because she can't stop remembering certain events no matter how much she tries. Just for a moment imagine not being able to forget all of the unpleasant life experiences you've had and have them play over and over in your mind with such clarity that you feel like you are actually reliving the moments. This is how Jill lives. She is stuck remembering both the good times and the bad (Neimark, 2009; E. S. Parker et al., 2006; Price, 2008).

A new super memory has recently been discovered: the extraordinary ability to recognize faces.

Super Memory for Faces

Can you remember the face of a person you saw in passing a few years ago?

"Super-recognizers" easily recognize familiar faces, even in large crowds.

Most of us cannot remember the faces of people we met a few years ago and only in passing. New research finds that some people (as many as 2%) in fact have this ability and are referred to as ***super-recognizers,*** meaning they can easily recognize someone they met in passing, even years later.

Super-recognizers have an extreme version of memory for faces. They may recognize someone they saw while shopping several months ago. They can also recognize people who have changed in appearance, such as hair color or aging. Because their memory for faces is so extreme, they often have to pretend to not recognize someone they simply saw in passing to avoid the awkwardness of interacting with them. Imagine how awkward it would be for someone to come up and say he saw you 3 years ago at the grocery store while you were buying milk and cookies! People with this incredible memory would be great working in security and law enforcement, as well as provide trustworthy eyewitness testimony (R. Russell et al., 2009; *Science Daily,* 2009b).

Many of us have experienced a very vivid and detailed memory that is called a "flashbulb memory."

Flashbulb Memory

What makes a memory so vivid?

Although it happened about 20 years ago, I (H. K.) have a detailed memory of my cabin in the Santa Cruz Mountains of California shaking and then seesawing on the edge of a mountain during a frightening earthquake. I can play back this terrible scene in great detail and vivid color as if I were actually experiencing an earthquake. Many individuals have had a similar experience, and this kind of memory event is called a flashbulb memory (R. Brown & Kulik, 1977).

Flashbulb memories **are vivid recollections, usually in great detail, of dramatic or emotionally charged incidents that are of interest to the person. This information is encoded effortlessly and may last for long periods of time.**

Impact and Accuracy

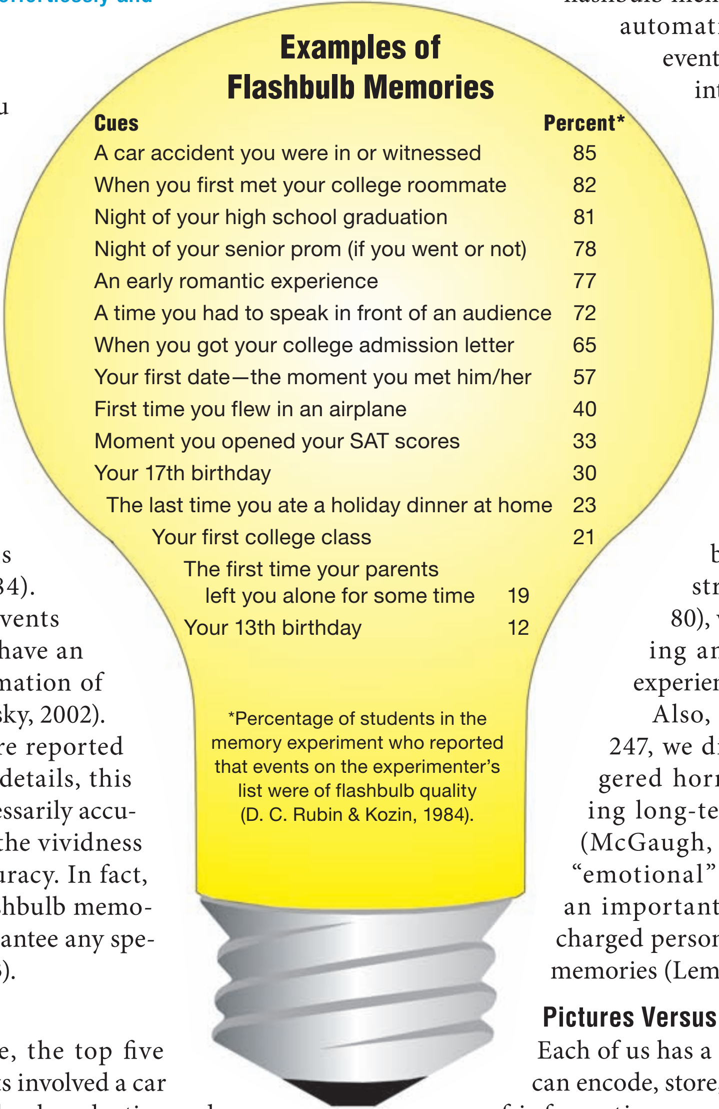
Do you remember precisely what you were doing when you first learned of the 9/11 attacks? Flashbulb memories usually involve events that are extremely surprising, are emotionally arousing, or have very important meaning or consequences for the person. For example, when people were questioned about what they were doing when they heard that President Kennedy or Reagan had been shot, or when the space shuttle *Challenger* exploded, about 80–90% could recall vivid details seven months later (Pillemer, 1984). Researchers concluded that only events that are personally significant and have an emotional impact result in the formation of flashbulb memories (Davidson & Glisky, 2002).

Although flashbulb memories are reported with great confidence and in vivid details, this does not mean the memories are necessarily accurate. That's because people mistake the vividness of flashbulb memories for their accuracy. In fact, researchers report that although flashbulb memories are very vivid, this does not guarantee any special accuracy (Talarico & Rubin, 2003).

Most-Remembered Events

As you can see in the center table, the top five flashbulb memories of college students involved a car accident, a college roommate, high school graduation and prom, and a romantic experience, all of which are emotionally charged events (D. C. Rubin & Kozin, 1984).

Initially, flashbulb memories were claimed to represent a special kind of memory that was complete, accurate, vivid, and immune to forgetting (R. Brown & Kulik, 1977). Since then, several studies have investigated these claims and reported that flashbulb memories do not seem to be a separate, special kind of memory because they are subject to inaccuracies, change with retelling, and are even forgotten over time (C. A. Weaver & Krug, 2004).



Examples of Flashbulb Memories

Cues	Percent*
A car accident you were in or witnessed	85
When you first met your college roommate	82
Night of your high school graduation	81
Night of your senior prom (if you went or not)	78
An early romantic experience	77
A time you had to speak in front of an audience	72
When you got your college admission letter	65
Your first date—the moment you met him/her	57
First time you flew in an airplane	40
Moment you opened your SAT scores	33
Your 17th birthday	30
The last time you ate a holiday dinner at home	23
Your first college class	21
The first time your parents left you alone for some time	19
Your 13th birthday	12

*Percentage of students in the memory experiment who reported that events on the experimenter's list were of flashbulb quality (D. C. Rubin & Kozin, 1984).

Remote Historical Events

In a study of flashbulb memory, Danes (people from Denmark) who lived through the Nazi occupation and liberation during World War II and Danes born during or after World War II were asked questions about the days of the occupation and liberation, such as what the weather conditions were like and what they were doing when they heard the news. Nearly all the older Danes reported having flashbulb memories, being able to recall detailed personal memories about the two war events. Also, the majority of older Danes but very few younger Danes accurately recalled weather conditions. These researchers concluded that flashbulb memories represent a special kind of automatic encoding that occurs when events are emotionally and personally interesting. The results of this study and other research show that flashbulb memories can last 60 years or even longer (Berntsen & Thomsen, 2005).

Brains and Hormones

Researchers think the reason flashbulb memories are so detailed and long-lasting is that their emotionally arousing content activates a special brain area and several hormones. For example, researchers believe that flashbulb memories involve a brain structure called the amygdala (p. 80), which plays a key role in processing and encoding strong emotional experiences (Squire & Kandel, 2009).

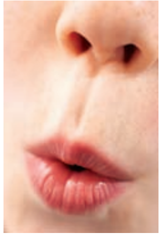
Also, in the Research Focus on page 247, we discussed how emotionally triggered hormones are involved in encoding long-term memories as if "in stone" (McGaugh, 1999). The secretion of these "emotional" hormones is thought to play an important role in encoding emotionally charged personal experiences into long-lasting memories (Lemonick, 2007).

Pictures Versus Impressions

Each of us has a remarkable memory system that can encode, store, and retrieve unlimited amounts of information over long periods of time. But it's important to remember that memories are not perfect pictures of objects, people, and events but rather our personal impressions of these things. For example, the things that you remember when you're in a good mood and having a "good day" are very different from the things that you remember when you're in a bad mood and having a "bad day." This means that what you remember and recall may be changed, biased, or distorted by a wide range of emotional feelings, personal experiences, stressful situations, or social influences (Roediger & McDermott, 2005).

Summary Test

A. Three Types of Memory



1. The study of memory, which is the ability to retain information over time, includes three separate processes. The first process—placing information in memory—is called (a) _______________. The second process, which is filing information in memory, is called (b) _______________. The third process—commonly referred to as remembering—is called (c) _______________.

2. Although we think of memory as a single event, it is really a complex sequence that may be separated into three different kinds of memory. The initial memory process that holds raw information for up to several seconds is called _______________. During this time, you have the chance to identify or pay attention to new information.

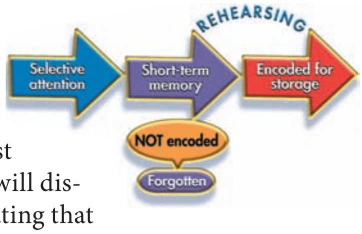
3. If you pay attention to information in sensory memory, this information is automatically transferred into a second kind of memory process, called _______________ memory.

4. If you rehearse or think about information in short-term memory, that information will usually be transferred or encoded into the third, more permanent kind of memory process called _______________.

B. Sensory Memory: Recording

5. Visual sensory memory, known as (a) _______________ memory, lasts about a quarter of a second. Auditory memory, known as (b) _______________ memory, may last as long as 2 seconds. Sensory memory has many functions; for example, it prevents you from being overwhelmed by too much incoming information and gives you time to identify the incoming data and pay attention to them.

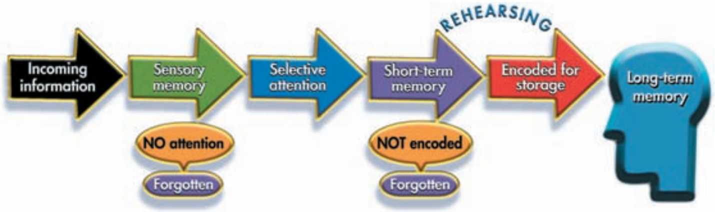
C. Short-Term Memory: Working



6. If you pay attention to information in sensory memory, it is automatically transferred to short-term memory, which has two main characteristics. The first is that unrehearsed information will disappear after 2–30 seconds, indicating that short-term memory has a limited (a) _______________. The second characteristic is that short-term memory can hold only about seven items (plus or minus two), indicating that short-term memory has a limited (b) _______________. You can increase the length of time that information remains in short-term memory by intentionally repeating the information, which is called (c) _______________. You can considerably increase the capacity of short-term memory by combining separate items of information into larger units, which is called (d) _______________.

D. Long-Term Memory: Storing

7. Let's follow the progress of information from the time it enters sensory memory to its storage in long-term memory. For an instant to several seconds, incoming raw information is held in (a) _______________. If you do not pay attention to this information, it disappears forever; if you pay attention, that information is automatically transferred to short-term memory. The transfer of information from sensory memory to short-term memory is controlled by the process of (b) _______________.



8. If information in short-term memory is not (a) _______________, it will disappear in 2–30 seconds. If you rehearse or think about information in short-term memory, it may be transferred into long-term memory. The transfer of information from short-term into long-term memory is controlled by a process called (b) _______________. In some cases, information is transferred automatically; in other cases, this transfer process may require deliberate effort.

9. The process of selecting information from long-term memory and transferring it back into short-term memory is called _______________. Because information has been encoded into long-term memory does not guarantee that such information can always or easily be remembered or retrieved.

10. One demonstration of the existence of, and difference between, short-term and long-term memory is observed in the order that subjects remember items from a multiple-item list. Subjects tend to have better recall of items at the beginning of a list; this tendency is called the (a) _______________ effect and involves long-term memory. Subjects tend to have better recall of items at the end of the list; this tendency is called the (b) _______________ effect and involves short-term memory. The order in which subjects recall items from a long list is called the (c) _______________ effect.

11. There are two different kinds of long-term memory. One kind involves memories of facts or events, such as scenes, stories, words, conversations, faces, or daily events. We can retrieve these memories and are conscious of them; they constitute (a) _______________ memory. There are two kinds of declarative memory. One kind consists of factual knowledge of the world, concepts, word definitions, and language rules; this is called (b) _______________ memory. The second kind of declarative

Photo Credits: (#1) © Royalty-Free/Masterfile; (#5) © PhotoDisc, Inc.

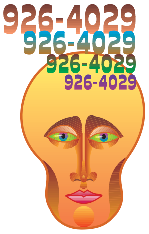
memory consists of knowledge about personal experiences (episodes) or activities; this is called (c) ______________ memory.

12. A second kind of long-term memory involves memories for performing motor or perceptual tasks, carrying out habits, and responding to stimuli because of classical conditioning; this is called ______________ memory. We cannot retrieve these memories and are not conscious of them.

E. Research Focus: Do Emotions Affect Memories?

13. There are times when for safety, moral, or ethical reasons researchers cannot use human subjects but instead use an (a) ______________ model. Using this model, researchers found that during emotional or stressful situations, the body secretes chemicals called (b) ______________, which make encoding so effective that these situations become very vivid long-term memories. One reason for the evolution of this carved-in-stone memory system is to help the species survive by remembering dangerous situations.

F. Encoding: Transferring



14. The process of storing information in memory by making mental representations is called (a) ______________. There are two processes for encoding information. Most procedural and episodic information is transferred from short-term into long-term memory without any effort, and usually without any awareness, through a process called (b) ______________ encoding. Much semantic information is transferred from short-term into long-term memory by deliberate attempts to repeat, rehearse, or make associations. Together, these deliberate attempts are referred to as (c) ______________ encoding.

15. There are two kinds of effortful encoding, which differ in their effectiveness. Encoding by simply repeating or rehearsing the information is called (a) ______________. This method is not very effective because it involves little thinking about the information or making new associations. Encoding that involves thinking about the information and making new associations is called (b) ______________.

16. One theory says that memory depends on how information is encoded in the mind. If we pay attention only to basic features of the information, it is encoded at a shallow level, and poor memory results. If we form new associations, the information is encoded at a deeper level, and good memory results. This theory is called ______________.

G. Repressed Memories

17. If something happens that is threatening, shocking, or traumatic, our minds may push that information deep into the unconscious, from which it may one day be released and enter consciousness. This phenomenon is called (a) ______________ and is the theory behind the formation of (b) ______________ memories. Unless there is corroborating evidence, the accuracy of repressed memories is difficult to establish.

H. Cultural Diversity: Oral Versus Written

18. Students from Ghana, Africa, remembered more information when it was read to them than did American students who heard the same information. These results show how Ghana's tradition of passing on information orally, which is an example of ______________ influences, improves both encoding and recalling or retrieving information.

I. Application: Unusual Memories

19. A person who can effortlessly remember life events that occurred many years ago with remarkable detail has extraordinary (a) ______________ memory. In adults, the ability to form sharp, detailed visual images after a short period and recall the entire image at a later date is called (b) ______________ memory. Memories that are vivid recollections, usually in great detail, of dramatic or emotionally charged incidents are called (c) ______________. Although very vivid, these memories are not necessarily completely accurate.

Answers: *1. (a) encoding, (b) storing, (c) retrieving; 2. sensory memory; 3. short-term, or working; 4. long-term memory; 5. (a) iconic, (b) echoic; 6. (a) duration, (b) capacity, (c) maintenance rehearsal, (d) chunking; 7. (a) sensory memory, (b) attention; 8. (a) rehearsed, (b) encoding; 9. retrieval, or retrieving; 10. (a) primacy, (b) recency, (c) primacy-recency; 11. (a) declarative, (b) semantic, (c) episodic; 12. procedural or nondeclarative; 13. (a) animal, (b) hormones; 14. (a) encoding, (b) automatic, (c) effortful; 15. (a) maintenance rehearsal, (b) elaborative rehearsal; 16. levels of processing; 17. (a) repression, (b) repressed; 18. cultural; 19. (a) episodic, (b) photographic, (c) flashbulb memories*

Critical Thinking

Can Phony Memories Change Your Behavior?

It's been well established that people can be made to believe "fake" memories, but can "fake" memories change people's behavior? Research psychologist Elizabeth Loftus of the University of California–Irvine and her colleagues studied whether simply suggesting food preferences can change what people decide to eat. To answer this question, these researchers asked college-aged subjects to complete questionnaires on their personalities and food experiences. As part of the questionnaires, subjects were asked about childhood food experiences, such as whether they "ate a piece of banana cream pie."

One week after completing the questionnaires, subjects returned and were told that their responses were used to create a "unique" profile of their early childhood food experiences. Everyone's profile included generic statements such as they disliked spinach, enjoyed eating bananas, and felt happy when a classmate brought sweets to school. In addition, the profiles of a group of subjects included one completely made-up point: "Felt ill after eating strawberry ice cream." The remaining subjects were the control group and their profiles did not include a statement about getting ill as a result of eating strawberry ice cream.

When subjects in the false memory group were told the questionnaire results showed they had a bad childhood experience with strawberry ice cream, researchers asked several follow-up questions about the phony memory, such as where they were when they got sick and who else witnessed the event. About 41% of subjects given the false memory believed they had once gotten sick from eating strawberry ice cream. Some of these subjects even reported details about the experience such as "may have gotten sick after eating seven cups of ice cream."

During this same visit, subjects completed a second questionnaire about eating preferences and many of these "believers" (20 of the 47) now reported less preference for and less willingness to eat strawberry ice cream. In contrast, the control group of subjects who did not receive false feedback did not show any change in their preference for strawberry ice cream.

As many people have learned, a strong and long-lasting aversion to a certain food can develop after only one bad childhood experience. Loftus gives an example that a novel food such as béarnaise sauce may make a person sick one time and lead to avoiding the food in the future. The current study suggests it is possible for such an aversion to occur based only on a false memory. Loftus and her colleagues are now examining whether false memories of really liking certain healthy vegetables during childhood can be implanted and make people more likely to eat such foods as adults. (Adapted from D. M. Bernstein et al., 2005; Loftus, 2005a; Park, 2005; Skloot, 2006; M. Smith, 2005)

QUESTIONS

1 What type of long-term memory is used to recall a bad childhood experience with food?

2 Why were researchers able to implant false memories in these subjects?

3 Is it possible for a person to have had a traumatic experience with strawberry ice cream as a teenager and not remember it as an adult?

4 Would the results be different if subjects were presented with a bowl of strawberry ice cream instead of being asked to report their preference on a questionnaire?

5 What type of learning occurs when a person has a bad experience with food and then avoids eating it?

6 Should physicians implant false memories to help patients lose weight?

Learning Activities

PowerStudy for Introduction to Psychology 4.5

Try out **PowerStudy's SuperModule** for Types of Memory! In addition to the quizzes, learning activities, interactive Summary Test, key terms, module outline and abstract, and extended list of correlated websites provided for all modules, the DVD's **SuperModule** for Types of Memory features:

- Self-paced, fully narrated learning with a multitude of animations.
- Video about Daniel's phenomenal ability to remember, as well as short-term memory, memory and the brain, chunking, and false memories.
- Numerous animations, including a virtual dolphin that teaches you about the training procedure for mine detection.
- Interactive versions of study resources, including the Summary Test on pages 256–257 and the critical thinking questions for the article on page 258.

Study Guide and WebTutor

Work through the corresponding module in your Study Guide for tips on how to study effectively and for help learning the material covered in the book. WebTutor (an online Study Tool accessed through your eResources account) provides an interactive version of the Study Guide.

Suggested Answers to Critical Thinking

1. When you recall a childhood event, such as feeling ill after eating a certain food, you are using a type of declarative memory called episodic memory. Episodic memory is a type of long-term memory that involves knowledge of specific events and personal experiences.

2. It is likely that false memories can be implanted only in people who are unaware of the mental manipulation. Subjects in this study did not know they were being deceived, and this is why they were highly suggestible.

3. Yes, it is possible to have forgotten a previous traumatic experience. Repression is the process by which the mind pushes a memory of some threatening or traumatic event deep into the unconscious.

4. The research design of the current study is limited because it involved a laboratory setting rather than a naturalistic setting. If this study was conducted in a naturalistic setting, such as at an ice cream shop, the results may be different.

5. Taste-aversion learning is associating a particular sensory cue (such as the taste of strawberry ice cream) with getting sick and thereafter avoiding that particular sensory cue in the future.

6. The results of this study may have implications for dieters, but it is unethical to lie to a patient even if the doctor believes it will benefit the patient. Also, false memories may work only for foods that are infrequently eaten. For instance, researchers have not been able to create false memories of people associating commonly eaten unhealthy foods, such as potato chips and chocolate chip cookies, with feeling ill.

Introduction

Watching a Crime

How much can you remember?

It was about nine at night when you entered the campus building, climbed one flight of stairs, and began walking down the long hallway. You had just finished your psychology paper and were going to slip it under the instructor's door.

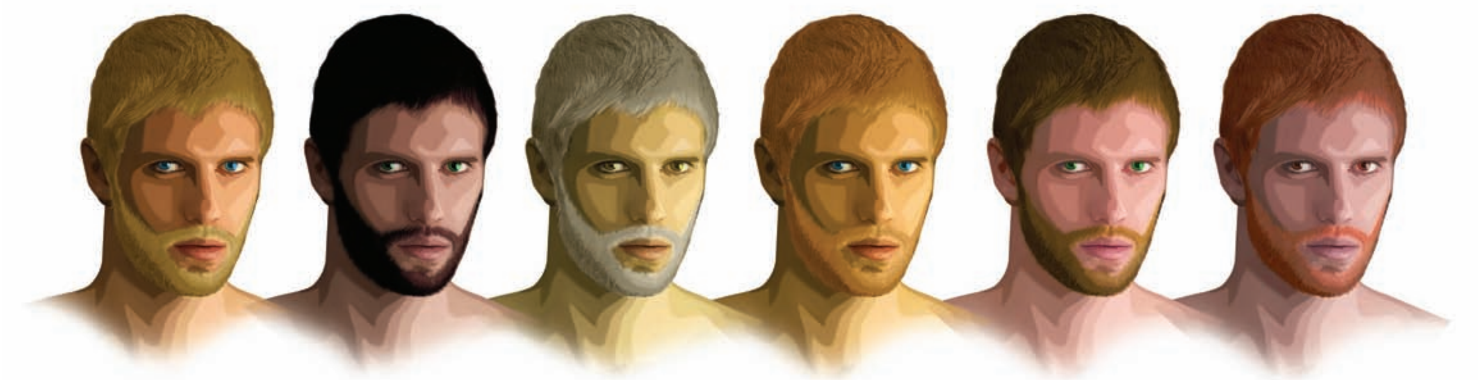
Everything happened very quickly.

From about the middle of the dimly lit hallway, a man with reddish hair and wearing a brown leather jacket jumped out from behind a half-open door and ran at you. Instinctively, you threw out your hands and tried to ward off the oncoming threat. With a quick motion, the man grabbed your blue shoulder bag and pushed you down. At that instant, your eyes met. He pointed at you with a menacing gesture and said, "Don't move or make a sound." Then he checked the hallway, stepped around you, and was gone (adapted from Buckout, 1980).

1,800 people identified the wrong mugger.

A 12-second filmed sequence with a storyline similar to this one was shown on television. In the TV film, the assailant's face was on the screen for several seconds. Next, the viewers were asked to watch a lineup of six men and then to call the TV station and identify which was the assailant. Of the more than 2,000 viewers who called in, only 200 identified the correct man; 1,800 selected the wrong one (Buckout, 1980).

Without looking back, try to answer the following questions (answers at bottom):



1. What color was the mugger's jacket? ____________
2. What color and type was the student's bag? ____________
3. Besides the bag, what else was the student carrying? ____________
4. The mugger's exact words were "Don't make a sound." True or false?
5. When thrown down, the student yelled out "Stop!" True or false?
6. Of the 2,000 viewers who called in, 1,800 identified the correct assailant. True or false?

Answers: *1. brown; 2. blue, shoulder bag; 3. psychology paper; 4. false; 5. false; 6. false*

Recall Versus Recognition

Which is easier?

You probably found the first three questions harder because they involve recall.

Recall **involves retrieving previously learned information without the aid of or with very few external cues.**

For example, in questions 1–3, you were asked to recall colors or objects without having any choices. Students must use recall to answer fill-in-the-blank or essay questions.

You probably thought the last three questions were easier because they involve recognition.

Recognition **involves identifying previously learned information with the help of external cues.**

In questions 4–6, you have only to recognize whether the information provided is correct. Students use recognition to decide which of the choices is correct on multiple-choice tests. Since multiple-choice tests involve recognition, they are generally considered easier than fill-in-the-blank and essay questions, which involve recall. Later in this module, we'll discuss why recall is more difficult than recognition.

Eyewitness Testimony

Which face did you see?

Question 6 asks about a very curious result. Although the assailant's face was on the television screen for several seconds, 90% of the viewers identified the ***wrong*** person in a six-man lineup. (For example, from the six faces below, can you identify the correct mugger? Answer below.) How can you clearly see someone's face and not remember it? The answer to this question comes from studies on how eyewitness memories can be affected by suggestions, misleading questions, and false information. Although we generally assume that eyewitness testimony is the most accurate kind of evidence, you'll see that this is not always true. We'll discuss accuracy and problems of eyewitness testimony at the end of this module. (Mugger had reddish hair.)

What's Coming

We'll discuss how you organize thousands of events, faces, and facts and file this information in long-term memory. We'll explain the most common reasons for forgetting, the biological bases for memory, methods to improve memory, the accuracy of memory, and the accuracy of eyewitness testimony.

We'll begin with a huge problem that you face every day: How do you file away and organize your many, many thousands of memories?

Figure/Text Credit: Adapted from "Nearly 2,000 Witnesses Can Be Wrong," by R. Buckout, 1980, *Bulletin of the Psychonomic Society, 16,* 307–310.

A. Organization of Memories

Filing and Organizing 87,967 Memories

How do you store memories?

One of the great puzzles of memory is how you file and store zillions of things over your lifetime. Suppose this past month you stored 91 faces, 6,340 concepts, 258 songs, 192 names, 97 definitions, 80,987 personal events, 1 dog, and 1 cat. How did you store these 87,967 memories so that you can search and retrieve one particular item from long-term memory?

There are several theories for how we file and organize memories; we'll discuss one of the more popular theories, which is called network theory (J. L. McClelland, 2005).

Network theory says that we store related ideas in separate categories, or files, called nodes. As we make associations among information, we create links among thousands of nodes, which make up a gigantic interconnected network of files for storing and retrieving information.

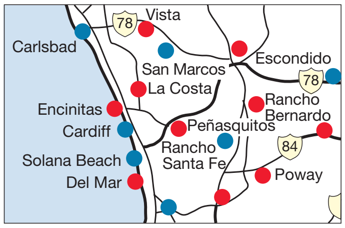
Network theory says we store memories by filing them into categories.

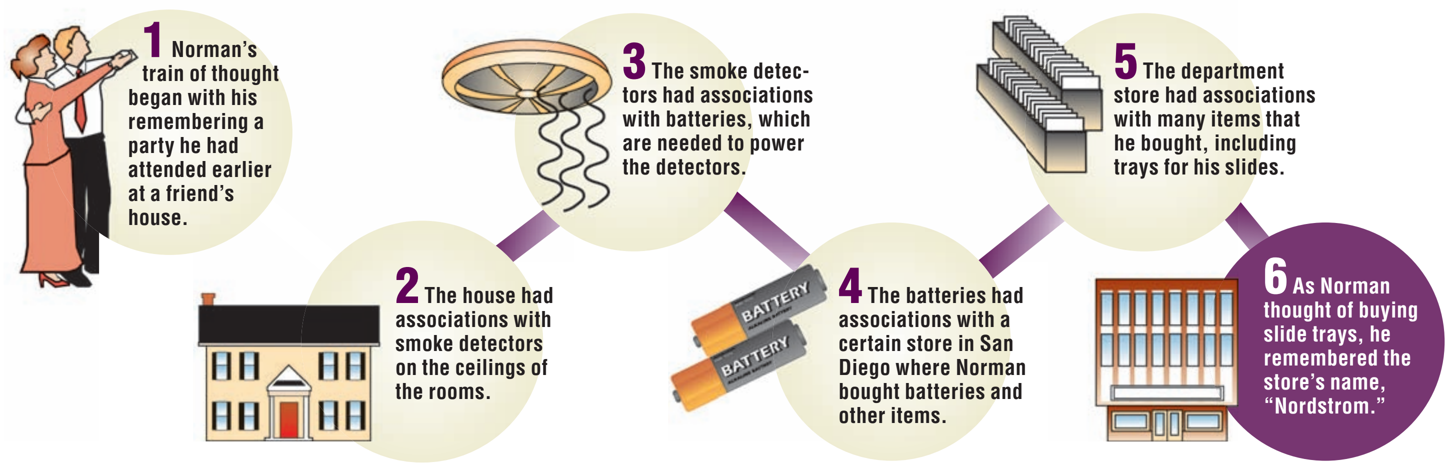
Network theory may become clearer if you imagine that the mental files, or nodes, are like thousands of cities on a map and the connections or associations between them are like roads. Just as you follow different roads to go from city to city, you follow different associative pathways to go from idea to idea. Storing new events, faces, and thousands of other things would be similar to erecting new buildings in the cities and also building new roads between the cities (B. Schwartz & Reisberg, 1991). Here's how one cognitive psychologist, Donald Norman, used network theory to explain how he retrieved a particular memory.

Network Theory of Memory Organization

Where do the roads lead?

Just as you might follow a road map (right figure) to reach a particular city, cognitive psychologist Norman followed a cognitive map to remember the name of a particular store in San Diego. Although the mental roads that Norman takes may seem strange, these roads represent personal associations that he created when he filed, or stored, information in long-term memory. As he follows his associations, or mental roads, he travels the cognitive network from node to node or memory to memory in search of a particular name (Norman, 1982). Please begin reading at node 1 and continue to node 6.





1 Norman's train of thought began with his remembering a party he had attended earlier at a friend's house.

2 The house had associations with smoke detectors on the ceilings of the rooms.

3 The smoke detectors had associations with batteries, which are needed to power the detectors.

4 The batteries had associations with a certain store in San Diego where Norman bought batteries and other items.

5 The department store had associations with many items that he bought, including trays for his slides.

6 As Norman thought of buying slide trays, he remembered the store's name, "Nordstrom."

Norman mentally followed a cognitive map, starting with node 1 and following nodes 2, 3, 4, 5, to the name of a store at node 6.

Searching for a Memory

We've all shared Norman's problem of knowing we know something but having difficulty recalling it. This problem relates to how we store memories in long-term memory. According to the network theory of memory, we store memories in nodes that are interconnected after we make new associations. Because the network theory is somewhat complicated, we'll review how it applied to Norman's problem of trying to recall a particular memory.

Nodes. Norman organizes or stores related ideas in separate files, or categories, called nodes. We simplified this process by showing only six nodes, but there may be dozens. Nodes are categories for storing related ideas, such as birds, faces, friends, and store names.

Associations. Norman links the nodes, or categories of ideas, together by making associations or mental roads between new information and old information that was previously stored.

Network. Norman has thousands of interconnected nodes, which form an enormous cognitive network for arranging and storing files. Norman must search through this cognitive network to find a particular node or file, where a specific memory is stored.

Researchers have developed a theory of how we search through thousands of nodes to find a particular one (J. L. McClelland, 2005).

Figure/Text Credit: Memory figure based on *Learning and Memory*, by D. A. Norman, 1982. W. H. Freeman & Company.

Organization of Network Hierarchy

How do you find a specific memory?

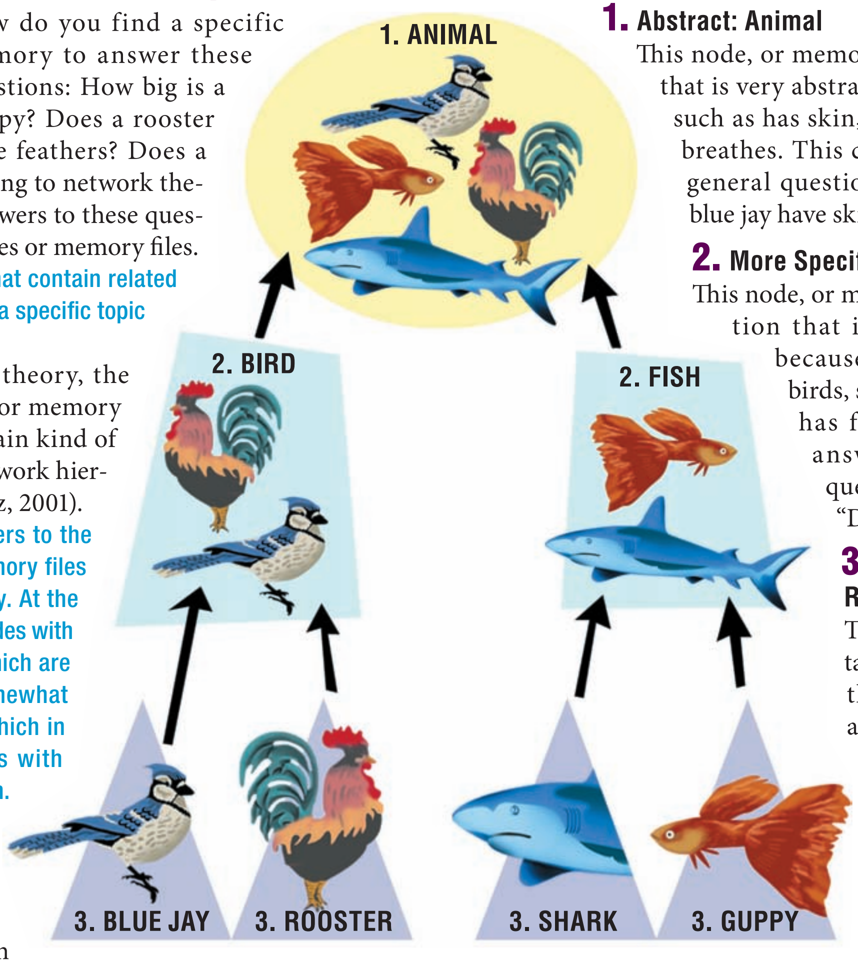
How do you find a specific memory to answer these questions: How big is a guppy? Does a rooster have feathers? Does a blue jay have skin? According to network theory, you will search for answers to these questions by using different nodes or memory files.

Nodes are memory files that contain related information organized around a specific topic or category.

According to network theory, the many thousands of nodes or memory files are arranged in a certain kind of order, which is called a network hierarchy (Diesendruck & Shatz, 2001).

A ***network hierarchy*** refers to the arrangement of nodes or memory files in a certain order or hierarchy. At the bottom of the hierarchy are nodes with very concrete information, which are connected to nodes with somewhat more specific information, which in turn are connected to nodes with general or abstract information.

For example, a partial network hierarchy for nodes or memory files containing information about animals is shown on the right. Depending on whether you're looking for a specific memory (How big is a guppy?) or a more abstract memory (Does a blue jay have skin?), you will search different nodes, as explained next.



1. Abstract: Animal

This node, or memory file, contains information that is very abstract and applies to all animals, such as has skin, can move around, eats, and breathes. This category has answers to very general questions about animals—"Does a blue jay have skin?"

2. More Specific: Bird or Fish

This node, or memory file, contains information that is somewhat more specific because it applies to many fish or birds, such as has wings, can fly, and has feathers. This category has answers to somewhat specific questions about fish or birds—"Does a rooster have feathers?"

3. Concrete: Blue Jay, Rooster, Shark, or Guppy

This node, or memory file, contains very concrete information that applies only to a specific animal. This category has answers to very specific questions—"How big is a guppy?" "What color is a shark?"

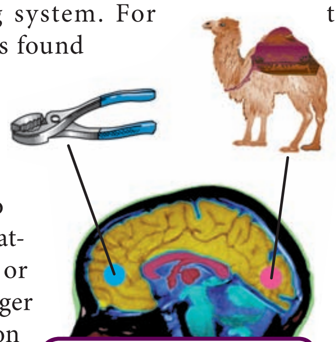
Conclusion. Because network theory doesn't have all the answers to how you file and store information, researchers are developing more complex models, such as neural networks, that try to imitate how the brain organizes and files millions of bits of information (Ratcliff & McKoon, 2005).

Network hierarchy: Arranging memory files (nodes) so that general information is in top file (node #1) and specific information is in bottom files (nodes #3)

Categories in the Brain

Does the brain come with a built-in filing system?

The network theory's idea that information is filed in interconnected nodes or categories is partly supported by recent findings showing that the brain seems to have its own built-in filing system. For example, researchers found that, depending on which area of the brain is damaged, patients lose the ability to identify or process information dealing with a specific category. In some cases, patients could no longer identify faces but had no problems identifying information in other categories, such as tools, animals, furniture, or plants. In other cases, patients could no longer identify plants but could identify information in different categories (tools, animals, etc.) (Schacter et al., 2005). These findings indicate that the brain has built-in categories for sorting and filing different kinds of information.



The brain seems to have built-in files or categories.

By using another research approach involving brain scans (p. 70), researchers found further evidence that we use different areas of the brain to process different categories. For example, when subjects were asked to think of objects in specific categories, such as faces, tools, or furniture, researchers found that maximum neural activity occurred in different areas of the brain. As shown at the left, when people were thinking of animals, the maximum neural activity occurred in the back of the brain, while thinking of tools produced maximum neural activity in the front of the brain (A. Martin et al., 1996). The finding that the brain comes with prewired categories for processing information helps explain how you can easily sort through a tremendous amount of information and quickly find the answer to a specific question, such as "Does a camel have a hump?" (Low et al., 2003).

B. Forgetting Curves

Early Memories

What's your earliest memory?

The earliest that people in different cultures can recall personal memories averages 3½ years old (Q. Wang, 2003). Researchers did find that children as young as 13 months can recall visual events, such as a sequence of moving toys. However, recalling moving objects is different from recalling personal memories, which is based on having developed a sense of oneself (recognizing the face in mirror as yours), which occurs after age 2 (Howe, 2003). Another reason we rarely remember personal events before age 3½ is that very young children have little or no language skills, so they cannot verbally encode early personal memories and cannot recall them even after they do develop language skills (Baddeley, 2004; Simcock & Hayne, 2002). Also, very young children have not yet developed a complete memory circuit in the brain, which is necessary for encoding and retrieving personal memories (Baddeley, 2004; Bauer, 2002). But even though you're now an adult with a completely developed memory brain circuit, why do you still forget things, especially when taking exams?

Earliest memories at about age 3½

Unfamiliar and Uninteresting

Could you remember LUD, ZIB?

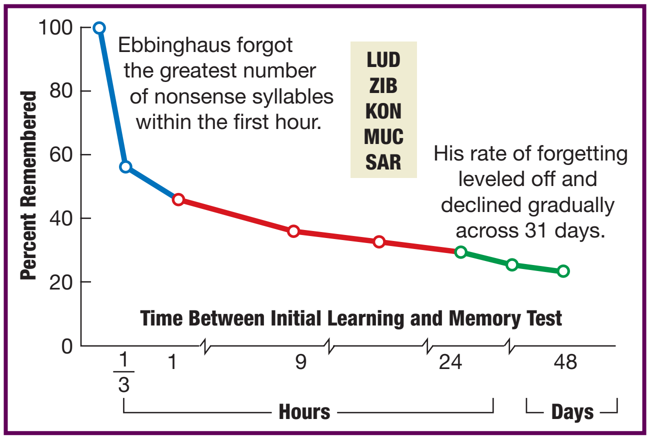
From your experience studying for exams, you know that just because you verbally encode information by listening, reading, or writing doesn't mean that you'll automatically recall this information on exams.

The kinds of events that you are more likely to remember or forget can be demonstrated with forgetting curves.

A ***forgetting curve*** measures the amount of previously learned information that subjects can recall or recognize across time.

We'll examine how two different kinds of information—unfamiliar and familiar—are remembered by using forgetting curves.

One of the earliest psychologists to study memory and forgetting was Hermann Ebbinghaus, who used himself as his only subject. He got around the fact that people have better memories for more familiar events by memorizing only three-letter nonsense syllables, such as **LUD, ZIB, MUC.** He made up and wrote down hundreds of three-letter nonsense syllables on separate cards and arranged these cards into sets of varying length. To the ticking of a metronome, he turned over each card and read aloud each of the syllables until he had read all the cards in the set. He used only rote memory (made no associations) and needed only one or two readings to memorize a set of seven cards (containing seven nonsense syllables). He needed about 45 readings to memorize a set of 24 cards (Ebbinghaus, 1885/1913).



The forgetting curve on the left shows that Ebbinghaus forgot about half the unfamiliar and uninteresting nonsense syllables within the first hour.

How long do we remember familiar information?

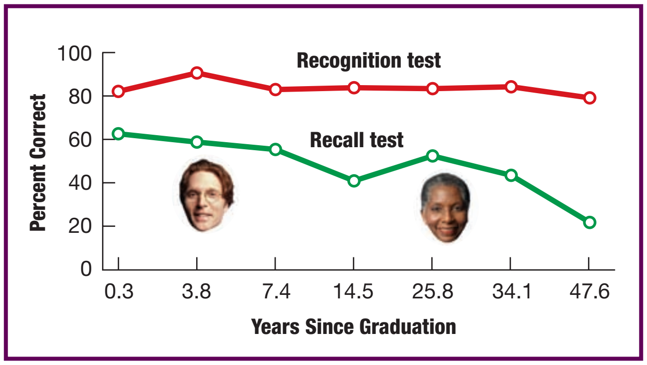
Familiar and Interesting

Can you remember the names of your high school classmates?

Ebbinghaus's nonsense syllables are certainly uninteresting, which helps explain why he forgot half within the first hour. But what about information that is both familiar and interesting, such as the names and faces of your high school graduating class?

The graph at right shows that even after 47 years, subjects correctly matched about 80% of their high school classmates' names with faces; they correctly recalled about 25% after 47 years (Bahrick et al., 1975). Subjects did better on recognition tests (matching names to faces) because they were given clues (names). They did poorer on recall tests (seeing faces and asked to recall the names) because they were not given any clues. Similarly, students also show better memory on recognition tests (multiple-choice) than on recall tests (essay or fill-in-the-blank).

Notice that even though names and nonsense syllables were both encoded verbally, subjects correctly recalled about 60% of familiar and interesting information (names and faces) after 7 years, while Ebbinghaus forgot about 80% of the unfamiliar and uninteresting nonsense syllables after about a week. One researcher found that, after 20 years, he best remembered those events that were vivid, rare, and emotionally intense (R. White, 2002).



These studies show that remembering is partly related to how familiar or interesting the information is. However, there are other reasons for forgetting, as you'll see next.

Photo Credits: top, © Laura Dwight; bottom left and right, © PhotoDisc, Inc.

C. Reasons for Forgetting

Overview: Forgetting

Why do I forget things?

If asked to describe what happened today, you can accurately recall many personal events, conversations, and countless irritations. However, in spite of hours of study, there are many things you seem to have forgotten when you take an exam.

Forgetting **refers to the inability to retrieve, recall, or recognize information that was stored or is still stored in long-term memory.**

We'll summarize a number of reasons people forget things.

Repression

There is a documented case of a man, J.R., who became anxious while watching a movie that featured a main character who struggled with memories of being sexually molested. Later that night, J.R. had a vivid recollection of being sexually abused by a parish priest (Schooler, 1994). J.R.'s case is an example of repression.

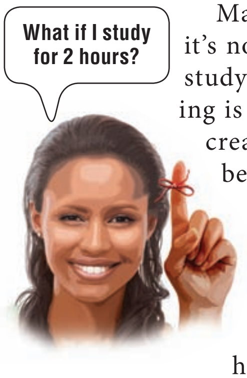
Repression, **according to Freud, is a mental process that automatically hides emotionally threatening or anxiety-producing information in the unconscious, from which repressed memories cannot be recalled voluntarily, but something may cause them to enter consciousness at a later time.**

Earlier we discussed the accuracy of recovered repressed memories involving sexual abuse (pp. 250–251). The J.R. example suggests that a traumatic sexual event can be repressed and recovered later. However, prominent memory researchers have questioned the validity of repressed memories, pointing to the possibility that such memories may have been suggested or implanted during the therapeutic process (Lynn et al., 2003).

Poor Retrieval Cues/Poor Encoding

Studying for exams by cramming or using rote memory may lead to forgetting because these techniques result in poor retrieval cues and thus poor encoding or storing.

Retrieval cues **are mental reminders that we create by forming vivid mental images or creating associations between new information and information we already know.**



What if I study for 2 hours?

Many students don't realize that it's not how long but how well they study that matters. Effective studying is not only memorizing but also creating good retrieval cues. The best retrieval cues, which ensure the best encoding, are created by associating new information with information already learned. For example, instead of just trying to remember that the hippocampus is involved in memory (pp. 80, 84, 229), try to make a new association, such as a hippo remembered its way around campus.

We'll discuss the importance of and how to form good retrieval cues for effective encoding on page 267.

Interference

If you have to study for several exams and take them on the same day, there is a good chance that you may mix up and forget some of the material because of interference.

Interference, **one of the common reasons for forgetting, means that the recall of some particular memory is blocked or prevented by other related memories.**

PSYCHOLOGY
SOCIOLOGY

What if you have 2 exams on the same day?

For example, if you are studying for and taking psychology and sociology tests on the same day, you may find that some of the material on social behavior in psychology is similar to but different from material in sociology, and this mix-up will cause interference and forgetting. Because psychologists believe that interference between material is a common cause of forgetting, we'll focus on two different kinds of interference on the next page.

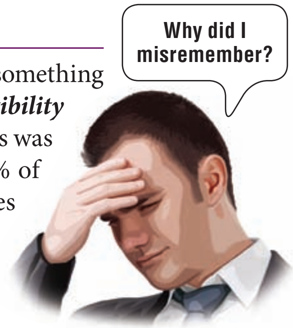
Amnesia

While showing off her new skates, my sister (R.P.) fell down and cracked her head on the hard Minnesota ice. She was knocked unconscious for a short time, and when she woke up the first thing she said was, "What happened?" She couldn't remember what happened because the blow had caused temporary amnesia.

Amnesia, **which may be temporary or permanent, is loss of memory that may occur after a blow or damage to the brain or after disease (Alzheimer's, p. 47), general anesthesia, certain drugs, or severe psychological trauma.**

Depending on its severity, a blow to the head causes the soft jellylike brain to crash into the hard skull, and this may result in temporary or permanent damage to thousands of neurons (p. 50), which form the communication network of the brain. The reason people who strike their heads during car accidents usually have no memories of the events immediately before and during the accident is that the brain crashed into the skull, which interferes with the neurons' communication network, disrupts memory, and results in varying degrees of amnesia (Riccio et al., 2003).

Distortion



Why did I misremember?

We may not be aware of the times we misremember something due to memory distortions caused by ***bias*** or ***suggestibility*** (G. H. Bower, 2005; Schacter, 2001). For example, bias was operating when college students remembered 89% of their high school A grades but only 29% of D grades or when divorcing couples remembered mostly the bad times, not the good (Bahrick et al., 1996). Suggestibility was operating when victims of crimes wrongly identified persons who were later cleared by DNA evidence (Zernike, 2006). Because of bias and suggestibility, we forget or misremember things, often without being aware of the memory distortion.

Next, we'll more closely examine two important reasons for forgetting—interference and poor retrieval cues.

C. Reasons for Forgetting

Interference

What if you study for three exams?

Sooner or later, every student faces the problem of having to take exams in several different courses on the same day. This situation can increase the chances of forgetting material because of something called interference.

The theory of ***interference*** says that we may forget information not because it is no longer in storage or memory but rather because old or newer related information produces confusion and thus blocks retrieval from memory.

Students who take multiple tests on the same day often complain of studying long and hard but forgetting information that they knew they knew. In this case the culprit may be interference. Similarly, if you take two or more classes in succession, you may find that information from one class interferes with learning or remembering information from the others. We'll explain the two kinds of interference—proactive and retroactive—and how each can lead to forgetting.

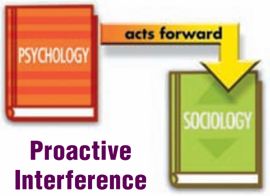
Proactive Interference

The first thing to remember about interference is that it can act forward, which is called proactive, or act backward, which is called retroactive. The prefix *pro* means "forward," so *proactive* interference "acts forward" to interfere with recalling newly learned information.

Proactive interference occurs when old information (learned earlier) blocks or disrupts the remembering of related new information (learned later).

Here's how proactive interference can work.

1. Psychology information.
For two hours you study for a test in psychology. The more psychology terms you store in memory, the more potential this psychology information has to "act forward" and disrupt any new and related information you study next.



Material learned EARLIER (psychology) interferes with learning new information (sociology).

2. Psychology information acts forward.
For the next two hours you study for a test in sociology. You may experience difficulty in learning and remembering this new sociology information because the previously learned psychology terms can "act forward" and interfere with remembering new and related terms from sociology.

3. Proactive interference.
When you take your sociology exam, you may forget some of the sociology terms you studied because of proactive interference: Previously learned psychology terms "act forward" to interfere with or block the recall of the more recently learned and related sociology terms (M. C. Anderson, 2009a).

Retroactive Interference

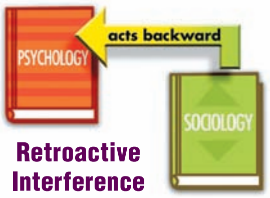
Note that the prefix *retro* means "backward," so *retroactive* interference means "acting backward" to interfere with recalling previously learned information (M. C. Anderson, 2009a).

Retroactive interference occurs when new information (learned later) blocks or disrupts the retrieval of related old information (learned earlier).

Here's how retroactive interference works.

1. Psychology information.
From 1:00 to 3:00, you study for a test in psychology. Then from 3:00 to 6:00, you study for a test in sociology.

2. Sociology information acts backward.
You may experience difficulty in remembering the psychology terms you learned earlier because the sociology terms recently learned may "act backward" and disrupt earlier learned and related psychology terms.



Material learned LATER (sociology) disrupts learning new information (psychology).

3. Retroactive interference.
When you take the psychology exam, you may forget some of the psychology terms you studied earlier because of retroactive interference: Recently learned sociology terms "act backward" to interfere with or block the recall of earlier learned and related psychology terms.

Interference, both proactive and retroactive, is one of the two most common reasons for forgetting (Roediger & McDermott, 2005). Interference may also cause serious mistakes if eyewitnesses identify the wrong person, as happened in the study we discussed at the beginning of this module.

Why Did Viewers Forget the Mugger's Face?

We began this module by asking why only 200 out of 2,000 viewers correctly identified a mugger's face that was shown for several seconds on television. One reason viewers forgot the mugger's face is that one or both kinds of interference were operating.

If ***proactive interference*** was operating, it means that previously learned faces acted forward to block or disrupt remembering of the newly observed mugger's face.

If ***retroactive interference*** was operating, it means that new faces learned since seeing the mugger's face acted backward to block or disrupt remembering of the mugger's face.

Thus, we may forget information that we did indeed store in long-term memory because of one or both kinds of interference.

Besides interference, the other most common reason for forgetting involves inadequate retrieval cues, our next topic.

Retrieval Cues

Where did I park it?

Have you ever parked your car in a mall and later roamed around the huge lot trying to find it? In that case, the reason for your forgetting probably involved poor retrieval cues (M. C. Anderson, 2009c).

Retrieval cues are mental reminders that you create by forming vivid mental images of information or associating new information with information that you already know.

psychology
computer
freud
library

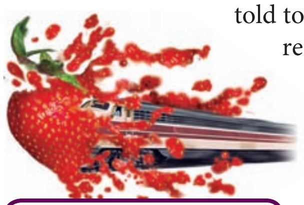
Poor retrieval cues result in haphazard memory storage.

Retrieval cues are also important in hiding things. Researchers asked students to hide things either in common places, such as drawers or closets, or in unusual places, such as old shoes or cereal boxes. Later, when asked to locate the hidden objects, students remembered objects hidden in common places and forgot those hidden in unusual places (Winograd & Soloway, 1986). Forgetting hiding places (which we have done) and forgetting parking places (which we have done) point to the need for creating good retrieval cues.

Forming Effective Retrieval Cues

One reason we forget things (definitions, names, phone numbers) is that we did not take the time to create effective retrieval cues (discussed on pp. 248–249). You can form effective retrieval cues by creating vivid mental images of the information, making associations between new and old information, or making somewhat bizarre but memorable associations.

For example, researchers wondered which types of sentences students would remember better: common sentences, such as “The sleek new train passes a field of fresh, juicy strawberries,” or bizarre sentences, such as “The sleek new train is derailed by the fresh, juicy strawberries.” As a computer randomly presented 12 common and 12 bizarre sentences, students were told to form vivid mental images of the scenes. When retested later, subjects recalled significantly more bizarre than common sentences. Researchers concluded that subjects remembered better the bizarre sentences because they formed better mental images or associations, which produced better retrieval cues (Robinson-Riegler & McDaniel, 1994). Poor retrieval cues may also be a problem in eyewitness testimony.



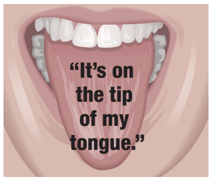
Vivid mental images make great retrieval cues.

Retrieval cues and interference. There have been cases in which eyewitnesses identified assailants who were later proven innocent based on DNA evidence (Dowling, 2000). One reason eyewitnesses were mistaken is that the emotional and traumatic events prevented them from forming effective ***retrieval cues.*** Another reason the eyewitnesses made mistakes is ***interference;*** that is, the faces of the accused assailants somewhat resembled and interfered with their recognizing the real assailants. These examples show that forgetting can result from poor retrieval cues, no associations, or interference (S. C. Brown & Craik, 2005).

Another example of forgetting, which involves retrieval cues and interference, usually begins with someone saying, “It’s on the tip of my tongue.”

Tip-of-the-Tongue Phenomenon

Most of us have had the frustrating experience of feeling we really do know the name of a movie, person, or song but cannot recall it at this moment. This kind of forgetting is called the tip-of-the-tongue phenomenon.



“It’s on the tip of my tongue.”

The ***tip-of-the-tongue phenomenon*** refers to having a strong feeling that a particular word can be recalled, but despite making a great effort, we are temporarily unable to recall this particular information. Later, in a different situation, we may recall the information.

Research shows the tip-of-the-tongue phenomenon is nearly universal, occurs about once a week, and most often involves names of people and objects. Its frequency increases with age, and usually the thing is remembered some minutes later (Branan, 2008; B. L. Schwartz, 1999).

There are three explanations for the tip-of-the-tongue phenomenon. In some cases, information was encoded with inadequate retrieval cues, and so we must think up other associations (first letter of name, where last seen) for recall (Neath & Surprenant, 2003). In other cases, information is being blocked by interference from similar-sounding names or objects. Once we think of something else, the interference stops and the information pops into our memory (Koriat, 2005). Last, the brain region responsible for processing and producing sound has been reported to be less active as tip-of-the-tongue moments become more frequent (Shafto et al., 2007).

An interesting feature of retrieval cues is that such cues can also come from our states of mind.

State-Dependent Learning

What happens when you get angry?

When you yell at someone for doing the same annoying thing again, why is it that a long list of related past annoyances quickly comes to mind? One answer involves state-dependent learning.

State-dependent learning means that it is easier to recall information when you are in the same physiological or emotional state or setting as when you originally encoded the information.

For example, getting angry at someone creates an emotional and physiological state that triggers the recall of related past annoyances. Evidence for state-dependent learning comes from a wide range of studies in which subjects (humans, dogs, rats) learned something while they used a certain drug, were in a certain mood, or were in a particular setting and later showed better recall of this information when tested under the original learning conditions (M. C. Anderson, 2009c; S. C. Brown & Craik, 2005). These state-dependent studies indicate that retrieval cues are created by being in certain physiological or emotional states or in particular settings and returning to these original states helps recall information that was learned under the same conditions.

Being in the same state (emotional) improves recall.

Next, we’ll look inside the brain to see what happens during remembering and forgetting.

D. Biological Bases of Memory

Location of Memories in the Brain

Where do you put all those memories?

If you learned only 500 new things every day, that adds up to storing 180,000 new memories every year and 3,600,000 memories after twenty years. To figure out how the brain stores and files away 3,600,000 memories (a very conservative estimate), researchers have studied the formation of memories in sea slugs, which have a relatively simple nervous system, in brain-damaged individuals, who show deficits in some kinds of memory but not others, and in individuals who are having their brains scanned for neural activity while they are using different kinds of memory (Cabeza & Nyberg, 2003; Zola & Squire, 2005). Based on these studies, researchers have identified the several different areas of the brain that are involved in processing and storing different kinds of thoughts and memories.

1 Cortex: Short-Term Memories

When you look up a new phone number, you can hold it in short-term memory long enough to dial the number. Your ability to hold words, facts, and events in short-term memory depends on activity in the ***cortex,*** which is a thin layer of brain cells that covers the surface of the forebrain (indicated by the thin red line on the outside of the brain).

People may have brain damage that prevents them from storing long-term memories, but if their cortex is intact, they may have short-term memory and be able to carry on relatively normal conversations. However, if they cannot store long-term memories, they would not later remember having those conversations.

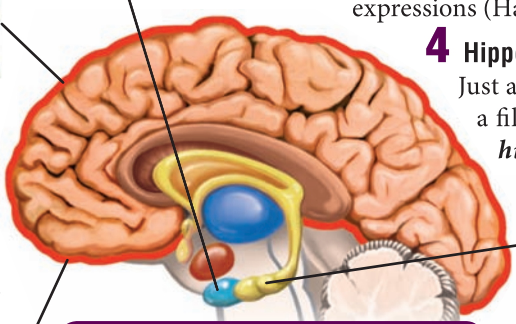
2 Cortex: Long-Term Memories

If you learn the words to a song, these words are stored in long-term memory. Your ability to remember or recall songs, words, facts, and events for days, months, or years depends on areas widely spread throughout the ***cortex.***

People may have brain damage that prevents them from learning or remembering any new songs. However, if they have an intact cortex, they may remember the words from songs they learned before their brain damage because such information would have already been safely stored in their cerebral cortex (indicated by the thin red line on the outside of the brain).

3 Amygdala: Emotional Memories

Suppose that each time you hear a particular song associated with a special person, you have a romantic feeling. The romantic feeling associated with this emotional memory is provided by the ***amygdala,*** which is located in the tip of the temporal lobe and receives input from all the senses. Research using brain scans found that the amygdala plays a critical role in the long-term processing of emotionally intense experiences (Squire & Kandel, 2009). For example, the amygdala helps us recognize emotional facial expressions, especially fearful or threatening ones, and adds a wide range of emotions (positive and negative) to our memories (R. J. Dolan, 2002; Ohman, 2002). So, humans with damage to the amygdala still have memories but the memories lose their emotional impact, such as no longer finding loud noises unpleasant or no longer recognizing emotional facial expressions (Hamann et al., 2002).



Areas of the brain involved in memory

4 Hippocampus: Transferring Memories

Just as the "Save" command on your computer transfers a file into permanent storage on your hard drive, the ***hippocampus*** transfers words, facts, and personal events from short-term memory into permanent long-term memory. The hippocampus is a curved, finger-sized structure that lies beneath the cortex in the temporal lobe.

The hippocampus is vital for storing certain kinds of memories. For example, individuals with hippocampal damage cannot save any declarative memories, such as new words, facts, or personal events, because the hippocampus is necessary for transferring declarative information from short-term into long-term memory (Zeineh et al., 2003). However, people with hippocampal damage CAN learn and remember nondeclarative or procedural information, such as acquiring motor skills or habits (tying one's shoes, walking up the stairs, playing tennis) (R. D. Fields, 2005). But, if asked, people with hippocampal damage CANNOT remember actually performing a motor skill (playing tennis) because performing the skill (I played tennis) is a personal event (declarative memory). Thus, the hippocampus is necessary for transferring declarative information (words, facts, and events) from short-term into long-term memory but not for transferring nondeclarative or procedural information (motor skills and habits) (Zola & Squire, 2005).

Hippocampus: Retrieving Memories

Researchers have long assumed that the hippocampus is also somehow involved in retrieving memories. Only recently have they discovered that the storage and retrieval of memory actually involve activation of the same neurons located in the hippocampus (Gelbard-Sagiv et al., 2008).

5 Brain: Memory Model

Recent findings indicate that your ***cortex*** stores short-term memories as well as long-term memories; your ***hippocampus*** transfers or saves declarative information in long-term memory but does not transfer nondeclarative or procedural information into long-term memory; and your ***amygdala*** adds emotional content to positive and negative memories (Tulving & Craik, 2005). Now that you know the location of memories in the brain, we can examine how individual memories are formed.

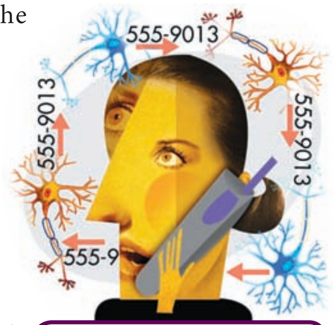
Making a Short-Term Memory

How to make a short-term memory?

Suppose you just looked up the phone number 555-9013 and repeat it as you dial. Researchers believe that your brain may store that number in short-term memory by using interconnected groups of neurons that are called neural assemblies.

Neural assemblies are groups of interconnected neurons whose activation allows information or stimuli to be recognized and held briefly and temporarily in short-term memory.



Example of neural assembly

The figure on the right shows how a very simplified neural assembly might work. Some information, such as repeating a phone number, activates a neural assembly that holds the phone number in short-term memory. However, if you switch your attention to something else before encoding the number in long-term memory, this neural assembly stops and the phone number is gone and forgotten. Researchers believe that neural assemblies are one mechanism for holding information in short-term memory (E. E. Smith, 2000). However, as you'll see next, permanently storing information in long-term memory involves chemical or structural changes in the neurons themselves.

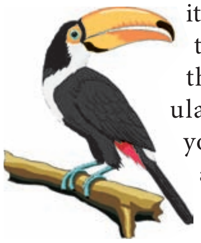
Making a Long-Term Memory

How to make a long-term memory?

Besides studying memory by genetically altering mice brains, researchers also study memory in sea slugs because their nervous system contains about 20,000 neurons versus billions in the human brain. After the sea slug has learned a simple task, such as tensing its muscular foot in response to a bright light, researchers can dissect the sea slug's nervous system and look for chemical or physical changes associated with learning (Kandel & Abel, 1995). We'll focus on one mechanism—long-term potentiation, or LTP—that researchers believe is involved in forming long-term memories.

Long-Term Potentiation (LTP)

1 One way to learn the name of the large orange-beaked bird on the left is to repeat its name, "toucan," several times. After you repeat this name (repeated stimulation), some neurons in your brain actually grow and change to form new connections with other neurons (Goldstein, 2008; Stickgold & Ellenbogen, 2008). This neural change, which is involved in forming long-term memories, is part of a complicated process called LTP.

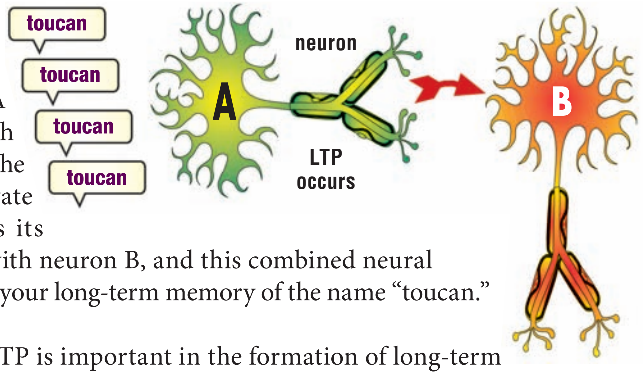


Long-term potentiation, or ***LTP,*** refers to changes in the structure and function of neurons after they have been repeatedly stimulated.

For example, by repeating the name "toucan," you are repeatedly stimulating neurons.

2 We'll use only two neurons (perhaps many hundreds are involved) to make the LTP process easier to understand. In the figure below, repeating the name "toucan" stimulates neuron A, which produces LTP and causes neuron A to grow and form new connections with neuron B.

3 LTP changes the structure and function of neuron A so it becomes associated with the name "toucan." To recall the name of this bird, you activate neuron A, which activates its newly formed connections with neuron B, and this combined neural activation forms the basis for your long-term memory of the name "toucan."



4 Researchers found that LTP is important in the formation of long-term memory because when the occurrence of LTP was chemically or genetically blocked in sea snails or mice, these animals could not learn a classically conditioned response or a water maze (Mayford & Korzus, 2002; Tonegawa & Wilson, 1997). Blocking the occurrence of LTP blocked the formation of long-term memories. Thus, neuroscientists believe the LTP process, which changes the ***structure*** and function of neurons, is the most likely basis for learning and memory in animals and humans (Goldstein, 2008; Tsien, 2000).

Forgetting Unwanted Long-Term Memories

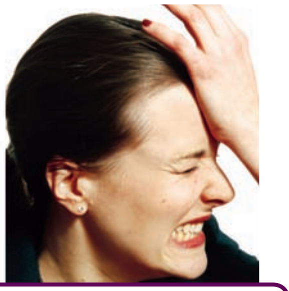
Can the brain forget bad memories?

Once a long-term memory is made, can you intentionally forget an unwanted memory? Researchers have been examining this question and have found some remarkable biological findings that suggest we do have the ability to intentionally forget bad memories.

Researchers have shown that reduced activity in the hippocampus and amygdala (brain structures responsible for consciously thinking about memories and fear conditioning) leads people to forget their unwanted memories (M. C. Anderson et al., 2004; Depue et al., 2007). Researchers can actually predict how much forgetting people experience by examining their pattern of brain activity!

As a result of this research, we have a better understanding of how people cope with memories after traumatic experiences and the brain dysfunction that occurs in people who experience ongoing traumatic memories.

We'll further explore the topic of forgetting unwanted memories in the Critical Thinking section (p. 278).



Brain dysfunction may explain why this woman can't forget her bad memories.

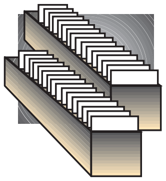
Concept Review

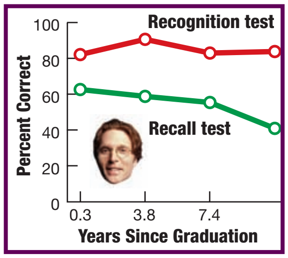
1. If you retrieve previously learned information without the aid of any external cues, you are using a process of remembering called (a) ____________. If you identify or match information that you have previously learned, you are using a process of remembering called (b) ____________.



2. Memory files or categories that contain related information organized around a specific topic are called (a) ____________. One theory of memory organization says that the separate memory files, or nodes, in which we file related ideas are interconnected in a gigantic system. This idea is called (b) ____________.

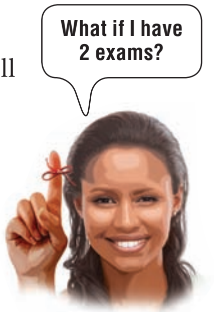
3. According to network theory, some nodes are arranged so that more concrete information is at the bottom and more abstract information is at the top; this order is called a ____________.

4. A diagram of the amount of previously learned information that subjects can recall or recognize across time is called a ____________. We tend to remember information that is familiar and interesting and forget information that is unfamiliar and uninteresting.



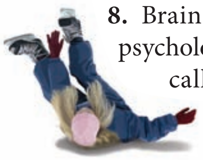
5. According to Sigmund Freud, information that is threatening to our self-concept is automatically driven into our unconscious, from which we cannot retrieve it at will. This process is called ____________.

6. One common reason for forgetting is that other related memories already stored in long-term memory may interfere with or block recall of some particular memory; this idea is called ____________.



What if I have 2 exams?

7. Another reason for forgetting comes from a lack of associations between new information and information we already know; this reason has to do with the quality of the ____________.



8. Brain damage, a blow to the head, drug use, or severe psychological stress may cause a form of forgetting called (a) ____________, which results when the brain's (b) ____________ network is temporarily or permanently disrupted.

Why did I misremember?

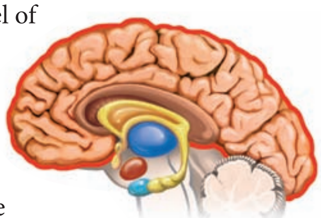
9. We may not be aware of times when we misremember something because of distortions in memory. Two common causes of memory distortions are ____________ and ____________.

PSYCHOLOGY
SOCIOLOGY

10. If we forget information not because it is lost from storage but rather because other information gets in the way and blocks its retrieval, this process is called (a) ____________. If information learned earlier blocks, interferes with, or disrupts the retrieval of information that was learned later, it is called (b) ____________. If information learned later blocks, interferes with, or disrupts the retrieval of information learned earlier, it is called (c) ____________.

11. Mental reminders that we create by making images or associating new information with information that we already know are called (a) ____________. If you do not form effective retrieval cues when learning new information, you will likely have a difficult time (b) ____________ this information from long-term memory.

12. Sometimes, despite making a great effort, you are temporarily unable to recall information that you absolutely know is in your memory. This is called the ____________ phenomenon.



13. According to one memory model of the brain, short-term memories are formed and stored in different parts of the (a) ____________. Long-term memories are also stored in different parts of the (b) ____________, although these kinds of memories are not formed there. Declarative information is transferred by the (c) ____________ into long-term memory, which is stored in different parts of the cortex. However, the hippocampus is not involved in transferring motor skills or habits, which are part of (d) ____________ information, into long-term memory. Both positive and negative emotional associations are added to memories by an area in the temporal lobe called the (e) ____________.

Answers: *1. (a) recall, (b) recognition; 2. (a) nodes, (b) network theory; 3. hierarchy; 4. forgetting curve; 5. repression; 6. interference; 7. retrieval cues; 8. (a) amnesia, (b) communication; 9. bias, suggestibility; 10. (a) interference, (b) proactive interference, (c) retroactive interference; 11. (a) retrieval cues, (b) recalling or retrieving or remembering; 12. tip-of-the-tongue; 13. (a) cortex, (b) cortex, (c) hippocampus, (d) procedural, (e) amygdala*

E. Mnemonics: Memorization Methods

Improving Your Memory

Do you complain about forgetting things?

At one time or another, almost everyone complains about forgetting something. Many of our students complain about forgetting information that they really knew but couldn't recall during exams. This kind of forgetting has several causes: There may be ***interference (proactive and retroactive)*** from information studied for related classes; there may be ***poor retrieval cues*** that result from trying to learn information by using rote or straight memorization; or students may not use elaborative rehearsal (p. 249), which involves making associations between new and old information.

How can I improve my memory?

After about age 40, adults begin to complain about forgetting things that they never forgot before. For example, memory researcher Daniel Schacter, at age 50, complained, "Reading a journal article 15 years ago, I would have it at my fingertips. Now, if I don't deliberately try to relate it to what I already know, or repeat it a few times, I'm less likely to remember it" (Schacter, 1997, p. 56). This kind of forgetting is commonly caused by poor retrieval cues, which result from being busy or distracted and not having or taking the time to create meaningful associations.

If you hear about memory courses that claim to greatly improve your memory, what these courses usually teach are how to use mnemonic methods.

Mnemonic *(ni-MON-ick)* ***methods*** are ways to improve encoding and create better retrieval cues by forming vivid associations or images, which improve recall.

We'll discuss two common mnemonic methods—method of loci and peg method—that improve memory (M. W. Eysenck, 2009b).

Method of Loci

If you need to memorize a list of terms, concepts, or names in a particular order, an efficient way is to use the method of loci.

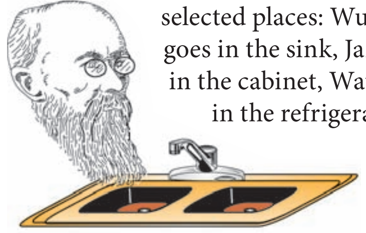
The ***method of loci*** *(LOW-sigh)* is an encoding technique that creates visual associations between already memorized places and new items to be memorized.

We'll use the following three steps of the method of loci to memorize names of early psychologists: Wundt, James, and Watson.

Step 1. Memorize a visual sequence of places (*loci* in Latin means "places"), such as places in your apartment where you can store things. Select easily remembered places such as in your kitchen: sink, cabinet, refrigerator, stove, and closet.

Step 2. Create a vivid association for each item to be memorized. For example, picture Wundt hanging from a bridge and saying, "I wundt jump."

Step 3. Once you have created a list of vivid associations, mentally put each psychologist in one of the selected places: Wundt goes in the sink, James in the cabinet, Watson in the refrigerator.



To recall this list of early psychologists, you take an imaginary stroll through your kitchen and mentally note the image stored in each of your memorized places.

Peg Method

Another useful mnemonic device for memorizing a long list, especially in the exact order, is the peg method.

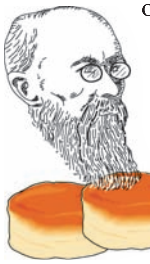
The ***peg method*** is an encoding technique that creates associations between number-word rhymes and items to be memorized.

The rhymes act like pegs on which you hang items to be memorized. Let's use the two steps of the peg method to memorize our three early psychologists: Wundt, James, Watson.

Step 1. Memorize the list of peg words shown on the left, which consists of a number and its rhyming word.

one is a bun
two is a shoe
three is a tree
four is a door
five is a hive

Step 2. Next, associate each of the items you wish to memorize with one of the peg words. For instance, imagine Wundt on a bun, James with two left shoes, and Watson stuck in a tree.



To remember this list of early psychologists, you recall each peg along with its image of an early psychologist that you placed there.

Effectiveness of Methods

A national magazine writer, who was 41 years old and complained about forgetfulness, decided to improve her memory by trying three methods (Yoffe, 1997).

First, she took a 3-hour memory-enhancement class ($49) that focused on the peg method. The magazine writer concluded that the peg method was impressive and if she were back in college, she would use it to memorize all the new facts.

Second, she listened to an audiocassette program ($79) that promised to release the "perfect photographic memory" that everyone already had. The audio program focused on using the peg method without much application to real life. Contrary to the audiocassette's promise, memory researchers report that photographic memories are as rare as duck's teeth (Schacter, 1996).

Third, she read a memory-improvement book ($10) that described the peg method, how to pay attention, and the importance of creating associations and images.

As this writer's experience illustrates, improving one's memory requires making the effort to use good encoding, such as elaborative rehearsal, which means creating good associations that, in turn, produce good retrieval cues and improve memory.

As the percentage of people over 50 increases, so does interest in ***memory-enhancing drugs,*** such as the popular herbal supplement ginkgo. However, researchers found that ginkgo did NOT improve memory or concentration in healthy adults (Solomon et al., 2002). Still, the search for effective memory enhancers continues. Researchers have found ways to improve memory in mice, and they are now testing memory-enhancing drugs in humans (Rovner, 2007).

Next, we'll discuss how cultural influences can affect what you remember.

F. Cultural Diversity: Aborigines Versus White Australians

Retrieval Cues

How do you survive in a desert versus an office meeting?

Suppose you lived in the harsh, endless, barren desert world of western Australia, where many of the native Aborigines live (top photo). For about 30,000 years, the Aborigines have survived by using visual landmarks to remember the exact locations of water, food, and game in vast stretches of unmapped country (R. A. Gould, 1969). Because the Aborigines use few, if any, written records, their survival in this barren desert largely depends on their ability to store, or encode, enormous amounts of visual information, such as landmarks for food, water, and game. Lacking reading and writing skills, Aborigines primarily encode information about the desert by using ***visual retrieval cues,*** which are later used to recall information.

Survival depends on VISUAL cues.

Survival depends on VERBAL cues.

In contrast, most of us live in an industrial urban culture, in which survival largely depends on the ability to read and write and store an enormous amount of verbal, written, and computer-related information (bottom photo). Successfully surviving in an industrial culture is greatly dependent on the ability to store, or encode, enormous amounts of written and verbal information by using ***verbal retrieval cues.***

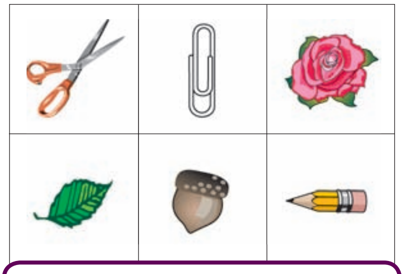
These two examples show that survival in the Aboriginal culture depends on encoding and remembering visual information, while surviving in an industrial culture depends on encoding and remembering verbal (written) information. This cultural difference predicts that people would perform differently on tests, depending on whether the tests emphasized visual or verbal retrieval cues.

Visual Versus Verbal Memory

Psychologist Judith Kearins was not surprised to find that Aborigines scored low on Western-style intelligence tests because these tests emphasize verbal retrieval cues and put Aborigines at a disadvantage. Considering their desert culture, she suspected that Aborigines would perform better on tests that took advantage of their ability to encode with visual retrieval cues.

Using Visual Cues

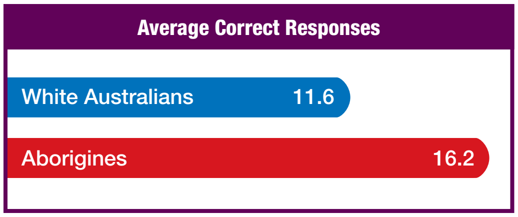
To see if Aborigines were better at visual encoding, Kearins developed a test that emphasized visual retrieval cues. This test consisted of looking at 20 objects that were placed on a board divided into 20 squares. Some objects were natural—stone, feather, leaf; others were manufactured—eraser, thimble, ring. Aborigines and White Australian adolescents were told to study the board for 30 seconds (sample section on right). Then all the objects were heaped into a pile in the center of the board and the children were asked to replace the items in their original locations. The 44 Aborigine adolescents had been reared for the most part in desert tribal ways, had learned a nontraditional form of English as a second language, and were now attending school. The 44 White Australian adolescents lived and attended high school in a relatively large urban area (Perth).



Aborigine students are better at using VISUAL cues than White Australian students.

Performance

Kearins tested the adolescents using four different sets of objects—natural, manufactured, and two combinations. The graph below shows that the Aborigine adolescents performed significantly better in placing objects back in their original locations than did the White Australian adolescents (Kearins, 1981). Another group of researchers essentially replicated Kearins's results using a younger population (average age of 9) of Aborigines and White Australians (Klich & Davidson, 1983).



Culture and Retrieval Cues

Kearins concluded that the Aborigines' survival in the harsh desert landscape encouraged and rewarded their abilities to encode information using visual retrieval cues. In comparison, the urban school setting of the White Australians encouraged and rewarded their ability to encode information using verbal retrieval cues. For example, when questioned about their strategies, many of the Aborigines said that they remembered only the look of the objects on the board. In comparison, White Australians described their strategies in great detail: "I looked at the bottom row and remembered onion, banksia nut, rock, bone, and apple core." These descriptions support the idea that the Aborigines used visual retrieval cues, while the White Australians used verbal retrieval cues. These interesting results suggest that survival needs do shape and reward a particular way of encoding information in memory.

The better performance of Aborigines on visual tasks indicates that culture does influence the encoding and recall of information. Besides culture, other factors, such as the type of information having to be recalled, may also influence memory, as shown next in a study on recalling sexual history in adolescents.

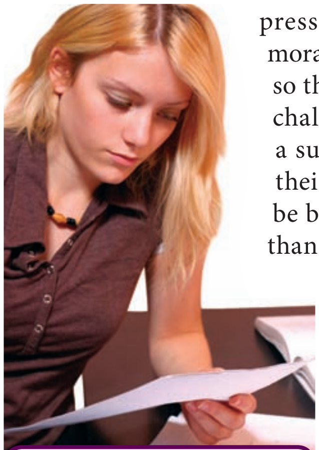
G. Research Focus: Memory Accuracy

How Accurate Are Students' Memories?

Are students telling the truth?

Many schools across the United States offer sex education in an effort to reduce adolescent sexual activity. Some sex education programs encourage students to take virginity pledges to abstain from sexual intercourse until marriage. These programs are considered to be so important that they are promoted by the U.S. government (Rosenbaum, 2006). But, how do we know whether or not these programs actually reduce adolescent sexual activity? Since sexual activity is not a behavior researchers can observe, research methods used to study sexual activity are limited to the survey method (see p. 28).



Surveys are used to question teenagers about their sexual histories.

Using surveys to question teenagers about intimate behaviors, especially their sexual histories, is very challenging. Adolescents may deliberately report false information because they want to present a desirable self-image or because they are being influenced by social pressures. If adolescents' behaviors go against their moral or religious beliefs, they may falsify their answers so they are more consistent with their values. Another challenge in obtaining accurate information by using a survey is that when people are asked to report on their past experiences, their survey responses tend to be based on their current beliefs and behaviors more than on past beliefs and behaviors. Thus, if adolescents have recently changed their beliefs or their sexual behaviors, their recollection of the past may be biased (Rosenbaum, 2006).

If adolescents are inaccurately reporting their sexual histories, it becomes impossible to determine whether sex education programs are effective in reducing sexual activity. This serious concern led a researcher to study whether adolescents accurately recall their sexual histories.

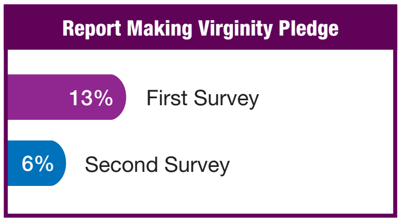
Research Method to Evaluate Memory Accuracy

Why do so many students change their answers?

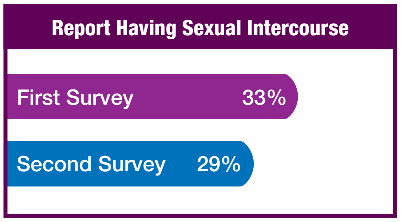
To answer the question of how well adolescents recall their sexual histories, Janet Rosenbaum (2006), a health policy researcher at Harvard University, studied more than 13,000 students in grades 7 to 12 from schools across the United States.

Procedure. The students were questioned two times, a year apart. To respect students' privacy, many personal questions were asked through headphones and students typed their answers into a computer. The questions they were asked included: "Have you ever taken a public or written pledge to remain a virgin until marriage?" Students were also asked if they ever had sexual intercourse.

Results. In the first survey, about 13% of subjects reported having taken a virginity pledge. In the second survey (a year later), only 6% of subjects reported having ever taken a virginity pledge (see left bar graph). Thus, more than half of the subjects who reported having taken a virginity pledge in the first survey later denied having done so. Also, subjects who reported having sexual intercourse for the first time in the second survey were more likely to deny having taken a virginity pledge than those who did not report having sexual intercourse.



When first asked about their sexual histories, about 33% of subjects reported having sexual intercourse, but only 29% of subjects reported having sexual intercourse when questioned during the second survey (see right bar graph). Many subjects who reported having had sexual intercourse during the first survey and who made a virginity pledge for the first time during the second survey denied ever having sexual intercourse. Thus, many subjects changed their minds about their sexual histories, especially if they recently made a virginity pledge.



Conclusion. Many students changed their responses about their sexual histories and whether or not they had taken a virginity pledge. The results of this study show that adolescents who have sexual intercourse after making a virginity pledge are likely to deny having made a pledge. Also, adolescents who have sexual intercourse before making a virginity pledge are likely to deny their sexual histories.

These results raise concern about the reliability of surveys to collect information about sexual activity among adolescents. One explanation for why students changed their answers is that their beliefs changed during the course of the year between the two surveys and students may recall only memories that are consistent with their current beliefs. Students may even report behaviors that never happened but that are consistent with their new beliefs. These types of reporting errors are not uncommon when using surveys to collect information. Overall, the results show that adolescents' memories for sexual behaviors are often inaccurate.

Just as adolescents may misremember information about their sexual histories, research shows that some adults have difficulty recalling their sexual histories as well (Garry et al., 2002). Adults may also misremember when giving eyewitness testimony, our next topic.

Photo Credit: © Peter M. Corr/Alamy

H. Application: Eyewitness Testimony

How Accurate Is an Eyewitness?

On a hot and humid summer night, Jennifer Thompson, a 22-year-old college student, went to bed in her apartment only to wake up frightened by a man lying on top of her holding a knife to her throat. While the man proceeded to rape her, she was committed to studying his every physical feature so she could later help police put him behind bars. When police presented Jennifer with a photo and physical lineup of suspects, she picked Ronald Cotton in both instances. When she was asked if her rapist was present in the courtroom, she again confidently pointed to Ronald Cotton.

DNA evidence proved Poole (left) was the rapist, not Cotton (right), who was falsely identified through eyewitness testimony.

Eyewitness testimony **refers to recalling or recognizing a suspect observed during a potentially very disrupting and distracting emotional situation that may have interfered with accurate remembering.**

For example, Jennifer Thompson's eyewitness testimony was the damning evidence that sent the defendant (an alleged rapist) to prison. After Ronald Cotton spent 10 years in prison, DNA evidence proved that he was not the rapist and implicated another man, Bobby Poole. The man who had been sent to prison because of the victim's eyewitness testimony was found innocent and set free (Lithwick, 2009; L. Stahl, 2009). This example points to at least three problems with eyewitness testimony.

The first problem is that juries assume eyewitness testimony is the best kind of evidence because it is so accurate and reliable. However, in the United States, more than 230 people have been wrongfully convicted of crimes and later been freed because of DNA evidence. Of the 230 convictions, about 77% (177) had been based on (mistaken) eyewitness testimony (Lithwick, 2009).

Own-race bias. In the rape case discussed here, the eyewitness was a White female and the accused rapist was a Black man. This case brings up another source of eyewitness error: problems in correctly identifying individuals of another race. For example, researchers found that an eyewitness of one race is less accurate when identifying an accused person of another race (Scheck, 2008; G. Wells, 2009). The finding that people better recognize faces of their own race than faces of other races is called ***own-race bias,*** which can distort and decrease the accuracy of eyewitness testimony (Ferguson et al., 2001). For instance, when White people see the faces of Cotton and Poole (left photos), they report the faces look very similar, but when Black people look at the pictures, they say the two men look nothing alike (G. Wells, 2009).

A second problem with eyewitness testimony is that the police and juries generally assume that the more confident an eyewitness is, the more accurate is the testimony. For example, the witness in this rape case was very confident when she pointed at the accused man and said, "There is no doubt in my mind." However, there is only a moderate association or correlation (+0.37) between how correct the identification of an eyewitness is and how much confidence the eyewitness feels about his or her identification (G. L. Wells & Olson, 2003). This means that an eyewitness's confidence is not a good indication of accuracy.

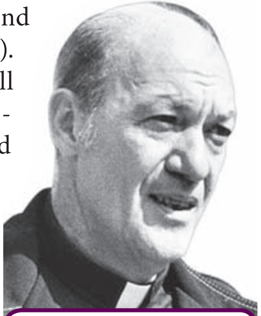
A third problem is eyewitnesses may make errors if law enforcement officials ask misleading or biased questions or make suggestions about the perpetrator's identification. In these cases, eyewitnesses may unknowingly accept the misinformation as fact and give unreliable testimony (B. Bower, 2003b). For example, consider the following case of an eyewitness's mistaken identity.

Can an Eyewitness Be Misled?

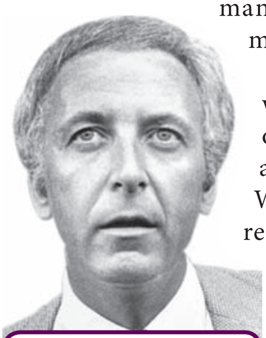
Some years ago a series of armed robberies occurred in the Wilmington, Delaware, area. The police had few leads in the case until a local citizen said that a Roman Catholic priest, Father Bernard Pagano, looked like the sketch of the robber.

At his trial, seven eyewitnesses positively identified Father Pagano (left photo) as the robber. But at the last minute, another man, Ronald Clouser (right photo), stepped forward and confessed to the robberies and Father Pagano was released (Rodgers, 1982).

As you look at these two photos, you will wonder how this case of mistaken identity could possibly have happened. Ronald Clouser is shorter, 14 years younger, and not nearly as bald as Father Pagano; besides, he has different facial features. Why, then, did seven eyewitnesses say with certainty that Father Pagano was the robber they had seen? One reason involves how the witnesses were questioned. Apparently, before the witnesses were questioned and shown photos of the suspects, the police had suggested the possibility that the robber was a priest. After being prompted to look for a priest, the witnesses focused on the few similarities Father Pagano had to the real robber. Because Father Pagano was the only suspect wearing a clerical collar, the witnesses concluded that he must be the robber. This example is but one of many that show how eyewitness testimony may be distorted or biased.



Seven people identified Father Pagano . . .



. . . but Ronald Clouser confessed to being the robber.

Because of potential problems with eyewitness testimony, the U.S. Department of Justice released a guide for collecting and preserving eyewitness evidence (G. L. Wells et al., 2000). This guide, based on research findings discussed in this Application section, warns law enforcement agencies about the kinds of errors that eyewitnesses may make. We'll next discuss more of the research findings that show how eyewitness testimony may be changed or biased.

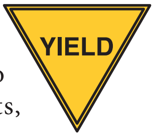
Can Questions Change the Answers?

Because of concern about the reliability of eyewitness testimony, Elizabeth Loftus (1979, 2003a) studied whether people can be misled and do misremember, especially if they are given false information. We'll describe some of Loftus's experiments that demonstrate how subjects misremembered what they saw or heard.

Did the Car Pass the Barn?

In one experiment, subjects watched a film of an automobile accident and then were questioned about what they saw. One of the questions contained a false piece of information: "How fast was the red sports car going when it passed the barn while traveling along the country road?" Although there was no barn in the film, 17% of the subjects said they had seen a barn, indicating that people may believe misinformation if it fits the overall scene or pattern (Loftus, 1975).

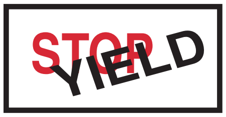
Was There a Stop Sign?



In a well-known study by Loftus and colleagues, subjects were first shown slides of a traffic accident involving a stop sign and then asked a series of questions about the accident. Some of the questions were not misleading and asked about the presence of a stop sign. Other questions were deliberately misleading and did not mention the stop sign but asked about the presence of a yield sign. Later, when subjects were asked whether they had seen a stop sign or a yield sign, those subjects who had been misled by earlier questions about a yield sign were more likely to report seeing a yield sign than subjects who were not misled (Loftus et al., 1978). These results, which show that subjects can be misled by being given false but related information, have been replicated by many other researchers (Neisser & Libby, 2005).

How Does False Information Alter Memory?

Based on many such studies, Loftus and Hoffman (1989) concluded that if misleading information is introduced during questioning after an event, people may believe this misinformation and report events that they did not see.



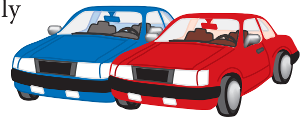
According to Loftus, eyewitnesses believed the false information they were told, rather than what they saw, because the false information altered or overwrote their original, true memory (Loftus & Loftus, 1980). This explanation, which has generated much research and debate, says that people misremember because of a memory impairment: the true memory was erased or overwritten (D. G. Payne et al., 1994). However, other researchers argue that the original, true memory is still there but is difficult to retrieve (Zaragoza & Lane, 1994). Whatever the cause, these many studies indicate that people (witnesses) do misremember when given misleading information.

Is What You Say, What You Believe?

The debate over whether false information overwrites the original memory has not been settled. However, what has been settled is that sometimes people do come to believe that they actually remember seeing things that were merely suggested to them; this phenomenon is called source misattribution.

Source misattribution is a memory error that results when a person has difficulty deciding which of two or more sources a memory came from: Was the source something the person saw or imagined, or was it a suggestion?

For example, suppose you saw a hit-and-run accident involving a dark red car. During questioning, you are asked the color of the car that drove off. As you're thinking that the car was dark red, you remember hearing another bystander say, "The car was dark blue."

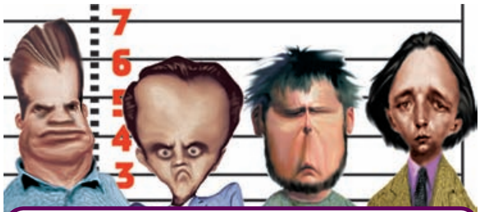


Did you see a red or blue car?

Source misattribution would occur if you said that the car was dark blue (suggestion you heard) rather than dark red (something you saw). Researchers have found that false suggestions, misleading questions, and misinformation can result in source misattribution and create false memories (Roediger & McDermott, 2005). False memories that can result from source misattribution, such as suggestions or misleading questions, are one reason that court officials may question the accuracy of eyewitness testimony.

Which Interview Technique Works Best?

Suppose you witnessed a robbery but had trouble picking the suspect out of a police lineup. To help you provide reliable information about the suspect, you might be questioned using a procedure called the cognitive interview (M. W. Eysenck, 2009a).



A cognitive interview is a more effective method for questioning eyewitnesses.

The ***cognitive interview*** is a technique for questioning people, such as eyewitnesses, by having them imagine and reconstruct the details of an event, report everything they remember without holding anything back, and narrate the event from different viewpoints.

The cognitive interview has proved very useful in police interrogation: Detectives trained in cognitive interview techniques obtained 47–60% more information from victims and suspects than detectives using the standard police interrogation method (Gwyer & Clifford, 1997). The cognitive interview is a very effective way to increase correct recall and avoid making suggestions that might create false memories and increase errors of source misattribution in children, adults, and senior citizens from varying educational backgrounds (L. M. Stein & Memon, 2006).

Psychologists have answered many questions about how eyewitnesses can be misled as well as how to improve the reliability of their testimony, which may result in life-or-death decisions. Because most jurors do not know that eyewitness testimonies are unreliable, many courts in the United States allow experts to testify about the reliability of eyewitnesses so juries are made aware of the same studies and findings that you have just read (McVeigh, 2006; Pezdek, 1995). England has gone as far as barring cases when the only evidence is an eyewitness.

Summary Test

A. Organization of Memories

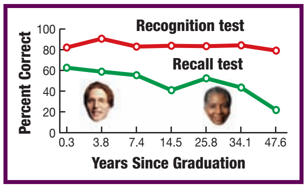
1. If you are asked to retrieve previously learned information without the aid of external cues, you are using a process of remembering called (a) ________________, which is generally more difficult. If you are asked to answer multiple-choice questions, you can identify or match information and use a process of remembering called (b) ________________, which is generally less difficult.

2. According to one theory of memory organization, we encode or file related ideas in separate categories called ________________.

3. We form links between nodes by forming associations. The idea that the interconnected nodes form a gigantic system is called ________________ theory.

4. An arrangement in which nodes are organized in a logical manner, with more concrete information at the bottom and more abstract information at the top, is called a ________________.

B. Forgetting Curves



5. If the amount of previously learned information that subjects can recall or recognize across time is plotted, the resulting graph is called a ________________. For example, Ebbinghaus demonstrated that the majority of nonsense syllables are forgotten relatively quickly—within hours. However, other studies showed that more relevant and interesting information may be remembered for many years.

C. Reasons for Forgetting

6. If you forget because other memories interfere with or prevent retrieval of some particular memory, it is called (a) ________________. If you forget because information that was learned earlier interferes with information learned later, it is called (b) ________________ interference. If you forget because information that was learned later interferes with information learned earlier, it is called (c) ________________ interference.

7. Forgetting information because it was poorly encoded means that you failed to form new associations or reminders, which results in poor or inadequate ________________.

8. Freud said you may forget information that is threatening to your self-concept because it is automatically pushed into your unconscious, from which you cannot retrieve it at will. This idea of Freud's is called ________________.

9. If a person experiences a blow to the head, has severe psychological trauma, or takes or is given certain drugs, that person may forget things because of having ________________.

10. You may not always be aware of when you misremember something or when your memory is distorted because of the influence of ________________ and ________________.

11. To increase the chances of remembering items from long-term memory, we can create reminders that associate new information with information that we already know; these reminders are called ________________.

12. There are times you are absolutely sure that certain information is stored in memory but you are unable to retrieve it. This experience is called the ________________ phenomenon.

13. Besides creating retrieval cues, it may also be easier to recall information when you are in the same physiological or emotional state as when you originally learned it; this phenomenon is called ________________.

D. Biological Bases of Memory

555-9013
555-9013
555-9013
555-9

14. Different areas of the brain are involved in different memory processes. For example, the ability to hold words, facts, or events (declarative information) in short-term memory depends on activity in the (a) ________________. The ability to transfer information about words, facts, and events (declarative information) from short-term into long-term memory depends on activity in the (b) ________________. If this structure were damaged, a person could carry on a conversation but would not (c) ________________ the conversation the next day.

15. The ability to recall words, facts, and events (declarative information) from the past involves activity in the outer covering of the brain, which is called the (a) ________________. For example, if patients have an intact cortex, they can remember past events because these events are already stored in the cortex. However, they may have difficulty remembering any new words, facts, or events (declarative information) because of damage to their (b) ________________.

16. The ability to transfer motor skills and habits, which is part of ________________ memory, does not involve the hippocampus. Even though a person with damage to the hippocampus can store procedural information, that person would have no memory of having engaged in that event (declarative information).

17. The area of the brain that adds emotional feelings to memories is called the ________________. This area is involved in forming a wide range of happy, sad, and fearful memories.

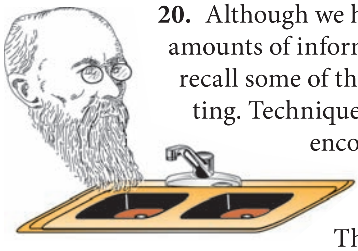
Figure/Text Credit: (#5) Graph data from "Fifty Years of Memory for Names and Faces," by H. P. Bahrick, P. O. Bahrick & R. P. Wittlinger, 1975, *Journal of Experimental Psychology: General, 104,* 54–75.

18. Researchers believe that the brain forms and briefly stores short-term memories by using a circuit of interconnected neurons called ________. When these interconnected neurons stop being activated, the short-term memory vanishes unless it has been encoded in long-term memory.

19. Researchers have evidence that the formation and storage of long-term memories involve the repeated stimulation of neurons, which in turn causes neurons to grow and change to form new connections with other neurons; this phenomenon is called (a) ________. When this process was chemically or genetically blocked, animals were unable to form (b) ________, which points to the importance of LTP in forming long-term memories.

E. Mnemonics: Memorization Methods



20. Although we have the capacity to store great amounts of information, we may not be able to recall some of this information because of forgetting. Techniques that use efficient methods of encoding to improve remembering and prevent forgetting are called (a) ________. The major function of these techniques is to create strong (b) ________ that will serve as effective (c) ________.

21. A method that creates visual associations between memorized places and items to be memorized is called the (a) ________. With another method, one creates associations between number-word rhymes and items to be memorized; this method is called the (b) ________.

F. Cultural Diversity: Aborigines Versus White Australians

22. Data from Aborigine and White Australian children suggest that survival needs may shape and reward a particular way of (a) ________ information in memory. For example, in the industrialized world, people (White Australians) are required to store large amounts of (b) ________. However, Aborigines in the wilds of Australia need to be able to store environmental information, or (c) ________, to find their way, locate watering places, and thus increase their chances of survival. Researchers found that Aborigines performed better on tests that required (d) ________ retrieval cues and performed less well on tests that required (e) ________ cues.

G. Research Focus: Memory Accuracy

23. Since sexual activity is not a behavior researchers can observe, research methods used to study sexual activity are limited to the (a) ________. Janet Rosenbaum at Harvard University asked more than 13,000 adolescents questions about their sexual histories and whether or not they had ever taken a virginity pledge. Overall, the results of this study show that adolescents' memories for sexual behaviors are often (b) ________.

H. Application: Eyewitness Testimony

24. In 177 out of 230 cases, eyewitnesses identified the wrong suspect, which indicates that such eyewitness testimony is not always (a) ________. Another problem is that the accuracy of an eyewitness is only moderately related to the how much (b) ________ the eyewitness feels. Eyewitnesses have difficulty identifying a suspect of another race; this is called (c) ________. Eyewitness testimony may not be reliable because witnesses may be influenced by officials who ask (d) ________ questions.

25. When a person has difficulty deciding which of two or more sources is responsible for a memory, it is called (a) ________. Researchers found that misleading questions and false information can cause subjects to (b) ________ events.

26. The recall of eyewitnesses may be improved by having them imagine and reconstruct the details of an event, report everything that they remember, and report things from different viewpoints. This method is called the (a) ________. With this method, eyewitnesses remember much more information about the event than they do when asked standard questions. This questioning procedure also helps to eliminate suggestions or source misattributions, which can result in implanting (b) ________ in witnesses.

Answers: *1. (a) recall, (b) recognition; 2. nodes; 3. network; 4. hierarchy; 5. forgetting curve; 6. (a) interference, (b) proactive, (c) retroactive; 7. retrieval cues; 8. repression; 9. amnesia; 10. bias, suggestibility; 11. retrieval cues; 12. tip-of-the-tongue; 13. state-dependent learning; 14. (a) cortex, (b) hippocampus, (c) remember; 15. (a) cortex, (b) hippocampus; 16. procedural; 17. amygdala; 18. neural assemblies; 19. (a) long-term potentiation, or LTP, (b) long-term memories; 20. (a) mnemonics, (b) associations, (c) retrieval cues; 21. (a) method of loci, (b) peg method; 22. (a) encoding, (b) verbal information, (c) visual information, (d) visual, (e) verbal; 23. (a) survey method, (b) inaccurate; 24. (a) accurate or reliable, (b) confidence, (c) own-race bias, (d) misleading; 25. (a) source misattribution, (b) misremember; 26. (a) cognitive interview, (b) false memories*

Critical Thinking

Can Bad Memories Be Erased?

Imagine a world where no one had any bad memories. New research discoveries suggest that such a world may not be so implausible. For people who are frequently haunted by painful, unpleasant memories, there may be a simple way to alter or even erase the events from their mind.

Scientists believe that after a person experiences a traumatic event, the body releases stress hormones, which act to make the bad memory stronger. To test this theory, Roger Pitman, a scientist, found patients who had just experienced a traumatic event and gave some of them a drug called propranolol (commonly used to treat blood pressure), which blocks the release of stress hormones, and others a placebo. Patients also tape-recorded their recollection of the traumatic experience in detail. Months later, patients listened to the tapes. Over half of the placebo patients exhibited intense physical symptoms of anxiety and fear (high heart rate, sweaty palms), whereas none of the patients who received propranolol had such responses.

Other research also supports the use of propranolol to decrease fear associated with bad memories. For instance, Merel Kindt and her colleagues created fearful memories in subjects by administering shocks when they looked at pictures of spiders while instructed to "actively remember" the pictures. One day later, half of the subjects were given propranolol and half a placebo. All were shown pictures of spiders again, and the subjects given medication showed less fearful responses.

The almost magical effects of propranolol occur because the drug affects brain cells in the amygdala, a critical brain structure involved in the processing of emotions in memories and learning fear responses. Using propranolol while actively remembering traumatic events seems to break down unpleasant memories by removing the fear responses associated with them.

Many scientists are excited about using drugs not only to modify memory, but also to permanently erase memory. One such scientist has achieved promising results in his animal research. He found that increasing a particular enzyme to high levels while the subject actively remembers a traumatic experience may actually make the memory vanish.

The future of memory research is full of possibilities. There are, of course, many ethical concerns. For instance, what if murderers and rapists were able to erase from their memory all of the horrific actions they committed? They would thereby eliminate any feelings of guilt or remorse and forfeit the ability to learn from experience. Also, people could interfere with the criminal justice system by erasing the memories of important eyewitnesses. Then, there's always the risk of permanently erasing positive, wanted memories in the process.

For now, scientific advances don't help people forget bad memories altogether, but they do help remove the trauma and fear associated with these memories. However, a scientific breakthrough making it possible to completely erase memories in humans may occur sooner than our society prepares itself for the ethical implications of such a discovery. (Adapted from Gutierrez, 2009; C. Kalb, 2009; Kindt et al., 2009; Lemonick, 2007a; McGowan, 2009)

QUESTIONS

1 What type of long-term memory includes our recollection of traumatic events we experienced?

2 In this research example, what is the neutral stimulus? Unconditioned stimulus? Conditioned stimulus?

3 Why are scientists primarily focusing on using a drug that targets brain cells in the amygdala and not the hippocampus?

4 Research shows it's more difficult to erase bad memories than to forget good memories. What explains this?

5 Does the phenomenon of source misattribution apply to a person whose memory of the witnessed event gets erased? Why or why not?

6 It's possible to make a memory weaker or even disappear, but is it possible to create false memories and have people believe them to be true?

Study Guide and WebTutor

Work through the corresponding module in your Study Guide for tips on how to study effectively and for help learning the material covered in the book. WebTutor (an online Study Tool accessed through your eResources account) provides an interactive version of the Study Guide.

Suggested Answers to Critical Thinking

1. Episodic memory is a type of declarative memory and involves knowledge of specific events and personal experiences.
2. In this example, subjects learn to associate pictures of spiders with receiving shocks. The neutral stimulus is the pictures of spiders, and the unconditioned stimulus is shocks. By repeatedly pairing the pictures of spiders with receiving shocks, subjects learn to associate pictures of spiders with shock, and as such, the conditioned stimulus is also the pictures of spiders.
3. The hippocampus transfers personal events from short-term to long-term memory and is involved in the recollection of memory, but is not involved in the emotional experiences connected to these memories. Scientists are trying to remove the emotions involved in memories of events, and the amygdala is the brain structure that processes emotions in memories.
4. It has to do with the intensity of the emotions connected to the memories. Essentially, the more intense the emotion, the more likely the event will be transferred to long-term memory and the more easily it can be recalled or retrieved. When we experience a pleasant event, the intensity of the emotion is simply not as strong because it is for an unpleasant, traumatic event.
5. Source misattribution is a memory error that results when a person has difficulty deciding which of two or more sources the memory came from. When a person's memory of the event is erased, there is no such confusion because no memory is recalled.
6. Yes, there have been hundreds of studies reporting that false memories can be implanted in children and adults. These studies show that implanting false memories is rather easy and they can grow into very vivid, detailed, and believable personal memories.

Introduction

Mirror, Mirror, on the Wall, Who Is the Most Intelligent of Them All?

Who is the most intelligent?

For the past 200 years, psychologists have been involved in defining and measuring intelligence, which turns out to be a very complicated business. For example, after reading about the five individuals described below, rank them according to your idea of intelligence. After you have read the module, come back to your ranking and see if you would make any changes.

Based on my idea of intelligence, here's how I have ranked the five individuals: #1___, #2___, #3___, #4___, #5___.

A. Gregg Cox

At age 37, he could speak 64 languages fluently, making him, says *The Guinness Book of World Records,* the planet's greatest linguist. He broke the old record of 58 languages. He began learning languages at age 5, starting with Spanish, Portuguese, Italian, German, and Chinese. Since then, he has been learning about 5 languages a year. He's writing a book—a dictionary.

B. Halle Berry

At age 44, she has already starred in over 30 Hollywood movies and become the highest paid African American actress in Hollywood. Not only has she earned an Emmy and a Golden Globe award for her acting, but she also won Best Actress at the Academy Awards in 2002, making her the first African American woman to ever win an Oscar for best actress.

C. Bill Gates

At age 54, he has become the richest man in the United States, worth around $40 billion. He began writing computer programs in eighth grade. As a college sophomore, he dropped out of Harvard and wrote one of the first operating systems to run a computer. In his twenties, he founded Microsoft, whose software operates 90% of the computers in the world.

D. Alia Sabur

At only 8 months, Alia began reading. She graduated from college at age 14 with highest honors, becoming the youngest female college graduate in American history. Her IQ is off the charts. Alia is the youngest person to ever receive awards from the U.S. Department of Defense, U.S. National Science Foundation, and NASA. At the age of 19, she became the world's youngest professor in history.

E. Jay Greenberg

At age 10, Jay enrolled in the world-renowned Juilliard School of Music. By age 14, he accomplished as much as talented composers do in a lifetime. Jay has composed more than 100 musical works, including five highly praised symphonies. He has earned many prestigious awards for his compositions and became the youngest composer ever to sign exclusive contracts with major recording labels.

Psychometrics

The problem you faced in trying to rank the intelligence of the above five individuals—Cox, Berry, Gates, Sabur, and Greenberg—is similar to what psychologists faced in having to define and measure intelligence. Since the late 1800s, psychologists have debated the question, What is intelligence? and have developed a number of tests to measure intelligence. Measuring intelligence is part of an area of psychology that is called psychometrics.

Psychometrics, **which is a subarea of psychology, is concerned with developing psychological tests that assess an individual's abilities, skills, beliefs, and personality traits in a wide range of settings—school, industry, or clinic.**

As you'll discover in this module, the measurement of intelligence and the development of intelligence tests are still being debated (Gill et al., 2009; R. J. Sternberg et al., 2003b).

What's Coming

We'll discuss the different theories of intelligence, how intelligence is measured, the meaning of IQ scores, the problems with intelligence tests, how genetics and environment influence intelligence, and ways to improve environmental opportunities.

We'll begin with a very old but very basic question: How do we define intelligence?

Photo Credits: (A) © Stephen Ellison/Corbis; (B) © AP Images/Luis Martinez; (C) © AP Images/Cheryl Hatch; (D) © WireImage/Getty Images; (E) Courtesy IMG Artists, photo by Bill Phelps

A. Defining Intelligence

Problem: Definition

What is intelligence?

Gregg Cox: speaks 64 languages

Halle Berry: Oscar-winning actress

Bill Gates: head of Microsoft; $40 billion

Alia Sabur: "off the charts" IQ; professor

Jay Greenberg: music composer; child prodigy

When college students were asked to estimate their overall IQs, men's reports of IQ were higher than estimates given by women, and both men and women reported higher IQs for their fathers than for their mothers (Petrides et al., 2004). In fact, over the past 20 years, men have consistently overestimated and women have consistently underestimated their IQs, even though researchers find no sex differences in IQ scores (Colom et al., 2000).

People generally believe IQ scores measure intelligence. But it's not so simple. For example, how did you rank the intelligence of the five individuals in the left photos, each of whom shows a different yet extraordinary skill or talent? Do these examples point to the existence of different kinds of intelligence (H. Gardner, 2006b)?

Many psychologists believe intelligence is best defined by measuring a variety of cognitive abilities, which is what most intelligence tests measure. For example, based on an intelligence test, Alia Sabur received an IQ score so high it was "off the charts." Others argue that a definition of intelligence based entirely on cognitive abilities is much too narrow. Instead, they believe there are many kinds of intelligence, such as involving acting skills (Halle Berry), musical abilities (Jay Greenberg), practical skills (Gregg Cox), or solving problems (Bill Gates) (E. Benson, 2003a; H. Gardner, 2006b).

More recently, researchers have pointed to the importance of emotional intelligence, which involves how well people perceive, express, and regulate emotions in themselves and others (Salovey et al., 2008). Award-winning actors (Halle Berry) certainly have high emotional intelligence. We'll discuss emotional intelligence in Module 16.

Here we'll examine three popular definitions of intelligence, beginning with the oldest and perhaps the most widely accepted definition of intelligence, the two-factor theory.

Two-Factor Theory

What is "g"?

In 1904, Charles Spearman reported that he had measured intelligence in an objective way. Spearman was one of the first to use the psychometric approach.

The ***psychometric approach*** measures or quantifies cognitive abilities or factors that are thought to be involved in intellectual performance.

Spearman (1904) reasoned that by measuring related cognitive factors he would have an objective measure of intelligence. This idea led to his two-factor theory of intelligence.

Spearman's two-factor theory says that intelligence has two factors: a general mental ability factor, ***g,*** which represents what different cognitive tasks have in common, plus many specific factors, ***s,*** which include specific mental abilities (mathematical, mechanical, or verbal skills).

Spearman believed that factor ***g,*** or general mental ability, represented a person's mental energy. Today, factor ***g*** is defined and measured by a person's performance on various and related cognitive abilities. In other words, modern intelligence tests have essentially changed or transformed Spearman's ***g*** into an objective score, which is commonly known as the IQ score. Today, many psychologists believe that ***g,*** as represented by IQ scores, is a good measure of a person's general intelligence (Jenson, 2005).

On the basis of Spearman's two-factor theory, which of the five individuals (left photos) is most intelligent?

Alia Sabur: "off the charts" IQ; professor

Many psychologists believe that ***g*** is the definition of general intelligence, which can be measured by an IQ test and represented by an IQ score. Thus, one way to compare people on intelligence is by using scores from IQ tests. Ranking intelligence by using IQ scores would favor Sabur ("off the charts" IQ score), Gates (one colleague said Gates was "the smartest person he ever knew"), and probably Cox (speaks 64 languages). However, although Berry (Oscar-winning actress) and Greenberg (composer) might score high on IQ tests, they would get little or no credit for having exceptional motor, acting, or music skills.

Advantages and Disadvantages

One advantage of ***g*** is that it can be objectively defined and measured by an IQ test, which gives a single IQ score that is presumed to reflect a person's general intelligence. Another advantage is that ***g*** is a good predictor of performance in academic settings and has some success in predicting performance in certain careers (discussed later) (N. Brody, 2000).

One disadvantage of Spearman's ***g*** is the continuing debate over whether it is the best measure of intelligence. Or as one researcher states, "We know how to measure something called intelligence, but we do not know what has been measured" (N. Brody, 2000, p. 30). A second disadvantage of ***g*** is that it focuses on cognitive abilities but neglects motor, perceptual, musical, practical, and creative abilities, which some believe indicate other kinds of intelligence (H. Gardner, 2006b). A third disadvantage is that ***g*** and its focus on cognitive abilities are popular in Western cultures but not in many Asian and African cultures, where being intelligent includes other abilities, such as how one relates to and understands others (E. Benson, 2003b). For these reasons, psychologists critical of ***g***'s narrow approach to measuring general intelligence have proposed other definitions and ways to measure intelligence. We'll discuss two other definitions of intelligence.

Multiple-Intelligence Theory

Multiple kinds of intelligence?

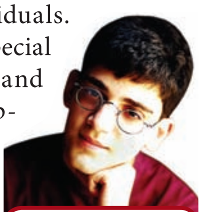
Some psychologists reject the idea that intelligence can be reduced to *g* and expressed by a single number, an IQ score. Howard Gardner (1999, 2006b) argues for broadening the definition of intelligence to include different kinds of abilities, an idea he calls the multiple-intelligence theory.

Gardner's multiple-intelligence theory **says that instead of one kind of general intelligence, there are at least nine different kinds, which include verbal intelligence, musical intelligence, logical-mathematical intelligence, spatial intelligence, body movement intelligence, intelligence to understand oneself, intelligence to understand others, naturalistic intelligence, and existential intelligence.**

Gardner states that standard IQ tests measure primarily verbal and logical-mathematical intelligence and neglect other but equally important kinds of intelligence, such as the ones listed above. Gardner (1999, 2006b) arrived at his theory of multiple kinds of intelligence after studying which abilities remain following brain damage, how savants and prodigies develop their specialized kinds of intelligence, and how people in different environments develop different abilities to adapt and be successful.

Halle Berry: Oscar-winning actress

On the basis of Gardner's multiple-intelligence theory, which of the five individuals (previous page) is most intelligent?



Jay Greenberg: music composer; child prodigy

According to Gardner's multiple-intelligence theory, there isn't one kind of general intelligence for ranking all individuals. Rather, Gardner views the special abilities of Berry in acting and Greenberg in music as representing other kinds of intelligence. Gardner argues that none of the five is more intelligent but rather that each of the five individuals shows a different kind of ability or intelligence that was developed and adapted to his or her environment.

Advantages and Disadvantages

One advantage of Gardner's multiple-intelligence approach is that it does not reduce intelligence to a single IQ score but rather credits people with having different kinds of intelligence.

Two disadvantages of this approach are not knowing how many kinds of intelligence there are and not having standard measuring techniques to assess different kinds of intelligence (Callahan, 2000).

Agreeing with Gardner that *g* is too narrow a measure of intelligence, Sternberg proposed a triarchic theory.

Triarchic Theory

Three kinds of intelligence?

Criticizing Spearman's *g* as too narrow and current IQ tests as limited to measuring only problem-solving skills and cognitive abilities, psychologist Robert Sternberg defined intelligence by ***analyzing*** three kinds of reasoning processes that people use in solving problems. Sternberg (2003a) calls his approach the triarchic theory of intelligence.

Sternberg's triarchic theory **says that intelligence can be divided into three different kinds of reasoning processes (*triarchic* means "three components"). The first is using analytical or logical thinking skills measured by traditional intelligence tests. The second is using problem-solving skills that require creative thinking and the ability to learn from experience. The third is using practical thinking skills that help a person adjust to, and cope with, his or her sociocultural environment.**

Analytical

Problem solving

Unlike Spearman's *g,* which measures general intelligence by measuring cognitive abilities, Sternberg's theory breaks intelligence down into three reasoning processes: analytical, problem solving, and practical skills.

Practical

On the basis of Sternberg's triarchic theory of intelligence, which of the five individuals (previous page) is most intelligent?

According to Sternberg's triarchic theory, there isn't one kind of general intelligence for evaluating these five individuals but rather three different reasoning processes (analytical, problem solving, practical) that contribute to and predict the success of each of the five individuals.

Advantages and Disadvantages

One advantage of Sternberg's triarchic theory of intelligence is that it doesn't limit the definition of intelligence to cognitive abilities. Instead, Sternberg's theory evaluates a person's intelligence by measuring three different kinds of reasoning processes and how they contribute to a person's success. For example, a person may be "street smart" or have exceptional practical reasoning skills but may not necessarily score high on traditional intelligence tests.

One disadvantage of the triarchic theory is that Sternberg's research and tests for measuring his proposed three kinds of reasoning processes have so far been criticized as providing little support for his triarchic theory (N. Brody, 2003; Gottfredson, 2003).

Current Status

Western psychologists used the psychometric approach to measure cognitive abilities, which led to the development of intelligence tests and IQ scores and the concept of *g* as the best measure of intelligence (N. Brody, 2000). Standard intelligence tests remain popular because they have proved useful in predicting performance in academic settings. Critics argue these IQ tests measure only analytical intelligence and ignore other types of intelligence (Nisbett, 2009). Newer approaches, such as Gardner's multiple-intelligence approach and Sternberg's triarchic approach, measure additional abilities and skills and represent different kinds of intelligence. They may replace *g* and its IQ score as the best measure of intelligence (H. Gardner, 2006b; R. J. Sternberg & Pretz, 2005). Many educators have already adopted a multiple-intelligence approach in designing classroom curriculum (Kelly & Tangney, 2006).

To see how far intelligence testing has come, we'll go back in time and discuss early attempts to define and measure intelligence.

B. Measuring Intelligence

PowerStudy 4.5™

Module 4

B. Studying the Living Brain

H. Cultural Diversity: Brain Size & Racial Myths

Earlier Attempts to Measure Intelligence

Head Size and Intelligence

Are bigger brains better?

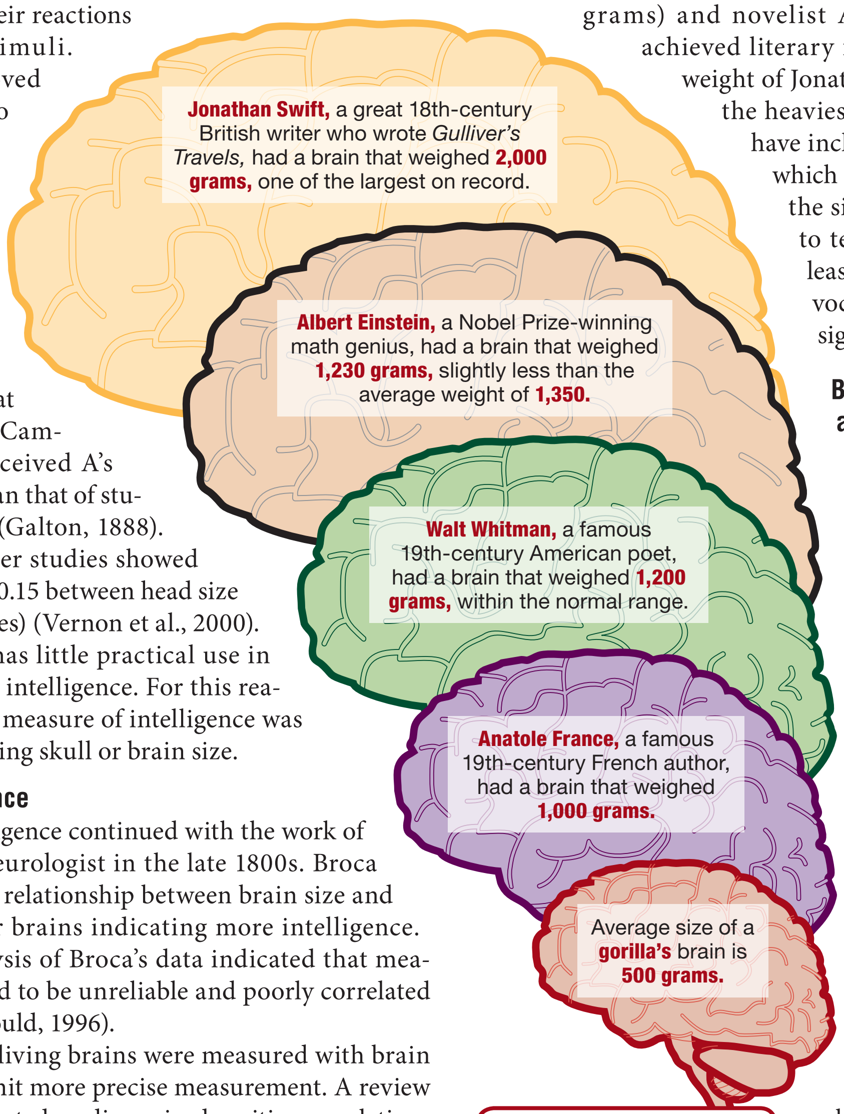
Efforts to measure intelligence began in earnest in the late 1800s. That's when Francis Galton noticed that intelligent people often had intelligent relatives and concluded that intelligence was, to a large extent, biological or inherited. In trying to assess inherited intelligence, Galton measured people's heads and recorded the speed of their reactions to various sensory stimuli. However, measures proved to be poorly related to intelligence or academic achievement (S. J. Gould, 1996).

Galton switched gears and tried to correlate head size with students' grade point average. For example, he reported that the average head size of Cambridge students who received A's was about 3.3% larger than that of students who received C's (Galton, 1888). However, a review of later studies showed a very low correlation of 0.15 between head size and intelligence (IQ scores) (Vernon et al., 2000). Such a low correlation has little practical use in measuring or predicting intelligence. For this reason, using head size as a measure of intelligence was abandoned in favor of using skull or brain size.

Brain Size and Intelligence

Efforts to measure intelligence continued with the work of Paul Broca, a famous neurologist in the late 1800s. Broca claimed that there was a relationship between brain size and intelligence, with larger brains indicating more intelligence. However, a later reanalysis of Broca's data indicated that measures of brain size proved to be unreliable and poorly correlated with intelligence (S. J. Gould, 1996).

Recently, the sizes of living brains were measured with brain scans (p. 70), which permit more precise measurement. A review of brain scan studies reported medium-sized positive correlations (+0.33) between brain size and intelligence (IQ scores) (McDaniel, 2005). However, such correlations indicate only that a relationship exists; correlations cannot tell us whether bigger brains lead to increased intelligence or whether more cognitive activity leads to bigger brains. These medium-sized correlations indicate a positive relationship between brain size and intelligence (IQ scores) but are too low to have practical value in actually predicting an individual's intelligence.



Jonathan Swift, a great 18th-century British writer who wrote *Gulliver's Travels,* had a brain that weighed **2,000 grams,** one of the largest on record.

Albert Einstein, a Nobel Prize-winning math genius, had a brain that weighed **1,230 grams,** slightly less than the average weight of **1,350.**

Walt Whitman, a famous 19th-century American poet, had a brain that weighed **1,200 grams,** within the normal range.

Anatole France, a famous 19th-century French author, had a brain that weighed **1,000 grams.**

Average size of a **gorilla's** brain is **500 grams.**

Brain size doesn't necessarily match performance.

Brain Size and Achievement

Early researchers were reluctant to give up the idea that bigger brains were better. They looked for a relationship between brain size and personal achievement, another measure of intelligence. However, as shown in the center illustration, there is enormous variation in brain size and achievement (S. J. Gould, 1996). Notice that Nobel Prize–winner Einstein's brain (1,230 grams) was slightly below average weight and that two famous authors, poet Walt Whitman (1,200 grams) and novelist Anatole France (1,000 grams), achieved literary fame with brains about half the weight of Jonathan Swift's (2,000 grams), one of the heaviest on record. For comparison, we have included a gorilla brain (500 grams), which is actually quite small considering the size of a gorilla head. It is difficult to test a gorilla's intelligence, but at least one is reported to have learned a vocabulary of more than 1,000 hand signs ("Koko's World," 2006).

Brain Size, Sex Differences, and Intelligence

Still believing that bigger brains are better, some researchers claimed that women had lower IQ scores than men because women's brains weigh about 10% less than men's (Holden, 1995). However, a recent study of over 4,000 women and 6,000 men reported that there was little or no difference in intelligence (IQ scores) between men and women. Researchers concluded that the larger size of men's brains does not result in higher IQs (Colom et al., 2000).

Measuring Intelligence

As you have seen, there is a long history of scientists trying to measure intelligence. However, all the early attempts to use head, skull, body, or brain size to measure intelligence failed. In fact, a paper presented in 1904 to a German psychological society concluded that there was little hope of developing psychological tests to measure intelligence in an objective way (Wolf, 1973). What's interesting about this paper is that one of the authors was Alfred Binet, who went on to develop the first intelligence test.

We'll explain how Binet succeeded in developing an intelligence test when so many others had failed.

Binet's Breakthrough

Why did Binet develop an intelligence test?

In the late 1800s, a gifted French psychologist named Alfred Binet realized that Broca and Galton had failed to assess intelligence by measuring brain size. Binet strongly believed that intelligence was a collection of mental abilities and that the best way to assess intelligence was to measure a person's ability to perform cognitive tasks, such as understanding the meanings of words or being able to follow directions.

Binet was very pessimistic about developing an intelligence test. By a strange twist of fate, he was appointed to a commission that was instructed to develop tests capable of differentiating children of normal intelligence from those who needed special help. Binet accepted this challenge with two goals in mind: The test must be easy to administer without requiring any special laboratory equipment, and the test must clearly distinguish between normal and abnormal mental abilities (N. Brody, 1992). In 1905, Binet and psychiatrist Theodore Simon succeeded in developing the world's first standardized intelligence test, the Binet-Simon Intelligence Scale (Binet & Simon, 1905).

Alfred Binet (1857–1911)

The ***Binet-Simon Intelligence Scale*** **contained items arranged in order of increasing difficulty. The items measured vocabulary, memory, common knowledge, and other cognitive abilities.**

The purpose of this first Binet-Simon Intelligence Scale was to distinguish among mentally defective children in the Paris school system. In Binet's time, intellectually deficient children were divided into three groups: idiots (most severely deficient), imbeciles (moderate), and morons (mildest). These terms are no longer used today because they have taken on very negative meanings. The problems with this first test were that it classified children into only three categories (idiots, imbeciles, and morons) and that it did not have a way to express the results in a single score. However, several years later, Binet corrected both of these problems when he introduced the concept of mental level, or mental age.

Mental Age: Measure of Intelligence

Which items could an average 3-year-old answer?

Which items could an average 9-year-old answer?

Binet and Simon revised their intelligence scale to solve several problems in their original scale. In this revised test, they arranged the test items in order of increasing difficulty and designed different items to measure different cognitive abilities. For each test item, Binet determined whether an average child of a certain age could answer the question correctly. For example, a child at age level 3 should be able to point to various parts of the face. A child at age level 9 should be able to recite the days of the week. Because the test items were arranged for each age level (age levels 3 to 13), this new test could identify which average age level the child performed at. If a particular child passed all the items that could be answered by an average 3-year-old but none of the items appropriate for older children, that child would be said to have a mental age of 3. Thus, if a 6-year-old child could answer only questions appropriate for a 3-year-old child, that child would be given a mental age of 3 and would be considered retarded in intellectual development. Binet's intelligence test became popular because a single score represented mental age.

Mental age **is a method of estimating a child's intellectual progress by comparing the child's score on an intelligence test to the scores of average children of the same age.**

At this point, the Binet-Simon scale gave its results in terms of a mental age but not an IQ score. The idea for computing an IQ score did not occur until some years later, when the scale was revised by L. M. Terman.

Formula for IQ

What was the big change?

The first big change was when Binet and Simon introduced the concept of mental age. The second big change occurred in 1916, when Lewis Terman and his colleagues at Stanford University in California came up with a new and better method to compute the final score. Improving on the concept of expressing the test results in terms of mental age, Terman devised a formula to calculate an intelligence quotient (IQ) score (Terman, 1916).

Intelligence quotient (IQ) **is computed by dividing a child's mental age (MA), as measured in an intelligence test, by the child's chronological age (CA) and multiplying the result by 100.**

Remember that in Binet's test, mental age was calculated by noting how many items a child answered that were appropriate to a certain age. For example, if a 4-year-old girl passed the test items appropriate for a 5-year-old, she was said to have a mental age of 5. A child's chronological (physical) age is his or her age in months and years. To compute her IQ score, we use Terman's formula, shown below.

$$\underset{\text{(Intelligence quotient)}}{\text{IQ}} = \frac{\text{MA}\ \text{(Mental age)}}{\text{CA}\ \text{(Chronological age)}} \times 100$$

Formula for calculating IQ score

Thus, for the child in our example, we substitute 5 for MA, 4 for CA, and multiply by 100. We get: 5/4 = 1.25 × 100 = 125. So the child's IQ is 125. An IQ score computed in this traditional way is called a ***ratio IQ*** because the score represents a ratio of mental to chronological age. Today the ratio IQ has been replaced by the ***deviation IQ,*** whose computation is too complex to explain here. The reason for the switch from ratio IQ to deviation IQ is that deviation IQ scores more accurately reflect test performance as children get older.

Since the original Binet-Simon scale in 1905, IQ tests have become very popular and have grown into a large business. We'll look more closely at one of the most widely used IQ tests.

B. Measuring Intelligence

Is IQ the same as intelligence?

We are all curious to learn someone's IQ because we believe that this single score reveals a person's real intelligence. For example, try to match these IQ scores—104, 114, 228—with three famous people—John F. Kennedy, 35th president of the United States; J. D. Salinger, famous novelist *(Catcher in the Rye);* and Marilyn vos Savant, columnist for *Parade* magazine (answers on right). Knowing the IQ scores of these individuals tells us something of their cognitive abilities, but some psychologists believe that cognitive abilities represent only one kind of intelligence. For example, would you expect Salinger, with his average IQ, to be a very creative novelist, or vos Savant, columnist for *Parade* magazine, to have a high IQ twice that of President Kennedy? The achievements of individuals with average or slightly above average IQs suggest that there are other kinds of intelligence, such as practical, emotional, social, and creative, which may be equally important to one's success in life and career (H. Gardner, 2003, 2006b; R. J. Sternberg et al., 2003b). Now, let's see how IQ scores are measured.

John F. Kennedy: 35th U.S. president

Marilyn vos Savant: columnist for *Parade* magazine

J. D. Salinger: author of *Catcher in the Rye*

Answers: Salinger, 104; Kennedy, 114; and vos Savant, 228, the highest IQ on record (Cowley, 1994)

Examples of IQ Tests

The most widely used IQ tests are the Wechsler Adult Intelligence Scale (WAIS), for ages 16 and older, and the Wechsler Intelligence Scale for Children (WISC), for children of ages 6–16. A trained examiner administers the Wechsler scales on a one-to-one basis.

The ***Wechsler Adult Intelligence Scale (WAIS)*** and ***Wechsler Intelligence Scale for Children (WISC)*** have items that are organized into various subtests. For example, the verbal section contains a subtest of general information, a subtest of vocabulary, and others. The performance section contains a subtest that involves arranging pictures in a meaningful order, one that requires assembling objects, and one that involves using codes. The verbal and performance scores are combined to give a single IQ score.

Examples of the subtests for WAIS, currently in its fourth version, are shown on the right. The Verbal Scale (top right) emphasizes language and verbal skills. Because of this emphasis, a person from a deprived environment or for whom English is a second language might have difficulty on this scale because of lack of verbal knowledge rather than lack of cognitive ability.

In an attempt to measure nonverbal skills and rule out other cultural or educational problems, Wechsler added the Performance Scale (lower right). These performance subtests, which measure problem-solving abilities, require concentration and focused effort, which may be difficult for individuals who are very nervous, are poor test takers, or have emotional problems. Although these IQ tests carefully try to measure verbal and nonverbal abilities, you can see that part of one's success on IQ tests depends on nonintellectual factors, such as cultural, educational, or emotional factors (Kaplan & Saccuzzo, 2009). We'll discuss other problems with IQ tests later in this module.

One reason these IQ tests are widely used is that they have two characteristics of good tests: validity and reliability.

WAIS Verbal Scale: Subtests

Subtests for the verbal scale include information, comprehension, arithmetic, similarities, digit span, and vocabulary. These examples resemble the WAIS items.

Information
On what continent is France?

Comprehension
Why are children required to go to school?

Arithmetic
How many hours will it take to drive 150 miles at 50 miles per hour?

Similarities
How are a calculator and a typewriter alike?

Digit span
Repeat the following numbers backward: 2, 4, 3, 5, 8, 9, 6.

Vocabulary
What does *audacity* mean?

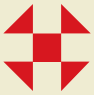
WAIS Performance Scale: Subtests

Subtests for the performance scale include digit-symbol coding, block design, picture completion, and cancellation test. These examples resemble the WAIS items.

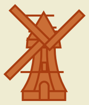
Digit-symbol coding

Shown:				Fill in:			
1	2	3	4	1	4	3	2
○	□	△	⊙	___	___	___	___

Block design
Assemble blocks to match this design.



Picture completion
Tell me what is missing.



Cancellation test
When I say go, draw a line through each *red* square and *yellow* triangle.

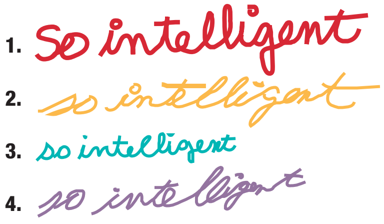
Two Characteristics of Tests

Can you analyze handwriting?

How truthful are the claims that intelligence and other personality traits can be identified through analyzing handwriting (Searles, 1998)? For example, which one of the four handwriting samples on the right indicates the highest IQ? (Answer at bottom of page.)

Although handwriting analysis may claim to measure intelligence, research shows that its accuracy is usually no better than a good guess (Tripician, 2000).



Which handwriting sample, 1, 2, 3, or 4, is from the person with the highest IQ?

The reason handwriting analysis or so-called IQ tests in popular magazines are poor measures of intelligence (IQ) is that they lack at least one of the two important characteristics of a good test. These two characteristics are validity and reliability, which mark the difference between an accurate IQ test (WAIS) and an inaccurate test (handwriting analysis).

Validity

Handwriting analysis is fun, but it is a very poor intelligence test because it lacks validity, which is one of the two characteristics of a good test.

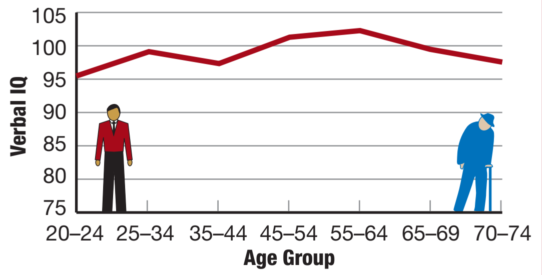
Validity **means that the test measures what it is supposed to measure.**

Although the definition of validity seems simple and short, this characteristic makes or breaks a test. For example, numerous studies have shown that handwriting analysis has little or no validity as an intelligence or personality test (Basil, 1989; Tripician, 2000). Because handwriting analysis lacks the characteristic of validity, it means that this test does not accurately measure what it is supposed to measure. Thus, a test with little or no validity produces results that could be produced by guessing or by chance.

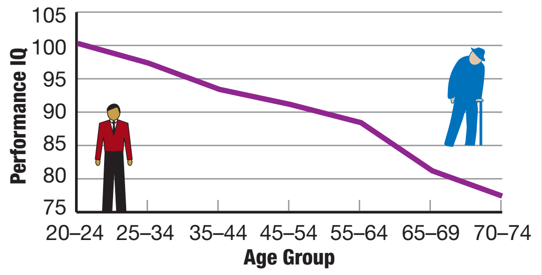
The reason handwriting analysis or tests in popular magazines are not checked for validity is that checking validity is a long, expensive, and complicated process. One way to show a test's validity is to give the new test to hundreds of subjects along with other tests whose validity has already been established. Then the subjects' scores on the new test are correlated with their scores on the tests with proven validity. Another way that the validity of intelligence tests, such as the WAIS, was established was to show that IQ scores correlated with another measure of intelligence, such as academic achievement (Deary et al., 2007).

However, if IQ scores are valid measures of cognitive abilities and correlate with academic performance, why do some individuals with high IQs do poorly in college? The developer of the Head Start program, Ed Zigler, believes that academic performance depends on three factors: cognitive abilities; achievement, or the amount of knowledge that a person has accumulated; and motivation (Zigler, 1995). This means that a person may have outstanding cognitive abilities but may lack either the achievement or the motivation to succeed in college.

Besides validity, a good intelligence test should also have reliability.



No change in VERBAL IQ scores in seven different age groups indicates that test is reliable.



Decrease in OVERALL IQ scores across ages is due to psychological and physiological changes and not reliability problems with IQ test.

Reliability

If your style of handwriting remained constant over time, such as always boldly crossing your *t*'s, then this trait would be reliable.

Reliability **refers to consistency: A person's score on a test at one point in time should be similar to the score obtained by the same person on a similar test at a later point in time.**

For example, if boldly crossed *t*'s indicated that a person is intelligent, then this measure of intelligence would be reliable. However, there is no evidence that boldly crossed *t*'s indicate that a person is intelligent. So, in this case, handwriting analysis would be a reliable test of intelligence, but since it lacks validity (doesn't measure intelligence) it is a worthless test of intelligence.

Now, suppose you took the WAIS as a senior in high school and then retook the test as a junior in college. You would find that your IQ scores would be much the same because each time you would be compared with others of your same age. Because your IQ scores remain similar across time, the Wechsler scales, like other standardized IQ tests, have reliability (C. A Berg, 2000; A. S. Kaufman, 2000).

For example, the top graph shows the results of verbal IQ scores when seven different age groups of subjects were given the WAIS. Notice that verbal IQ scores are quite stable from ages 20 to 74, indicating that the Wechsler scales score high in reliability (A. S. Kaufman et al., 1989).

But notice that the lower graph shows that there is an overall decrease in performance IQ scores from ages 20 to 74 (A. S. Kaufman et al., 1989). However, this general decrease in performance scores across one's lifetime reflects changes in psychological and physiological functioning rather than a decrease in the test's reliability.

Researchers have shown that current intelligence tests, which measure primarily cognitive abilities, have relatively good validity and reliability (Kaplan & Saccuzzo, 2009). Even though IQ scores can be measured with good reliability and validity, our next question to answer is: What good or use are IQ scores?

(Handwriting answer: I (R.P.) wrote all four samples so that no matter which one you picked, I would come out a winner!)

Figure/Text Credit: (center) Graphs adapted from "Age and WAIS-R A Cross-Sectional Analysis with Educational Level Controlled," by A. S. Kaufman, C. R. Reynolds & J. E. McLean, 1989, *Intelligence, 13,* pp. 246, 247. Copyright © 1989 by Ablex Publishing Company. Adapted by permission.

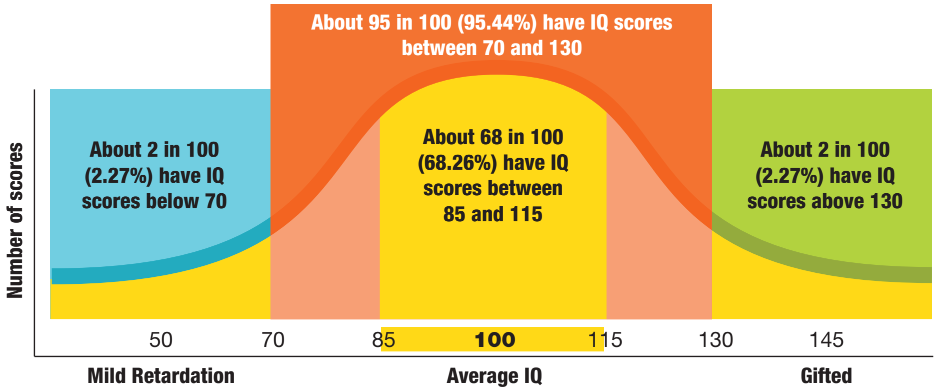
C. Distribution & Use of IQ Scores

Normal Distribution of IQ Scores

The left photo is of Chris Burke, who starred in the television series "Life Goes On." Burke has Down syndrome, a genetic defect that results in varying degrees of mental retardation and physical symptoms (slanting eyes, flattened nose, visual problems). Although Burke has mild or borderline mental retardation, he acted in a TV series and now sings in a band and gives inspirational talks (Horsburgh et al., 2001). Based on his abilities, Burke's IQ is probably between 50 and 85.

In comparison, the photo on the right is of Marilyn vos Savant, who writes a column for *Parade* magazine and has a reported IQ of 228, the highest on record. To compare the IQs of Burke and vos Savant with those of other people, we need to look at the distribution of IQ scores. IQ scores from established intelligence tests, such as the WAIS, are said to have a normal distribution.

A ***normal distribution*** refers to a statistical arrangement of scores so that they resemble the shape of a bell and, thus, is said to be a bell-shaped curve. A bell-shaped curve means the vast majority of scores fall in the middle range, with fewer scores falling near the two extreme ends of the curve.



For example, a normal distribution of IQ scores is shown at the left and is bell shaped. The average IQ score is 100, and 95% of IQ scores fall between 70 and 130. An IQ of 70 and below is one sign of mild retardation. An IQ of 130 or higher is one indication of a gifted individual. Thus, one widespread use of IQ tests is to provide general *categories* regarding mental abilities.

Next, we'll examine these guidelines in more detail, beginning with mental retardation.

Mental Retardation: IQ Scores

What is mental retardation?

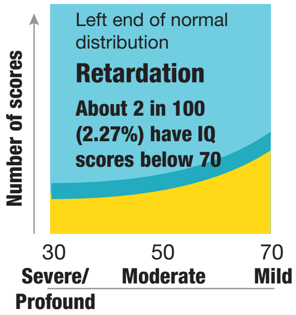
One use of IQ scores has been to help identify individuals with mental retardation.

Mental retardation refers to a substantial limitation in present functioning that is characterized by significantly subaverage intellectual functioning, along with related limitations in two of eleven areas, including communication, self-care, home living, social skills, academic skills, leisure, and safety (American Psychiatric Association, 2000).

Currently, there is a transition in progress to change the term ***mental retardation*** to ***intellectual disability*** (Schalock et al., 2007). IQ tests are used in combination with observations of adaptive skills, which include social, home living, and communication skills, to test for mental retardation. On the basis of IQ scores and adaptive skills, three levels of retardation have been identified.

1 Mild Mental Retardation

These individuals have IQs that range from 50 to 70. With special training and educational opportunities, they can learn to read and write, gain social competency, master simple occupational skills, and become self-supporting members of society. About 85% of individuals with retardation are in this category.



2 Moderate Mental Retardation

These individuals have IQs that range from 35 to 55. With special training and educational opportunities, they can learn to become partially independent in their everyday lives, provided they are in a family or self-help setting.

3 Severe/Profound Mental Retardation

These individuals make up 5% of those with mental retardation and have IQs ranging from 20 to 40. With special training and education, they can acquire limited skills in taking care of their personal needs. However, because of impaired motor and verbal abilities, they require considerable supervision their entire lives.

4 Causes

There are two general types of mental retardation: organic and cultural-familial.

Organic retardation results from genetic problems or brain damage.

Chris Burke is an example of someone with organic retardation.

Cultural-familial retardation results from a greatly impoverished environment. There is no evidence of genetic or brain damage.

About 5 million Americans have mental retardation.

Next, we move to the middle of IQ's normal distribution.

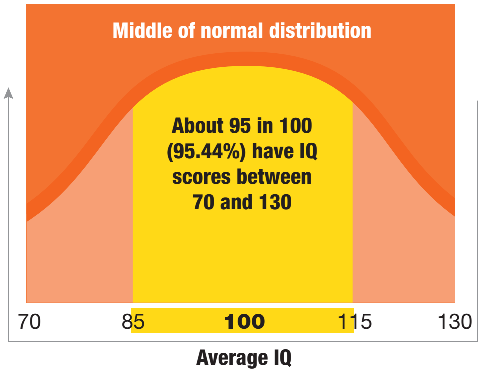
Vast Majority: IQ Scores

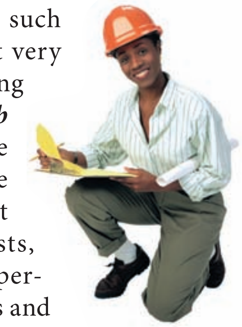
Since the vast majority of people, about 95%, have IQ scores that fall between 70 and 130, it is interesting to see what IQ scores can tell us.

Do IQ Scores Predict Academic Achievement? Because IQ tests measure cognitive abilities similar to those used in academic settings, it is no surprise there is a medium-strength association, or correlation, between IQ scores and grades (0.50) and between IQ scores and total years of education that people complete (0.50) (N. Brody, 1997). However, based on medium-strength correlations alone, it would be difficult to predict a ***specific person's academic performance*** because performance in academic settings also depends on personal characteristics, such as one's interest in school, willingness to study, and belief in one's ability to succeed (Klomegah, 2007; Neisser et al., 1996).



IQ scores are useful for predicting academic success.

Do IQ Scores Predict Job Performance? There is a low- to medium-strength correlation (+0.30 to 0.50) between IQ scores and job performance (Neisser et al., 1996). However, such correlations are not very accurate at predicting a ***specific person's job performance*** because several noncognitive factors that are not measured by IQ tests, such as personality traits (is a can-do person), emotional traits (can deal with stress and get along with co-workers), and practical know-how (figures out how to get the job done), play important roles in predicting job performance (Gottfredson, 2002; R. J. Sternberg, 2003b).

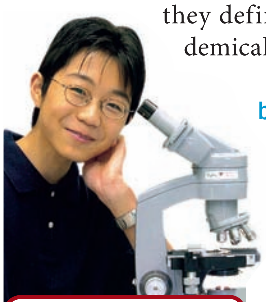


IQ scores are somewhat useful at predicting job performance.

Now, we'll examine the right end of the normal distribution—high IQ scores.

Gifted: IQ Scores

Sho Yano (photo below), whose IQ is 200 plus, entered college at age 9, graduated at age 12, plays classical works on the piano, and was the youngest person ever to start a dual M.D.-Ph.D. program at the University of Chicago. Sho Yano is considered a profoundly gifted child. Although researchers and educators differ in how they define gifted, this definition refers to academically gifted children.



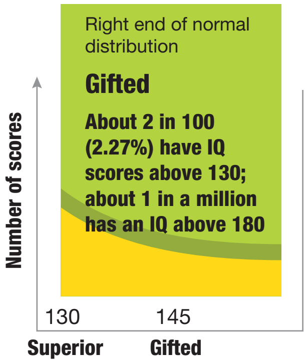
IQ of 200+ labels Sho Yano as gifted.

A moderately ***gifted*** child is usually defined by an IQ score between 130 and 150; a profoundly gifted child has an IQ score about 180 or above.

Like Sho Yano, who excels at the piano and medicine, gifted children usually have some superior talent or skill.

When placed in ***regular classrooms,*** gifted children face a number of problems: They are bored by the lack of stimulation and they may feel lonely or develop social problems because they are labeled nerds or geeks. Researchers recommend that gifted children be placed in special academic programs that challenge and help them develop their potentials (Goode, 2002; Winner, 2000).

How Do Gifted Individuals Turn Out? In the early 1920s, Lewis Terman selected a sample of over 1,500 gifted children with IQs ranging from 135 to 200 (the average was 151) (Hulbert, 2005). Over the next 65 years, researchers repeatedly tested these individuals to determine what they had achieved and how they had adjusted. Although 10–30% more of the gifted men obtained advanced degrees compared with men in the general population, 30% never finished college, and 2% actually flunked out. Although gifted individuals generally showed better health, adjustment, life satisfaction, and achievement than people with average IQs, about 9% had serious emotional problems, and 7% committed suicide (Hegarty, 2007; Holahan & Sears, 1995; Terman & Oden, 1959). As a group, these gifted individuals were generally very successful in life but not at the extraordinary level that might have been predicted from their high IQ scores (Colangelo, 1997).



Generally, despite the stereotype that gifted people are socially awkward, research finds that most are socially well adjusted and liked by their peers (Lubinski et al., 2006). Other research shows that only gifted children who have demanding and critical parents are more likely to have social and emotional problems than children with normal intelligence (Elias, 2005).

Researchers have long been interested in brain differences between gifted people and those with normal-range intelligence and have found that the brain areas responsible for higher cognitive reasoning develop differently in highly intelligent children (see the Research Focus on p. 297) (Shaw et al., 2006). Recently, there has been a growing focus on the role of practice and determination in giftedness. This view holds that practice and steadfast determination, rather than innate talent, are critical factors in developing giftedness (Ericsson et al., 2007; Gladwell, 2008).

Conclusion. IQ scores, the most popular measure of intelligence, have proven moderately useful in predicting academic performance, in helping to define mental retardation, and in identifying the gifted, but they have low to moderate success in predicting job performance. One reason IQ scores are not more predictive is that they do not measure numerous emotional, motivational, and personality factors that also influence behavior.

While IQ tests have proved useful, we'll next examine potential problems in taking and interpreting IQ tests.

D. Potential Problems of IQ Testing

Binet's Two Warnings

What problems did Binet foresee?

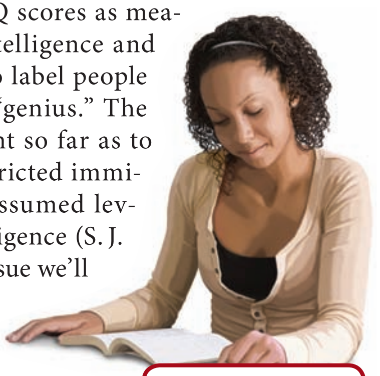
You may remember that Binet's original goal was to develop a test that would distinguish between normal and abnormal mental abilities and thus identify children who were mentally retarded and needed special help and education. Although previous attempts to measure intelligence had failed, Binet and Simon succeeded in developing the first scale that identified children with varying degrees of mental retardation. Binet and Simon's scale was the beginning of the modern-day IQ test. However, even in the early 1900s, Binet realized that intelligence tests could be used in two potentially dangerous ways, so he issued the following two warnings:

Binet's Warnings

1 Binet warned that ***intelligence tests do not measure innate abilities or natural intelligence;*** rather, they measure an individual's cognitive abilities, which result from both heredity and environment.

2 Binet warned that ***intelligence tests, by themselves, should not be used to label people*** (for example, "moron," "average," "genius"); rather, intelligence tests should be used to assess an individual's abilities and used in combination with other information to make academic or placement decisions about people.

History shows that neither of Binet's warnings were heeded. In the early 1900s it became common practice to treat IQ scores as measures of innate intelligence and to use IQ scores to label people from "moron" to "genius." The U.S. Congress went so far as to pass laws that restricted immigrants based on assumed levels of innate intelligence (S. J. Gould, 1996), an issue we'll discuss in the Cultural Diversity section (p. 296).



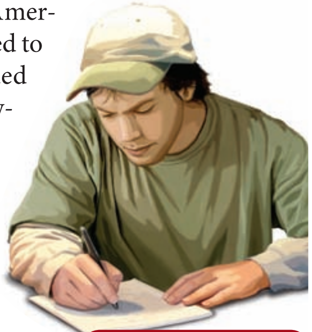
Along with using IQ scores to label individuals came racial and cultural discrimination, some of which continue to the present. For example, a controversial book, *The Bell Curve* (Herrnstein & Murray, 1994), suggested that racial differences in IQ scores are due primarily to genetic factors, something we'll discuss later in this module. For now, we'll examine three issues surrounding IQ tests: cultural bias, other cultures, and nonintellectual factors.

IQ tests have a history of being used to discriminate.

Racial Discrimination

Are IQ tests racially biased?

There have been a number of court cases regarding the appropriate use of IQ tests. Here is one important case and the judge's ruling.



Larry was an African American child who was assigned to special classes for the educable mentally retarded because he scored below 85 on an IQ test. However, several years later an African American psychologist retested Larry and found that his IQ score was higher than originally thought. Larry was taken out of the special classes, which were considered a dead end, and placed in regular classes that allowed for more advancement. On the basis of Larry's experience, a class action suit was brought against the San Francisco school system on behalf of all African American schoolchildren in the district. The suit was based on the finding that, although African American youngsters made up 27% of all the students enrolled in classes for the mentally retarded, they made up only 4% of the entire school population (Kaplan & Saccuzzo, 2005). African American parents wanted to know why their children were so much more numerous than White children in these special classes. They felt there must be a bias against African American children in the selection process.

IQ tests alone should not be used to define mental retardation.

Although Larry's case came to trial in the early 1970s, the final decision was given in 1979 by a judge of the federal court of appeals. The judge agreed with the African American parents and found that IQ tests being used in schools (kindergarten through grade 12) to determine mental retardation were biased against people of color. The court ruled that California schools could not place children of color in classes for children with mental retardation on the basis of the IQ test alone. The schools were instructed to come up with an intelligence test that does not favor Whites or else refrain from using a standardized test to identify slow learners.

Definition of mental retardation. In other states, there is disagreement about the role of IQ tests in defining mental retardation and making decisions about placing children in special education classes (BCSSE, 2002). Despite efforts to improve the educational opportunities for African American children in the United States, they continue to be more likely than White children to be placed in classes for children with mental retardation and less likely to be placed in classes for gifted children (R. Gardner et al., 2001; Losen & Orfield, 2002). Critics of the special education system argue that African American students are overrepresented not because of their especially high level of disability but because of discriminatory placement procedures, such as the culturally biased IQ tests (Losen & Orfield, 2002; J. P. Shapiro et al., 1993).

$$\underset{\text{(Intelligence quotient)}}{\text{IQ}} = \frac{\text{MA}\ \text{(Mental age)}}{\text{CA}\ \text{(Chronological age)}} \times 100$$

Educational decisions. Based on the concerns discussed above, psychologists and educators recommend that IQ tests alone not be used as the primary basis for making decisions about a child's educational future. Instead, they suggest that educational decisions, especially about placing a child in a special education class, be made only after considering a wide range of information, which may include IQ scores but also observations and samples of the child's behavior from other situations (Palomares, 2003).

Cultural Bias

What kind of questions?

One criticism of IQ tests is that they are culturally biased, especially in favor of industrialized communities, such as the White middle class in the United States (Serpell, 2000).

Cultural bias **means that the wording of the questions and the experiences on which the questions are based are more familiar to members of some social groups than to others.**

For example, consider this question from an older version of the Wechsler Intelligence Scale for Children: "What would you do if you were sent to buy a loaf of bread and the grocer said he did not have any more?"

If you think the answer is "Go to another store," you are correct according to the developers of the Wechsler scale. However, when 200 minority children were asked this same question, 61 said they would go home. Asked to explain their answers, they gave reasonable explanations. Some children answered "Go home" because there were no other stores in their neighborhood. Yet the answer "Go home" would be scored "incorrect," despite it being correct in the child's experience (Hardy et al., 1976). This example shows that different cultural influences and experiences may penalize some children when taking standardized tests of intelligence.

IQ tests are, to some extent, culturally biased.

In today's IQ tests, many of the above kinds of biases have been reduced (A.S. Kaufman, 2003). However, researchers still believe that it's virtually impossible to develop an intelligence test completely free of cultural bias because tests will reflect, to some degree, the concepts and values of their culture (Greenfield, 2003). For instance, researchers believe the reason Whites tend to score higher than African Americans on IQ tests is not differences in ability, but rather differences in knowledge. Whites may be more likely to be exposed to the information typically found on IQ tests (Fagan & Holland, 2007). This is another example of how cultural influences can affect a child's performance on standard IQ tests.

Other Cultures

Are there different definitions?

We have discussed how many Western psychologists believe the best definition of a person's intelligence is something called ***g***, which is primarily measured by assessing cognitive abilities and expressed by IQ scores.

The definition of intelligence differs cross cultures.

However, psychologists studying intelligence in non-Western countries, such as in Africa and Asia, find these cultures have different conceptions and definitions of intelligence.

For example, the Taiwanese conception of intelligence emphasizes how one understands and relates to others, including when and how to show intelligence (R.J. Sternberg & Yang, 2003). In Zambia (Africa), parents describe the intelligence of their children as including cognitive abilities as well as showing social responsibility, which is considered equally important (Serpell, 2003). In Micronesia, people demonstrate remarkable navigational skills as they sail long distances using only information from stars and sea currents (Ceci et al., 1997). These navigational abilities certainly indicate a high degree of intelligence that would not be assessed by traditional Western IQ tests. Thus, the definition of intelligence differs across cultures.

Nonintellectual Factors

What if a person is nervous?

Maria is 11 years old and has been in the U.S. for two years. She had a hard time learning English, is not doing well in school, and is terrified about taking tests. Maria comes to take an IQ test, and the psychologist tries to put her at ease. However, Maria is so afraid of failing the IQ test that she just sits and stares at the floor. The psychologist says, "I'm going to give you a word and you tell me what it means." When Maria hears the word, she is now so anxious that she can't concentrate or think of what to say. Maria will probably do poorly on this IQ test because of nonintellectual factors.

Nonintellectual factors **refer to noncognitive factors, such as attitude, experience, and emotional functioning, that may help or hinder performance on tests.**

For example, nonintellectual factors such as Maria's shyness, fear of strange situations, and anxiety about failing would certainly hinder her test performance (Oostdam & Meijer, 2003). Thus, students who have test anxiety or who come from an environment with poor educational opportunities would be disadvantaged in taking IQ tests. Also, children diagnosed with autism struggle with traditional IQ tests because they have great difficulty interacting with a stranger. One study compared the IQ scores of children with autism who took a test administered by a stranger and a test they could complete on their own. Healthy children without autism scored the same on both tests; however, children with autism scored much higher on the test they completed on their own. Clearly, nonintellectual factors play a role on a child's IQ (Begley, 2007a).

IQ scores are influenced by emotions and experience.

In comparison, a child who is experienced and confident at taking tests has nonintellectual factors that aid performance. It's well established that nonintellectual factors have a great influence on how a person performs on IQ tests (Kaplan & Saccuzzo, 2009).

Next, we'll discuss an old question about intelligence, the nature-nurture question.

E. Nature-Nurture Question

PowerStudy 4.5™

Module 4
A. Genes & Evolution

Definitions

What is the nature-nurture question?

Midori, child prodigy: "If I went back, I would probably do everything differently."

One of the greatest child music prodigies of our time is Midori (right photo), who began playing violin at age 3 and made her professional debut at age 10. Because Midori was a musical genius at such an early age, her exceptional skill was due to nature or heredity—that is, something she was born with. She played professionally until age 23, when she suddenly withdrew for four months. The official reason for her sudden withdrawal was a "digestive disorder," but some reports said that she was actually suffering from an eating disorder. Midori's problem raises questions about the effects of environment (nurture), specifically how to help a child genius adjust to difficult personal and professional pressures at such a young age (Cariaga, 1995). The difficulty Midori faced in balancing nature or heredity factors (being a child genius) with nurture or environmental factors (facing difficult personal and professional pressures) brings us to the nature-nurture question.

The *nature-nurture question* asks how nature—hereditary or genetic factors—interacts with nurture—environmental factors—in the development of a person's intellectual, emotional, personal, and social abilities.

In the early 1900s, intelligence was believed to be primarily inherited or due to nature (Terman, 1916). In the 1950s, psychology was heavily influenced by behaviorism, which emphasized nurture or environmental factors in the development of intelligence (B. F. Skinner, 1953). Today, researchers find nature and nurture interact and contribute about equally to the development of intelligence (O. S. P. Davis et al., 2008; Pinker, 2003).

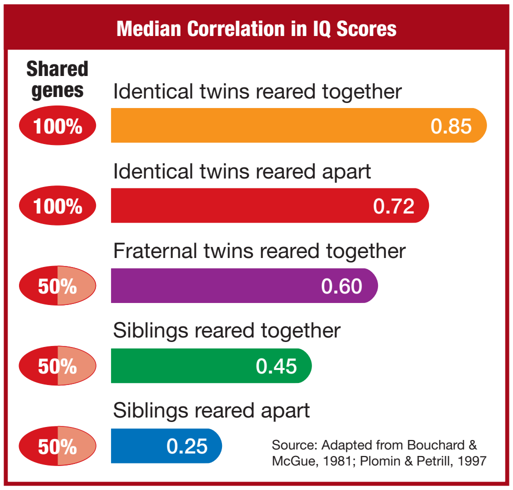
Twin Studies

What do genes do?

In exploring how nature and nurture contribute to and interact in the development of intelligence, researchers compared IQ scores in siblings (brothers and sisters) and in fraternal and identical twins.

***Fraternal twins,* like siblings (brothers and sisters), develop from separate eggs and have 50% of their genes in common. *Identical twins* develop from a single egg and thus have almost identical genes, which means they have nearly 100% of their genes in common.**

Genetic factors. The graph on the right shows that the correlation in IQ scores between identical twins (0.85), who share nearly 100% of their genes, was higher than the correlation between fraternal twins (0.60), who share 50% of their genes, or between siblings (0.45), who also share 50% of their genes (Plomin & Petrill, 1997). These findings, which come from over 100 studies, indicate genetic factors contribute about 50% to the development of intelligence, which has a rather specific definition (Plomin & Spinath, 2004).



Source: Adapted from Bouchard & McGue, 1981; Plomin & Petrill, 1997

Definition of intelligence. As we have discussed, many researchers define intelligence as relating to Spearman's ***g*** factor (see p. 282), which is measured by performance on cognitive tests and results in IQ scores. However, some researchers argue that there are other, equally important kinds of intelligence, such as practical (adjusting to one's environment), social (interacting with others), emotional (perceiving and understanding emotions), as well as creative, musical, and insightful intelligence (R. J. Sternberg et al., 2003b). As discussed earlier, these kinds of intelligence are not measured by standard IQ tests, which primarily focus on measuring cognitive abilities.

Interaction of nature and nurture. When researchers report that genetic factors influence intelligence (IQ scores), they mean that genetic factors influence cognitive abilities to varying degrees, depending on the environment (Bishop et al., 2003). For example, what would happen to cognitive skills if a child were rated as being high or low in interacting with his or her environment?

Interaction. An example of how genetic and environmental factors interact in the development of intelligence comes from a study of 3-year-old children who were identified as being either high or low in exploring their environments, which is a personality trait known as stimulation seeking. These children were later given IQ tests at age 11 to determine if being high or low in stimulation seeking affected their IQs. Researchers reported that children who had been rated high in stimulation seeking at age 3 scored significantly higher on IQ tests compared to children who had been rated low in stimulation seeking at age 3. This significant difference in IQ scores (11 points) was not related to the occupation or education of their parents. Researchers concluded that children high in stimulation seeking were more curious and open to learning from their environments, which in turn enhanced the development of their cognitive abilities and resulted in higher scores on IQ tests (A. Raine et al., 2002).

Thus, genetic factors contribute about 50% to the development of one's intelligence (IQ score), while the other 50% comes from the interaction with environmental factors, which we'll examine next.

Adoption and Foster-Care Studies

How much does environment contribute?

What would happen if children with limited social-educational opportunities and low IQs were adopted by parents who could provide better social-educational opportunities? Researchers reasoned that if environmental factors influence the development of intelligence, then providing more environmental opportunities should increase IQ scores.

To determine whether environment can increase IQ scores, one research study examined the IQs of African American children from impoverished environments who were adopted into middle-class families, some White and some African American; all of the families provided many social-educational opportunities for the adopted children. Researchers found that the IQs of the adopted children were as much as 10 points higher than those of African American children raised in disadvantaged homes (Scarr & Weinberg, 1976). In a follow-up study, researchers reported that the adopted children, now adolescents, had higher IQ scores than African American children raised in their own communities (Weinberg et al., 1992). Other studies also indicate that as experiences for African Americans improve, so do IQs (W. Williams, 2009).

A similar study, this time focusing on children living in Romania, examined the intellectual functioning of children abandoned at birth and placed in state-run institutions (well known for not providing children with appropriate cognitive stimulation). Those children who remained in the institutions during the first several years of life demonstrated significantly poorer intellectual functioning when compared with children who soon moved into foster care. Children living in foster care are much more likely to have good educational opportunities than the children remaining in state-run institutions (C. A. Nelson et al., 2007).

These kinds of studies show that children with poor educational opportunities and low IQ scores can show an increase in IQ scores when they are provided better educational opportunities. Researchers conclude that nurture or environmental factors contribute to intellectual development (Begley, 2009; Duyme, 1999).

Children adopted into advantaged homes had higher IQ scores.

Interaction: Nature and Nurture

What is heritability?

In the last 15 years, researchers have made significant progress in answering the nature-nurture question, and one tool they have used is a number called heritability.

***Heritability* is a number that indicates the amount or proportion of some ability, characteristic, or trait that can be attributed to genetic factors (nature).**

For example, the figure below shows that heritability (nature) for overall intelligence (measured by IQ tests) was about 50%, which means that 50% of general cognitive ability comes from genetic factors. Researchers were also able to calculate the heritability scores for specific cognitive abilities, such as spatial ability (32%), verbal ability (55%), and memory (55%) (McClearn et al., 1997). These studies on heritability show that genetic factors (nature) contribute about half to intelligence.

The next big step in genetic research is the identification of specific genes or groups of genes that contribute to specific cognitive traits used to measure intelligence (Plomin et al., 2008).

Notice that the heritability numbers in the graph on the left are in the 50% range, which means that genes do not determine or fix these abilities, because the other 50% is coming from environmental factors. You can think of genetic factors as establishing a range of potential abilities or behaviors, which are shaped and molded through interaction with one's environment. This idea of how genetic factors operate is called the reaction range (Bouchard, 1997).

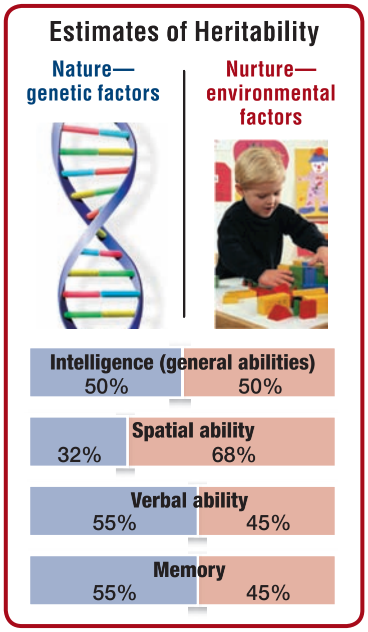
***Reaction range* indicates the extent to which traits, abilities, or IQ scores may increase or decrease as a result of interaction with environmental factors.**

Researchers estimate that the reaction range may vary up or down by as much as 10–15 points in one's IQ score. For example, the figure on the right shows that a person's IQ may vary from 85 to 110, depending on whether he or she has an impoverished or enriched environment (Zigler & Seitz, 1982).

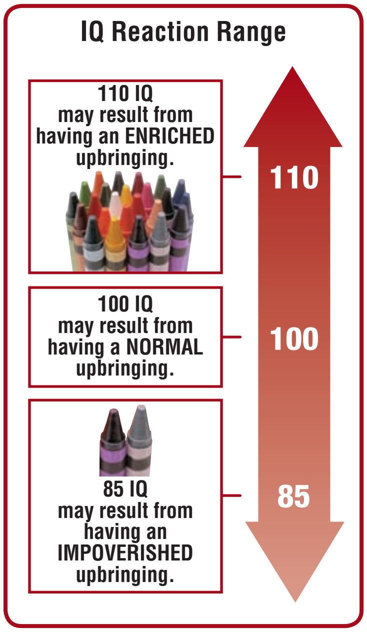
Conclusion. The studies on heritability, twins, and adopted children provide an answer to the nature-nurture question: Nature or heredity contributes about 50% to intelligence (IQ) and environment or nurture contributes about 50%. However, a person's IQ can vary by 10–15 points (IQ reaction range), depending on how heredity interacts with different kinds of environments.

Next, we'll examine the debate over racial differences in IQ scores.

Estimates of Heritability



IQ Reaction Range



110 IQ may result from having an ENRICHED upbringing.
110
100 IQ may result from having a NORMAL upbringing.
100
85 IQ may result from having an IMPOVERISHED upbringing.
85

E. Nature-Nurture Question

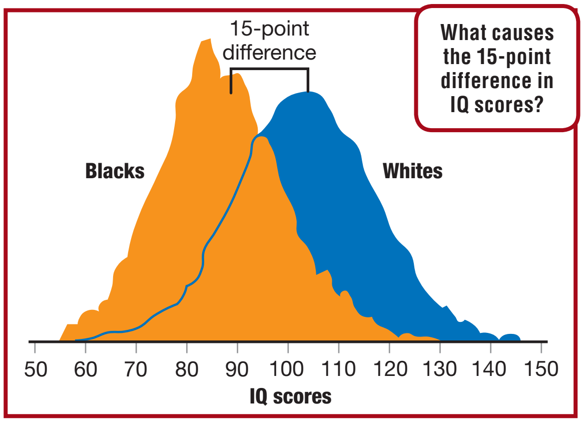
PowerStudy 4.5™

Module 4
H. Cultural Diversity: Brain Size & Racial Myths

Racial Controversy

What is the heated controversy?

In the early 1900s, psychologists believed intelligence was primarily inherited. This idea reappeared in a relatively recent book, *The Bell Curve,* by psychologist Richard Herrnstein and political scientist Charles Murray (1994). But what brought these authors the greatest publicity was their statement that racial differences in IQ scores were caused primarily by genetic or inherited factors. This and other statements from Herrnstein and Murray's book set off such a heated and often misguided public debate that the American Psychological Association (APA) formed a special task force of prominent researchers. The goal of the APA task force was to summarize what is known about intelligence (Neisser et al., 1996). The issues of race, genetics, and intelligence are still hotly debated (Rushton & Jensen, 2005). We will now focus on the complex question of racial differences in IQ scores.



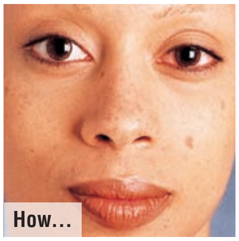
What causes the 15-point difference in IQ scores?

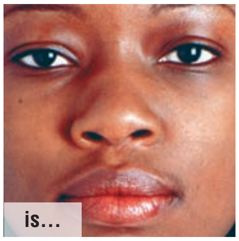
Difference between IQ Scores

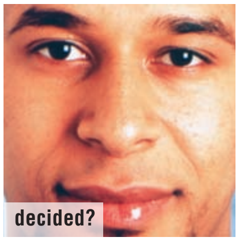
Findings. To help you understand the controversy surrounding racial differences in IQ scores, please look at the figure in the upper right. Notice that there are two distributions of IQ scores: The orange bell-shaped curve shows the distribution of IQ scores for African Americans (Blacks), and the blue bell-shaped curve shows the distribution of scores for Caucasians (Whites). Although there is much overlap in IQ scores (indicated by overlapping of orange and blue areas), researchers generally agree that the average or mean IQ score for African Americans is about 15 points lower than the average IQ score for Caucasians (Bouchard, 1995). This 15-point average difference in IQ scores means that although there are many African Americans with high IQ scores, they are proportionally fewer in number compared to Caucasians.

Two explanations. There are at least two possible explanations for this 15-point difference in average IQ scores. One explanation is that the differences are due to inherited or ***genetic factors:*** African Americans are genetically inferior to Whites. Another explanation is that the difference is due to a number of ***environmental factors:*** African Americans have fewer social, economic, and educational opportunities than Whites do.

Although the authors of *The Bell Curve* emphasized the role of genetic factors, you'll see that the APA task force and many other psychologists disagreed.







Cause of IQ Differences

Group differences. In a careful review of *The Bell Curve,* one of the leading researchers in the area of intelligence concluded the book offered no convincing evidence that genetic factors were primarily responsible for the 15-point IQ difference between African Americans and Caucasians (R. J. Sternberg, 1995). This conclusion is based largely on the distinction between whether genetic factors can influence the development of intelligence in an individual and whether they can influence the development of intelligence among races. The APA task force said there is good evidence that genetic factors play a significant role in the development of an ***individual's intelligence.*** However, there is no convincing evidence that genetic factors play a primary role in the differences in intelligence ***among races.*** A tremendous amount of research data challenges Herrnstein and Murray's statement that IQ ***differences among races*** are caused primarily by genetic factors (Neisser et al., 1996; R. J. Sternberg et al., 2005).

Although no one knows exactly what causes the difference in IQ scores shown in the above graph, many psychologists suggest a number of environmental factors, such as differences in social-economic classes, educational opportunities, family structures, and career possibilities (Loehlin, 2000). Recent research that shows the difference in IQs between African Americans and Whites is narrowing by 4–7 points suggests that environmental factors can significantly influence IQ (Dickens & Flynn, 2006). Thus, one of *The Bell Curve's* major conclusions—that racial differences in IQ scores are based primarily on genetic factors—is not supported by the evidence (Neisser et al., 1996). Two prominent researchers concluded that *The Bell Curve's* argument for racial inferiority appeared to be based on scientific evidence, but closer examination shows that it was not (S. J. Gould, 1996; R. J. Sternberg, 1995).

Differences in skin color. Another problem with *The Bell Curve* is its assumption that skin color is a meaningful way to identify races. For example, based on skin color, to which race would you assign the individuals in the four photos on the left? Researchers report that skin color is not reliable in identifying racial makeup because recent studies on DNA (genetic instructions) indicate that people around the world are much more alike than different (Shriver, 2005). In fact, no matter the color of one's skin, genetic instructions in people around the world vary by only about 3–5% (M. C. King & Motulsky, 2002). Thus, differences in skin color are only skin deep, and skin color is not a reliable measure to assign people to different races when comparing IQ scores (Venter, 2000).

After the Concept Review, we'll discuss how early racial discrimination was based on IQ scores.

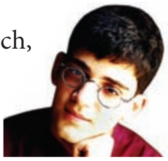
Concept Review

1. One approach to measuring intelligence focuses on quantifying cognitive factors or abilities that are involved in intellectual performance; this is called the (a) ______________ approach. Charles Spearman used this approach to develop a two-factor theory of intelligence: one factor is ***g***, or (b) ______________; the second factor is ***s***, or (c) ______________.



2. In comparison to Spearman's two-factor approach, Howard Gardner's theory says that there are nine kinds of ______________, such as verbal skills, math skills, spatial skills, and movement skills.

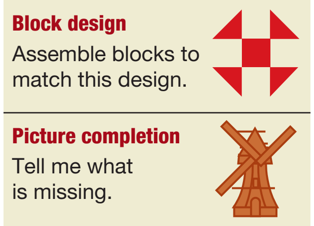
3. Another approach to measuring intelligence is by analyzing the kinds of (a) ______________ processes that people use to solve problems. An example of this approach is Robert Sternberg's (b) ______________ theory of intelligence.

4. Alfred Binet developed an intelligence test that estimated intellectual progress by comparing a child's score on an intelligence test to the scores of average children of the same age. Binet called this concept ______________.

$$IQ = \frac{?}{?} \quad ?$$

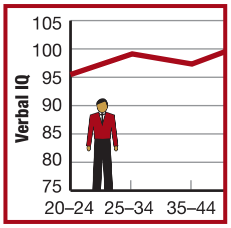
5. Lewis Terman revised Binet's intelligence test, and the most significant change he made was to develop a formula to compute a single score that represents a person's (a) ______________. This formula is IQ = (b) ______________ age divided by (c) ______________ age, times (d) ______________.

6. The most widely used series of IQ tests are the (a) ______________ Intelligence Scales. These tests organize items into two subtests, which are called (b) ______________ and (c) ______________ scales. In an attempt to measure nonverbal skills and rule out cultural problems, Wechsler added the (d) ______________ scale.



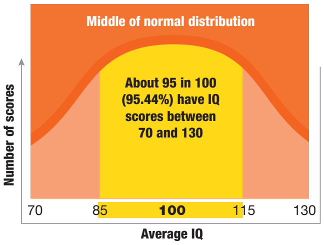
Block design
Assemble blocks to match this design.

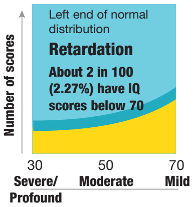
Picture completion
Tell me what is missing.



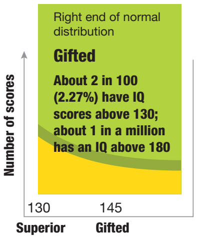
7. A good psychological test has two characteristics. It should give about the same score over time, which is called (a) ______________, and it should measure what it is supposed to measure, which is called (b) ______________.

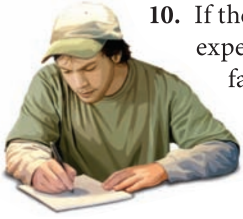
8. If IQ scores can be represented by a bell-shaped curve, the pattern is called a ______________. The scores have a symmetrical arrangement, so that the vast majority fall in the middle range and fewer fall near the extreme ends of the range.



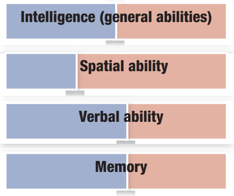


9. An individual who has a combination of limited mental ability (usually an IQ below 70) and difficulty functioning in everyday life is said to have some degree of (a) ______________. If this condition results from genetic problems or brain damage, it is called (b) ______________. If this condition results from a greatly impoverished environment, it is called (c) ______________. Individuals who have above-average intelligence (usually IQ scores above 130) as well as some superior talent or skill are said to be (d) ______________.





10. If the wording of test questions and the experiences on which they are based are more familiar to members of some social groups than to others, the test is said to have a (a) ______________. Depending on the culture, (b) ______________ can be defined in different ways.



11. When we ask how much genetic factors and how much environmental factors contribute to intelligence, we are asking the (a) ______________ question. There is good evidence that genetic factors contribute about (b) ______________ and environmental factors contribute about (c) ______________ to the development of one's intelligence. The extent to which IQ scores may increase or decrease depending on environmental effects is called the (d) ______________.

Answers: *1. (a) psychometric, (b) general intelligence, (c) specific abilities; 2. intelligence; 3. (a) reasoning, (b) triarchic; 4. mental age; 5. (a) intelligence quotient or IQ, (b) mental, (c) chronological, (d) 100; 6. (a) Wechsler, (b) verbal, (c) performance, (d) performance; 7. (a) reliability, (b) validity; 8. normal distribution; 9. (a) mental retardation, (b) organic retardation, (c) cultural-familial retardation, (d) gifted; 10. (a) cultural bias, (b) intelligence; 11. (a) nature-nurture, (b) 50%, (c) 50%, (d) reaction range*

F. Cultural Diversity: Races, IQs & Immigration

Misuse of IQ Tests

What were Binet's warnings about using IQ tests?

After Alfred Binet developed the first intelligence tests, he gave two warnings about the potential misuse of IQ tests. He warned that IQ tests do not and should not be used to measure innate intelligence and that IQ tests should not be used to label individuals. However, in the early 1900s the area we know as psychology was just beginning, and American psychologists were very proud of how much they had improved IQ tests. With their improved IQ tests, American psychologists not only used IQ tests to measure what they thought was innate, or inherited, intelligence but also used IQ tests to label people (as morons or imbeciles). As if that weren't bad enough, early psychologists persuaded the U.S. Congress to pass discriminatory immigration laws based on IQ tests. As we look back now, we must conclude that the use and abuse of IQ tests in the early 1900s created one of psychology's sorriest moments. Here's what happened.

In 1924, Congress passed an immigration law to keep out those believed to have low IQs.

Photo Credit: © UPI/Bettmann/Corbis

Innate Intelligence

One name that we have already mentioned is that of Lewis Terman, who was the guiding force behind revising Binet's intelligence test (which became the Stanford-Binet test) and also developing the formula for computing a single IQ score. Terman, who became head of the Department of Psychology at Stanford University, firmly believed that intelligence was primarily inherited, that intelligence tests measured innate abilities, and that environmental influences were far less important.

One of Terman's goals was to test all children and, on the basis of their IQ scores, to label and sort them into categories of innate abilities. Terman argued that society could use IQ scores (usually of 70 or below) to restrain or eliminate those whose intelligence was too low to lead an effective moral life (Terman, 1916).

Terman hoped to establish minimum intelligence scores necessary for all leading occupations. For example, he believed that people with IQs below 100 should not be given employment that involves prestige or monetary reward. Those with IQs of 75 or below should be unskilled labor, and those with 75–85 IQs should be semiskilled labor. In Terman's world, class boundaries were to be set by innate intelligence, as measured by his Stanford-Binet IQ test (S. J. Gould, 1996; Hunt, 1993).

Terman's belief that IQ tests measured innate intelligence was adopted by another well-known American psychologist, Robert Yerkes.

Classifying Races

Robert Yerkes was a Harvard professor who was asked to develop a test that could be used to classify applicants for the army. Under Yerkes's direction, over 1.75 million World War I army recruits were given IQ tests. From this enormous amount of data, Yerkes (1921) and his colleagues reached three conclusions:

1. They concluded that the average mental age of White American adults was a meager 13 years, slightly above the classification of a moron (a term psychologists used in the early 1900s). The reasons they gave for this low mental age were (using the terminology then current) the unconstrained breeding of the poor and feebleminded and the spread of Negro blood through interracial breeding.

2. They concluded that European immigrants could be ranked on intelligence by their country of origin. The fair peoples of western and northern Europe (Nordics) were most intelligent, while the darker peoples of southern Europe (Mediterraneans) and the Slavs of eastern Europe were less intelligent.

3. They concluded that Negroes were at the bottom of the racial scale in intelligence.

Many of Yerkes's outrageous and discriminatory views resurfaced in the book *The Bell Curve* (Herrnstein & Murray, 1994), which we discussed earlier. Following Yerkes's lead, IQ scores were next used for racial discrimination.

Immigration Laws

The fact that Yerkes ranked European races by intelligence eventually reached members of the U.S. Congress. Outraged by the "fact" that Europeans of "low intelligence" were being allowed into America, members of Congress sought a way to severely limit the immigration of people from southern and eastern Europe. In writing the Immigration Law of 1924, Congress relied, in part, on Yerkes's racial rankings and imposed harsh quotas on those nations they believed to have inferior stock (people from southern and eastern Europe, Alpine and Mediterranean nations).

Stephen Jay Gould (1996), a well-known evolutionary biologist, reviewed Yerkes's data and pointed out a number of problems: poorly administered tests, terrible testing conditions, inconsistent standards for retaking tests, written tests given to illiterate recruits (guaranteeing a low score), and no control for educational level or familiarity with the English language. As a result of these problems, Gould concluded that Yerkes's data were so riddled with errors as to render useless any conclusions about racial differences in intelligence.

Looking back, we see clearly that early psychologists badly misused IQ tests. They forgot that IQ tests are merely one of many tools to assess cognitive abilities, which many consider to be one of many kinds of intelligence (H. Gardner, 1995).

We've discussed how past IQ tests have been misused and how current IQ tests may be biased. Is there a new generation of intelligence tests on the horizon?

Can Genius Be Found in the Brain?

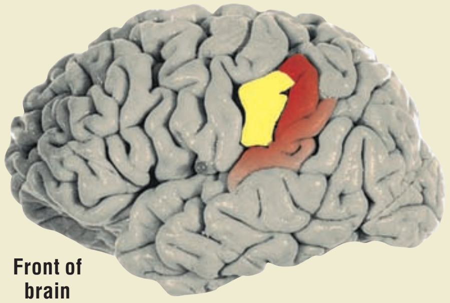
PowerStudy 4.5™

Module 4
B. Studying the Living Brain

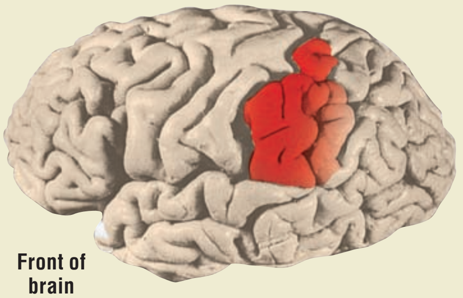
There is one question about intelligence that has especially interested researchers: How is the brain of a genius different? For example, how was Albert Einstein able to think of riding through space on a beam of light or create his famous formula ($E = mc^2$), which led to building the atomic bomb?

When Einstein died of heart failure in 1955 at age 76, Dr. Thomas Harvey, who performed the autopsy, removed Einstein's brain and kept it at Princeton University. In 1996, Harvey contacted Dr. Sandra Witelson, a neuroscientist at McMaster University, and asked if she wished to examine Einstein's brain. McMaster University in Ontario, Canada, has a bank of over 100 brains that people have donated for research. Dr. Witelson was able to compare Einstein's 76-year-old brain with brains of similar ages from 35 men and 56 women who were known to have normal intelligence when they died. The results of Dr. Witelson's examination of Einstein's brain are discussed in the figure at the right.

Normal brain weighs about 1,350 grams. This side view shows the wrinkled cortex, which contains separate areas for different functions (feeling, moving, reading, writing, seeing). Notice the yellow and red areas, which are part of the parietal lobe. The **red area, the inferior parietal lobe,** is especially used for thinking in visual-spatial terms, for mathematical thought, and for imaging how things move in space.



Einstein's brain weighed 1,230 grams, slightly less than normal. Einstein's brain was different in that it lacked the yellow area, which allowed his **red area, the inferior parietal lobe,** to be 15% wider than in normal brains. Also, his parietal lobe had rare grooves and ridges. Researchers believe that Einstein's unique parietal lobe increased his ability to think and imagine such things as space being curved and that time could slow down (Falk, 2009; Witelson et al., 1999).



Although the physical differences in Einstein's brain are obvious in the figure, Dr. Witelson cautions that they don't know if every brilliant mathematician has a larger inferior parietal lobe, which is something only further research can answer. Other researchers wonder if genius can ever be measured or located in the brain, since genius involves a mixture of creative insights, culture, and life experiences that may be unique to that person (S. C. Wang, 2000).

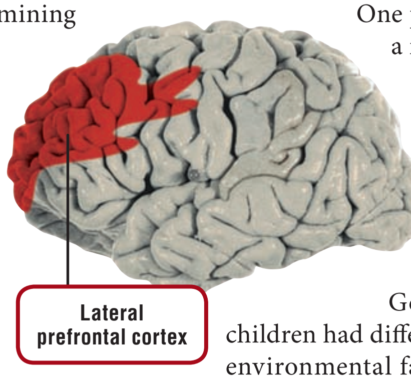
How Does a Prodigy's Brain Develop?

What do brain scans show?

With the recent advances in brain scans, researchers are now able to explore brain development like never before. Phillip Shaw and his colleagues (2006) at the National Institute of Mental Health and McGill University in Montreal completed a long-term study examining intelligence and brain development in children.

Method. The team of researchers followed a group of more than 300 children as they aged from 6 to 19. Each child was administered intelligence tests at the start of the study, and MRI brain scans (p. 70) were taken about every two years to measure the size of brain structures.

Results. The thickness of the cortex (p. 74), which is the outer layer of the brain that controls higher cognitive functioning, began thinner in highly intelligent children, but became thicker than the cortexes in children with average intelligence by adolescence. As shown in the brain above, the areas that changed the most were in the front of the brain and in a strip over the top of the brain, which are areas responsible for higher cognitive functioning, such as planning and reasoning. By the age of 19, the cortexes of highly intelligent children thinned such that they were equal in thickness to the cortexes of children with average intelligence.



Conclusions. This is the first study to show that the brain develops differently in highly intelligent children. However, it is uncertain what might be causing the changes in cortex thickness. One possible explanation is the thickening may be a result of highly intelligent children developing more neural connections during school years, and the later thinning of the cortex may be due to unused neural connections withering away to make cognitive functioning more efficient.

The role of genes and environment in the changes in the cortex is also unknown. Genes may play an important role as smarter children had different cortex thickness even at a young age. But environmental factors (social activities, schooling, diet) may also have an important role in the thickening of the cortex over the years (Grigorenko, 2006).

Last, this study examined only group differences, and making any predictions based on an individual child is not possible (Giles, 2006).

H. Application: Intervention Programs

Definition of Intervention Programs

Why might a child need a head start?

For a moment, imagine what will happen to Nancy's child. Nancy, who is in her mid-twenties, is a single mother with a 3-year-old child. Nancy lives in a lower-class neighborhood and earns less than $5,000 a year doing part-time work. She has completed only two years of high school and has no family and few friends. What effects do you think Nancy's background, educational level, and impoverished environment will have on her child? Psychologists would predict that Nancy's 3-year-old child will not likely acquire the social, emotional, and cognitive skills and abilities needed to do well in school or society. Her child may need outside help, which may come from an intervention program (Arnold & Doctoroff, 2003).

Intervention programs create a stimulating environment.

An ***intervention program*** helps disadvantaged children from low socioeconomic classes to achieve better intellectual, social, and personal-emotional development, as well as physical health.

Intervention programs can give Nancy training in how to be a good parent and provide her child with educational and social opportunities. Perhaps the best-known intervention program in the United States is Head Start, which began in 1965 as a six-to-eight-week program. Researchers later discovered that was too brief to be effective. As a result, Head Start was lengthened to two years, and in 2006, the program enrolled nearly one million 3- to 5-year-olds across the United States (ACF, 2006).

We'll focus on successful intervention programs for disadvantaged children.

Parent Training

Children growing up in disadvantaged environments, such as poverty, often experience negative effects on their cognitive development. New research has found that parents can improve their children's mental abilities by better relating to them at home.

This research study tested the mental abilities of children in two different groups. The parents of one group of children participated in parenting skills classes to learn how to provide consistent routines at home, discipline their children in constructive ways, and better communicate with their children overall. The parents of the second group of children did not receive training in parenting skills. Results showed that for those children whose parents received parent training, the scores on tests of memory, attention, language ability, and IQ increased. Additionally, the parents of these children reported less stress at home and an improvement in their children's behavior (Downs, 2008; Stevens & Neville, 2008).

This research suggests that children living in disadvantaged environments can benefit from intervention programs in many ways, such as improving their cognitive and behavioral skills.

Head Start

Head Start, which is a day-care program for disadvantaged children, usually lasts for two years, from ages 3 to 5, and has six goals: preschool education, health screening, mental health services, hot meals, social services for the child and family, and involvement and participation of parents in the program (Zigler & Styfco, 1994). More recently, Head Start has emphasized teaching basic academic skills, such as reading, in order to prepare disadvantaged children to do well in kindergarten (R. T. Cooper, 1999).

Head Start was initially viewed as something of a failure because two to three years after children left Head Start, few if any differences in IQ or other academic scores were found between those children and control groups (Clarke & Clarke, 1989). However, Head Start showed other important long-term beneficial effects (Kirp, 2004; Zigler & Styfco, 1994):

- Adolescents who had been in the Head Start program were more likely to be in classes appropriate for their ages rather than to have had to repeat a class, were less likely to show antisocial or delinquent behavior, and were more likely to hold jobs.
- Mothers whose children had been in the Head Start program reported fewer psychological symptoms, greater feelings of mastery, and greater current life satisfaction.
- Children who had two years of Head Start and an additional two to seven years of educational help were much more successful in graduating from high school (69%) than a control group (49%).
- At the age of 40, adults who had been in Head Start were more likely to have earned college degrees and to have owned a home and a car, and less likely to have criminal records and be drug users.

Head Start results in long-term personal and social gains.

Another program similar to Head Start, called the Chicago Child Parent Center Program, enrolled children 3–4 years old and lasted for 18 months. Over 1,500 children in this program were tracked from ages 5 to 20 and were found to be more likely to graduate from high school and less likely to be arrested than poor children not in the program (A. J. Reynolds et al., 2001).

From studies like these we can draw two conclusions. First, often early and rather large increases (up to 10 points) in IQ scores do not last after the child leaves the intervention program. Second, programs like Head Start result in a number of long-term benefits, such as better social and personal well-being and increased chances of graduating from high school and avoiding crime (Zigler, 1995; Zigler & Styfco, 2001). These long-term effects indicate that programs like Head Start should not be evaluated solely on IQ scores but also on other personality, motivational, and psychological benefits.

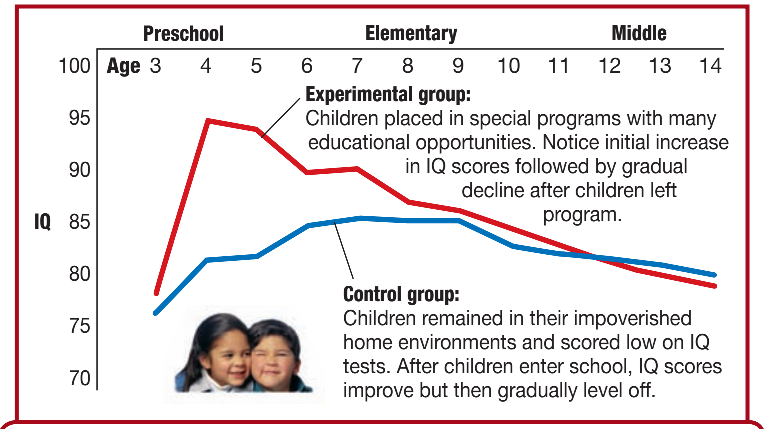
Raising IQ Scores

In the early days of Head Start, psychologists were very encouraged to find that the program initially increased disadvantaged children's IQ scores by about 10 points, a very significant amount. One reason IQ scores can be raised in young children from disadvantaged homes is that these children have not been exposed to and have not acquired the kinds of skills and cultural experiences assessed by IQ tests. However, when disadvantaged children are exposed to the enriched environment of Head Start, these children quickly acquire all kinds of new skills and abilities that help them score higher on IQ tests (Spitz, 1997).

For example, researchers compared two groups of disadvantaged children, all of whom had IQ scores below 80 (100 is considered the average IQ). Some of these children, called the experimental group, were placed in a special educational intervention program from ages 3 to 5. Other children, called the control group, were given no additional training and remained in their home environments.

The figure below shows that, after only one year, children in the experimental group (intervention program) showed a significant increase in IQ scores (about 10 points) compared to the children in the control group who remained in disadvantaged home environments (Schweinhart & Weikart, 1980). However, after the children left the intervention program at the age of 5 and entered public school, their IQ scores began a slow but consistent decline. At the same time, the IQ scores of control children began a gradual increase as they benefited from attending public school. By the age of 11, there was no longer any difference in IQ scores.



Initial increase in IQ scores (age 4) gradually disappears after children leave Head Start program and return to less stimulating environments.

One reason for this decline in IQ scores is that after children leave an intervention program, they usually return to less stimulating environments, which offer less educational, social, and motivational support. For this reason, researchers make two strong recommendations: First, programs like Head Start should be lengthened from three to at least five or more years so children have more time to learn and practice their newly acquired social, emotional, and academic skills; second, parents must become involved in helping their children develop cognitive skills, such as reading to their children (G. Nelson et al., 2003; Zigler & Styfco, 2001).

Finally, as we discussed earlier, intervention programs should not be evaluated solely on IQ scores but rather on other social, emotional, and psychological gains that are found to be long-lasting.

Need for Intervention Programs

The most successful intervention programs have a strong educational emphasis, well-trained teachers, and a low ratio of children to trained teachers.

Researchers make three important points about the usefulness of childhood intervention programs:

1 Currently, millions of children in the United States are living in poverty, which is known to have a devastating negative influence on a young child developing important social-emotional skills and cognitive abilities. In addition, living in poverty is known to lower academic achievement and goals, decrease motivation, and contribute to school failure and dropouts (Arnold & Doctoroff, 2003). Intervention programs help reduce the devastating effects that continuing poverty can have on families and give children a much needed head start (Zigler & Styfco, 2001).

2 About 25 to 30% of children live in single-parent families that are below the poverty line (Kassebaum, 1994). In some cases, impoverished family environments lead to neglect or abuse, which has very negative effects on a child's social, emotional, and intellectual development. Intensive intervention programs during the first years of life are effective in reducing and preventing the significant intellectual dysfunction that may result from continuing poverty and lack of environmental support (Zigler & Styfco, 2001).

3 Results from the most extensive and longest-term research study of intelligence show that childhood intelligence affects physical and mental illness later in life, overall quality of life, and even an individual's life span. We have known that childhood intervention programs improve children's mental abilities, but only recently have we learned that children's mental abilities affect their lives in significant ways for years to come (Deary et al., 2009).

It is for all the reasons stated above that researchers strongly advocate for the development of well-designed childhood intervention programs.

Summary Test

A. Defining Intelligence

1. A subarea of psychology that is concerned with developing psychological tests to assess an individual's abilities, skills, beliefs, and personality traits in a wide range of settings—school, industry, or clinic—is called ______________.

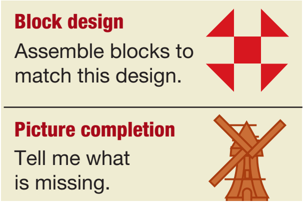
2. Spearman's two-factor theory of intelligence says there is a general factor, called (a) ______________, that represents a person's ability to perform complex mental work, such as abstract reasoning and problem solving. The general factor underlies a person's performance across tests. In addition, there is a second factor, called (b) ______________, that represents a person's specific mental abilities, such as mathematical or verbal skills. These specific mental abilities may differ across tests.

3. Gardner says that there are at least nine kinds of intelligence: verbal intelligence, musical intelligence, logical-mathematical intelligence, spatial intelligence, body movement intelligence, intelligence to understand oneself, intelligence to understand others, naturalistic intelligence, and existential intelligence. This is called the ______________ theory.

4. Sternberg's triarchic theory says that intelligence can be divided into three ways of gathering and processing information (*triarchic* means "three"). The first is using (a) ______________ skills, which are measured by traditional intelligence tests. The second is using (b) ______________ skills that require creative thinking, the ability to deal with novel situations, and the ability to learn from experience. The third is using (c) ______________ skills that help a person adjust to, and cope with, his or her sociocultural environment.

B. Measuring Intelligence

5. In trying to measure intelligence, researchers through the years have learned that neither skull size nor brain weight is an accurate predictor of ______________.



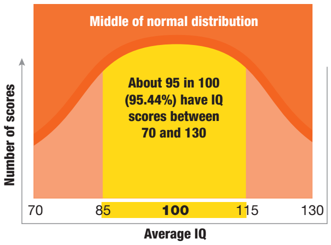
Block design
Assemble blocks to match this design.
Picture completion
Tell me what is missing.

6. The first intelligence test, which was developed by (a) ______________, measured vocabulary, memory, common knowledge, and other cognitive abilities. By comparing a child's score with the scores of average children at the same age, Binet was able to estimate a child's (b) ______________. Thus, the Binet-Simon Intelligence Scale gave its results in terms of mental age, while the IQ score was later developed by (c) ______________, who devised a formula to calculate an individual's intelligence quotient. The formula can be written as IQ = (d) ______________.

7. The Wechsler Adult Intelligence Scale (WAIS) and Wechsler Intelligence Scale for Children (WISC) have items that are organized into various subtests. Subtests for general information, vocabulary, and verbal comprehension are some of those in the (a) ______________ section. Subtests that involve arranging pictures in a meaningful order, assembling objects, and using codes are examples of subtests in the (b) ______________ section. An individual receives a separate score for each of the subtests; these scores are then combined to yield overall scores for verbal and performance abilities, which, in turn, are combined into a single score, called an (c) ______________ score.

8. A good psychological test must have two qualities. One quality ensures that a person's score on a test at one point in time is similar to a score by the same person on a similar test at a later date; this is called (a) ______________. The other quality ensures that a test measures what it is supposed to measure; this is called (b) ______________. Although the results from analyzing handwriting may be consistent from time to time, this is a poor test of personality or intelligence because handwriting analysis lacks the quality of (c) ______________.

C. Distribution & Use of IQ Scores



9. Suppose IQ scores are in a statistical arrangement that resembles the shape of a bell, with the vast majority of scores falling in the middle range and fewer scores falling near the two extreme ends of the curve. This arrangement is called a ______________.

10. Substantial limitation in present functioning that is characterized by significantly below average intellectual functioning, along with related limitations in two of eleven areas, including communication, self-care, home living, social skills, and safety, is called ______________.

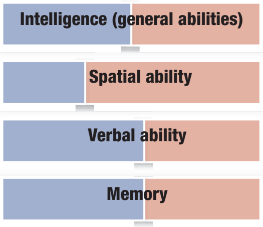
11. There are two general causes of mental retardation: genetic problems or brain damage give rise to (a) ______________ retardation, and in the absence of apparent genetic or brain damage, greatly impoverished environments can give rise to (b) ______________ retardation. Mental retardation is reflected in IQ scores at one end of the normal distribution. At the other end of the normal distribution of IQ scores are those who are considered (c) ______________; such people have above average intelligence (usually IQs above 130) as well as some superior talent or skill.

Photo Credit: (#1) © WireImage/Getty Images

D. Potential Problems of IQ Testing

12. Binet warned that intelligence tests should not be used to measure (a) ________ mental abilities because intelligence tests measure cognitive abilities, which are influenced by both heredity and environment. Binet also warned that intelligence tests, by themselves, should not be used to (b) ________ people—for example, a moron or a genius. Current IQ tests have been criticized for including wording or experiences that are more familiar to a particular culture, which is called (c) ________. The definition of intelligence differs across (d) ________ and may differ from the Western idea of ***g***. One reason individuals may do poorly on IQ tests is noncognitive factors, such as attitude, experience, and emotional functioning, which are called (e) ________.

E. Nature–Nurture Question



13. The (a) ________ question refers to the relative contributions that genetic and environmental factors make to the development of intelligence. On the basis of twin studies, researchers generally conclude that about (b) ________ of the contribution to intelligence (IQ scores) comes from genetic factors and about (c) ________ comes from environmental factors. Adoption studies support the idea that environmental factors contribute to intellectual development (as measured by IQ scores). The idea that about half of one's intellectual development is dependent on environmental factors has resulted in (d) ________ programs that give impoverished children increased social-educational opportunities. There is little or no cause-and-effect evidence that the average difference in IQ scores between African Americans and Whites is caused primarily by (e) ________ factors.

F. Cultural Diversity: Races, IQs & Immigration

14. Early psychologists ignored Binet's warning about misusing IQ tests. For example, in the early 1900s, Terman believed that IQ tests did measure (a) ________ intelligence, and he wanted to use IQ tests to sort people into categories. Terman's view was adopted by Robert Yerkes, who wanted to use IQ tests to rank the intelligence of (b) ________ entering the United States. In the 1920s, (c) ________ were written to exclude citizens from certain countries because Yerkes had ranked these individuals low in intelligence.

G. Research Focus: New Approaches

15. In looking for physical differences in Einstein's brain, researchers found that he had a 15% wider (a) ________, which is involved in visual–spatial and mathematical thinking. By using MRI brain scans and intelligence tests, researchers found that the thickness of the brain's cortex began (b) ________ in highly intelligent children, but became (c) ________ than the cortexes in children with average intelligence by adolescence. By the age of 19, the cortex of highly intelligent children was (d) ________ in thickness to that of children with average intelligence.

H. Application: Intervention Programs

16. A program that creates an environment with increased opportunities for intellectual, social, and personality-emotional development is called an (a) ________ program. New research finds that parents can improve their children's (b) ________ by better relating to them at home. Although data indicate that IQ increases resulting from intervention programs may be short-lived, there are other long-term positive benefits, such as being more likely to graduate from high school and less likely to be involved in (c) ________ activities. Results from the most extensive and longest-term research study of intelligence show that childhood (d) ________ affects physical and mental illness later in life, overall quality of life, and even an individual's life span.

Answers: *1. psychometrics; 2. (a)* ***g****, (b)* ***s****; 3. multiple-intelligence; 4. (a) analytical, cognitive, or logical, (b) problem-solving, (c) practical; 5. intelligence; 6. (a) Binet and Simon, (b) mental age, (c) Terman, (d) MA/CA × 100; 7. (a) verbal, (b) performance, (c) IQ; 8. (a) reliability, (b) validity, (c) validity; 9. normal distribution; 10. mental retardation; 11. (a) organic, (b) cultural-familial, (c) gifted; 12. (a) innate, (b) label or classify, (c) cultural bias, (d) cultures, (e) nonintellectual factors; 13. (a) nature–nurture, (b) 50%, (c) 50%, (d) intervention, (e) inherited, or genetic; 14. (a) innate, (b) immigrants, (c) immigration laws, or quotas; 15. (a) inferior parietal lobe, (b) thinner, (c) thicker, (d) equal; 16. (a) intervention, (b) mental abilities, (c) antisocial, delinquent, or criminal, (d) intelligence*

Critical Thinking

Smartest or Strongest Man in America?

Smartest, definitely. Though Chris Langan can bench press a whopping 500 pounds, his intellect is far more impressive. Chris's IQ score is off the charts at an estimated 195 (average IQ score is 100). Only one in several billion people has an IQ of 195 or above. Even Einstein didn't compare, as his IQ is estimated to have been 150. Chris is surely a rocket scientist, brain surgeon, or Nobel Prize winner, right? Wrong! Let's take a look at Chris's life to understand why he hasn't achieved the extraordinary career success we expect from him.

Chris's childhood left much to be desired. His family was so poor he had only one outfit, which consisted of unmatched socks and a shirt, pants, and shoes, all with holes in them. His father left before his birth and his mother had four husbands, three of whom died. Chris's fourth stepfather was physically abusive toward him. For instance, he asked Chris questions and when Chris answered them correctly, he punched Chris in the mouth. Chris took up weight-lifting in his early teens, and one day when his stepfather began beating him, he struck back so hard, his stepfather left and never returned.

Despite harsh living circumstances, Chris's intellect persevered. He began speaking at 6 months of age, and by age 3 he was reading. He skipped ahead in school and even then, he felt he knew more than his teachers. All he had to do to ace exams was to quickly skim his textbooks. Chris is one of the few to obtain a perfect score on the SAT, and he even squeezed in a nap during this challenging timed test.

Because of life circumstances, Chris never finished college. Instead, he has worked labor jobs throughout his life. Some of the jobs he's had include construction worker, lifeguard, farmhand, cowboy, factory worker, firefighter, and, for the past 20 years, a bouncer at a bar. Isn't working as a bouncer one of the last jobs you expect the smartest man in America, and quite possibly in the world, to have? So, you have to ask yourself, why did Chris end up like this? The answer is because of his disadvantaged environment. There was no one to help him. No one ever encouraged him to pursue greatness. Absolutely nothing in his background helped him take advantage of his remarkable talents.

Chris is now in his fifties, still lifting weights and working as a bouncer. He's also working on a theory that explains problems scientists and philosophers have been thinking about for thousands of years. He calls his theory Cognitive–Theoretic Model of the Universe (CTMU). He believes CTMU can answer all questions about reality and prove the existence of God. If anyone can answer such questions, surely Chris, with an IQ of 195, is a top contender.

We have to wonder what would have happened to Chris had he been born into a wealthy, well-respected, and well-connected family. Only if he were raised in such an environment could he have become the brain surgeon or Nobel Prize winner we expect from a man with an unmatched IQ. (Adapted from Brabham, 2001; Gladwell, 2008; L. Grossman, 2008; Preston, 2008)

QUESTIONS

1 Based on Chris's IQ score, what type(s) of intelligence does he excel at?

2 Based on the normal distribution, where does Chris rank in intelligence?

3 Which intelligence theory takes his weight-lifting and physical strength into consideration?

4 Is Chris's ability to speak and read at an early age mostly attributable to nature or nurture?

5 According to Sternberg's triarchic theory, which type of intelligence stands out most for Chris?

6 Given Chris's high IQ of 195, what size brain must he have?

Visit this book's companion website for more resources to help you study, including learning objectives, additional quizzes, flash cards, updated links to useful websites, and a pronunciation glossary.

Study Guide and WebTutor

Work through the corresponding module in your Study Guide for tips on how to study effectively and for help learning the material covered in the book. WebTutor (an online Study Tool accessed through your eResources account) provides an interactive version of the Study Guide.

Suggested Answers to Critical Thinking

1. Traditional IQ scores, such as the WAIS, assess verbal and performance abilities. Given his score is obtained by only one in several billion people, it is safe to say he does extremely well in both types of intelligence.
2. Based on a normal distribution of IQ scores, Chris's score of 195 falls in the profoundly gifted range and is extremely uncommon.
3. The only intelligence theory that includes physical strength as a type of intelligence is Gardner's multiple-intelligence theory, which states that body movement intelligence is one of the nine types of intelligence.
4. Because Chris began speaking when he was only 6 months old and reading by age 3, all while being in a severely disadvantaged environment, nature can be credited for his talents. Remember that nature is hereditary or genetic factors and nurture is environmental factors.
5. Sternberg's triarchic theory includes three kinds of intelligence: analytical, problem solving, and practical. Given Chris's high score on a traditional IQ test, we know he has extraordinarily high analytical intelligence. The progress he has made in his CTMU theory reflects his analytical intelligence and suggests he also has high problem-solving intelligence.
6. This question cannot be answered with certainty. There is a medium-sized positive correlation between head size and intelligence, but remember that correlations do not demonstrate cause and effect. For example, there are people who have an above-average brain size but below-average intelligence, and vice versa.

Concepts

What is that four-legged thing?

Jeff, who is only 14 months old, walks up to his mother and says, in a somewhat demanding voice, "Juice." Jeff's one-word sentence, "Juice," is shorthand for "Can I please have a glass of orange juice?" Even as a toddler, Jeff already knows a considerable number of words that represent a whole range of objects, such as cookie, car, bottle, bunny, baby, juice, ball, apple, and the most hated words of all for a young child, "wash up." So when Jeff points at an object and says, "Ball," his one-word sentence is short for "That is my ball." Jeff's use of these single-word "sentences" indicates that he is on his way to learning a very complex system of communicating by using language.

Jeff learned that this four-legged animal is a rabbit and not a cat or dog.

Jeff also uses one-word "sentences" to ask questions. For instance, he'll point to a picture in his animal book and ask, "Name?" This means "What is the name of that animal?" Jeff has already learned that a four-legged, fuzzy-tailed, large-eared animal is a bunny; a four-legged, long-nosed animal that barks is a dog; and a four-legged, short-eared animal with a long tail that says "meow" is a cat. Perhaps when Jeff sees an animal, such as a dog, cat, or rabbit, he takes a "mental photo" that he uses for future identifications. But that would mean storing an overwhelming number of "mental photos" of all the animals, objects, and people in his environment. We'll explain a more efficient system that Jeff probably uses to identify animals, objects, and people.

Creativity

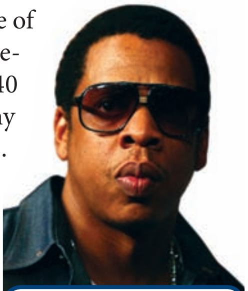
How does one become creative?

One of Jeff's favorite things to do is paint the animals in his picture books. Although Jeff makes a terribly wonderful mess, his parents encourage him because they hope that Jeff's early interest in painting may indicate that he has a creative talent for painting or art. How one becomes a creative person is quite a mystery. Take the case of Shawn Carter, better known as Jay-Z, for example.

Shawn Carter's early years showed no signs of his creativity. No one thought Carter would amount to much. He grew up in Brooklyn's Marcy projects, which were overrun with drugs and violence. When Carter was 11, his father left, and his mother had to raise him as well as his three older siblings. Only a year later, at the age of 12, Carter shot his brother for stealing his jewelry. He dropped out of high school to deal drugs, where he often faced dangerously close bullets. While dealing drugs, he began exploring the hip-hop scene. Even as he achieved some recognition for his music work and opportunities to pursue it became available, he was reluctant to give up the life of dealing drugs.

In his late thirties, Carter has become one of the most successful hip-hop artists and entrepreneurs in the country. He has sold nearly 40 million albums and received several Grammy Awards for his musical accomplishments. His creativity extends beyond his musical work and includes his own line of clothing, fragrances, restaurants, and hotels. Carter passionately describes these creative accomplishments as an "extension" of him (Ali, 2006; DeCurtis, 2009).

We'll discuss what creativity is and what makes creative people different.



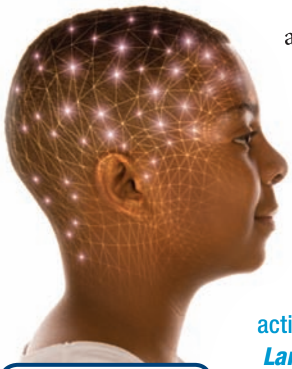
With little formal schooling, Shawn Carter became a very creative person.

Cognitive Approach

How does your mind work?

How do toddlers like Jeff learn to speak a complex language and to recognize hundreds of objects? How did Shawn Carter, with little formal schooling, develop his musical ability and express his creativity in so many ways? The answers to these kinds of questions involve figuring out how our minds work. One way to study mental processes is to use the cognitive approach.

The ***cognitive approach*** is one method of studying how we process, store, and use information and how this information, in turn, influences what we notice, perceive, learn, remember, believe, and feel.



Of all animals, humans have the greatest language ability.

We have already discussed several aspects of the cognitive approach: learning in Modules 9 and 10, and memory and forgetting in Modules 11 and 12. Here we'll explore two other cognitive processes: thinking and language.

Thinking, which is sometimes referred to as reasoning, involves mental processes that are used to form concepts, solve problems, and engage in creative activities.

Language is a special form of communication in which we learn and use complex rules to form and manipulate symbols (words or gestures) that are used to generate an endless number of meaningful sentences.

In fact, thinking and using language are two things we do much better than animals (Hoff, 2009; Woodard, 2005).

What's Coming

We'll discuss how we form concepts, solve problems, think creatively, acquire language, and make decisions. We'll examine why people have difficulty recognizing words (dyslexia) and how language used by animals is different from the language of humans.

We'll begin with the interesting question of how Jeff learned to distinguish a rabbit from a dog, and a dog from a cat.

A. Forming Concepts

Is it a dog, cat, or rabbit?

During your childhood, there was a time when every animal you saw was called a "dog." As a child, you gradually learned to tell the difference between a dog, a cat, and a rabbit by forming a different concept for each animal.

A ***concept*** is a way to group or classify objects, events, animals, or people based on some features, traits, or characteristics that they all share in common.

How you formed the concept of a dog or cat or rabbit has two different explanations: the exemplar model and the prototype theory (Nosofsky & Zaki, 2002; H. Olsson et al., 2004).

Exemplar Model

You easily recognize the animals on the left, but the question is: How did you know which animal was which? Is it because your mind contains definitions of hundreds of animals?

The ***exemplar model*** says that you form a concept of an object, event, animal, or person by defining or making a mental list of the essential characteristics of a particular thing.

According to the exemplar model, you formed a concept of a dog, cat, or rabbit by learning its essential characteristics. The essential characteristics of a dog might include that it barks and has a long nose, two ears, two eyes, four legs, some hair, and usually a tail. Similarly, you made mental definitions for all animals. Then, when you looked at the three animals on the left, you automatically sorted through hundreds of animal definitions until you found one that included the essential properties of a dog, cat, or rabbit. Once you found the definition, you knew what the animal was. Although the exemplar model seems like a reasonable method of forming concepts, it has two serious problems.

One way to form concepts is to make definitions.

Problems with the Exemplar Model

Too many features. In real life, it is very difficult to list all the features that define any object (Rey, 1983). For example, if your list of features to define a dog wasn't complete, the list might also apply to wolves, jackals, coyotes, and skunks. If your list of features to define a dog included every possible feature, such a mental list would be complete but take so long to go through that it would be very slow to use. And worse, you would need a long list of defining features for each and every animal, person, and object. Such a great number of mental lists would tax the best of memories.

dog (dog, dag) *n.; pl.* **dogs, dog.** 1. any of a large and varied group of domesticated animals *(Canis familiaris)* that have four legs, a tail, two ears, prominent nose, a hairy coat, and a bark.

Too many exceptions. After making a list of defining features, you would also need to list all the exceptions that do not fit into the dictionary definition of dog. For example, some dogs rarely bark, some are very tiny, some are very large, some are hairless, and some are very fuzzy.

Because of these two problems, you would need to check two mental lists—a long list that contained all the defining features and another that contained all the exceptions—before finding the concept that correctly identified the animal, person, or object.

For these reasons, the exemplar model has generally been replaced by a different theory of how we form concepts: the prototype theory.

Prototype Theory

Please look at the three animals on the right, #1, #2, and #3. Despite the great differences in size, color, and facial features of these animals, prototype theory explains why you can easily and quickly recognize each one as a dog.

Prototype theory says that you form a concept by creating a mental image that is based on the average characteristics of an object. This "average" looking object is called a prototype. To identify a new object, you match it to one of your already formed prototypes of objects, people, or animals.

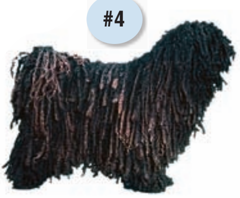
Based on many experiences, you develop prototypes of many different objects, persons, and animals (Rosch, 1978). For example, your prototype of a dog would be a mental image of any particular animal that has ***average features*** (nose, tail, ears, height, weight). By using your prototype of a dog, you can easily and quickly identify all three animals on the right—the large brown mutt (#1), the tiny Chihuahua (#2), and the colorful Dalmatian (#3)—as being dogs.

Another way to form concepts is to form prototypes.

Advantages of the Prototype Theory

Average features. One advantage of the prototype theory over the exemplar model is that you do not have to make a mental list of all the defining features of an object, which is often impossible. Instead, you form a prototype by creating a mental picture or image of the object, animal, or person that has only average features.

Quick recognition. Another advantage of the prototype theory is that it can result in quick recognition, as happened when you identified these different-looking animals (#1, #2, and #3) as dogs. The more a new object resembles a prototype, the more quickly you can identify it; the less it matches your prototype, the longer it takes.



For example, what is the strange animal on the right (#4) and where is its head? Because this animal's features are not close to your dog prototype, it will take you some time to figure out that it has hair like "dreadlocks," its head is on the right, and it's an unusual dog (called a Puli).

Prototype theory, which explains that you form concepts by creating and using prototypes, is widely accepted and has generally replaced the exemplar model (Geeraerts, 2006).

Next, we'll discuss when children begin forming concepts.

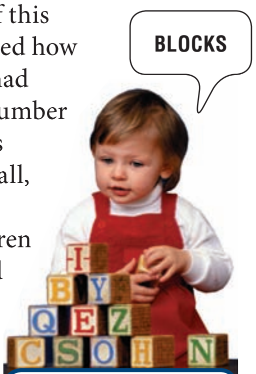
Early Formation



By 10 to 16 months, infants learn a number of concepts.

At the beginning of this module, we described how 14-month-old Jeff had already learned a number of concepts, such as juice, cookie, car, ball, apple, cat, dog, and bunny. Many children 10 to 16 months old can form concepts; that is, they can correctly identify different living things (cat, dog, rabbit) as animals and then place each living thing in the correct category (Quinn, 2002; Quinn & Oates, 2004).

Recent studies have reported that children develop many concepts or categories (animal, vegetable, face) by experiencing or interacting with objects and things in their environments, and children show their grasp of concepts even before they have developed much language ability (Mareschal & Quinn, 2001). For example, as 14-month-old Jeff (above photo) plays with different objects in his environment, he will learn that one kind of object is a nonliving thing called a block. Initially, a child's categories may be very broad, such as objects, people, animals, and events.

However, as children gain more experience with objects, animals, people, and things in their environments as well as develop increased language skills, which happens around age 5 (p. 315), they learn to form more complex concepts, such as the qualities of objects—*heavy, shiny, colorful, sweet, bitter*—and the position and placement of objects—*up, down, high, low.* The chances of a child interacting with a wide variety of objects and thus developing many concepts and categories are greatly increased by being raised in a stimulating environment, but the chances are hindered in an impoverished one (Quinn, 2002).

Thus, the development and formation of concepts depend, in large part, on the child's opportunity to interact with the environment and, as you'll see next, in part on how the brain is neatly organized to process information into categories.

Categories in the Brain

animal
fruit
person

Brain is prewired to make categories.

A child's ability to form and develop concepts is helped not only by having a stimulating environment but also by how the brain is organized. Brain scans and brain stimulation of normal subjects and tests on brain-damaged individuals showed that different visual concepts, such as animals, faces, vegetables/fruits, and nonliving things, as well as auditory concepts, such as animal, human, and tool sounds, are processed and stored in different parts of the brain (Ilmberger et al., 2002; J. W. Lewis et al., 2005). Thus, as children interact with and learn to identify different objects, they can easily place different objects into different categories because the brain is already set up to store different categories in different areas (Ilmberger et al., 2002).

This process of placing things into categories occurs very quickly. For example, you quickly and easily recognize the three objects on the right as turtle, apple, and clown, and you easily place them into three different categories: animal, fruit, and person. Researchers explain that you were able to recognize these three things by matching each to your already formed prototypes of a turtle, apple, and clown (Squire & Knowlton, 1995).

One reason you are not aware of forming prototypes or classifying things into categories is that these cognitive processes occur at an unconscious level, which means that you are unaware of and cannot recall what is happening (p. 246). Evidence that forming prototypes and matching things to prototypes occur at an unconscious (implicit) level comes from studies that found that although amnesic patients were able to form prototypes and correctly match things to prototypes, they could not explain how they did it. Researchers concluded that using prototypes involves implicit processes, which we are not aware of and cannot voluntarily recall (Squire & Knowlton, 1995).

As you'll see, not being able to form concepts would make every day a very bad day.

PowerStudy 4.5™

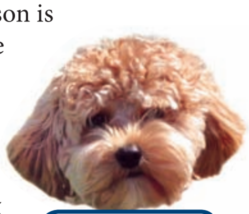
Module 4
B. Studying the Living Brain
Module 11
D. Long-Term Memory: Storing

Functions of Concepts

If you woke up one day to find that you had lost all your concepts, you would indeed have a very bad day. That's because concepts perform two important functions: They organize information and help us avoid relearning (Humphreys & Forde, 2001).

1 Organize information. Concepts allow you to group things into categories and thus better organize and store information in memory. For example, instead of having to store hundreds of mental images of many different kinds of dogs, you can store a single prototype of the average dog.

2 Avoid relearning. By having concepts that can be used to classify and categorize things, you can easily classify new things without having to relearn what each thing is. For example, once you have a concept for a dog, rabbit, cat, or cookie, you do not have to relearn what that thing is on each new encounter.



What if you had to always relearn this is a dog?

Without concepts, our cognitive worlds would consist of unconnected pieces of information. In fact, some forms of brain damage destroy a person's ability to form concepts, so that the person is unable to name or categorize what he or she sees (visual agnosia—see p. 79). By using concepts, you can identify, categorize, and store information very efficiently.

There is no doubt that concepts are useful for identifying objects and helping us make sense of our world. Next, you'll see that concepts are valuable for solving problems and thinking creatively.

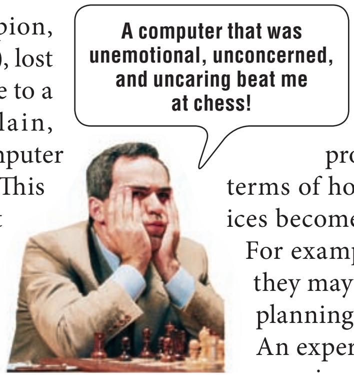
B. Solving Problems

How do experts solve problems?

In 1997, world chess champion, Garry Kasparov (photo below), lost a chess match for the first time to a powerful computer (McClain, 2005). He played another computer in 2003 and tied (three games each) (Byrne, 2003). This human-versus-computer chess match was all about thinking and problem solving.



A computer that was unemotional, unconcerned, and uncaring beat me at chess!

***Problem solving* involves searching for some rule, plan, or strategy that results in our reaching a certain goal that is currently out of reach.**

In previous matches, Kasparov had always beat the computer because he was the better thinker and problem solver. For Kasparov, as well as for most of us, problem solving involves three states: (1) the ***initial state,*** which is thinking about the unsolved problem; (2) the ***operations state,*** which involves trying various rules or strategies to solve the problem; and (3) the ***goal state,*** which is reaching the solution. One plan used by expert problem solvers, such as Kasparov, is to think in broad terms of how to solve the problem, while less successful novices become too focused on specifics (Abernethy et al., 1994). For example, when novice players are in a difficult position, they may spend much time calculating possible moves, often planning many moves ahead, yet never find the best solution. An expert player has more knowledge of chess positions and examines fewer, but better, possibilities in much less time (P. E. Ross, 2006). Being a successful problem solver involves using different kinds of thinking, some of which can be programmed into a computer.

Different Ways of Thinking

Can a computer think?

In this man-machine chess match, Kasparov's thinking involved a combination of intuition (clever guesses based on years of experience) and creative mental shortcuts, called heuristics. The computer's "thinking" was more fixed because it has been programmed to use a set of rules that lead to specific outcomes, called algorithms. Solving problems by using algorithms or heuristics illustrates two very different ways of thinking (Lohman, 2000).

Algorithms

If you wanted to win at a variety of games, such as chess, checkers, or bridge, you would follow a fixed set of rules that are called algorithms *(AL-go-rhythms).*

***Algorithms* are a fixed set of rules that, if followed correctly, will eventually lead to a solution.**

For example, learning to play chess involves following algorithms that define how pieces move and the results of those moves. The reason relatively few chess players become grand masters like Kasparov is that people vary in their ability to learn and use algorithms.

Initially, the computer was given little chance to beat world chess champion Kasparov because playing chess by using algorithms is a slow process. Instead of using algorithms, chess champion Kasparov was playing with a potentially more powerful set of rules called heuristics.

Heuristics

Kasparov's unique brain, together with his years of experience, allowed him to play chess using heuristics *(hyur-RIS-ticks).*

***Heuristics* are rules of thumb, or clever and creative mental shortcuts, that reduce the number of operations and allow one to solve problems easily and quickly.**

In the late 1990s, Kasparov's clever and creative shortcuts, or heuristics, had given him the advantage over the fixed and not so creative algorithms of computer programs. However, computers now have been programmed with new algorithms that increase their speed of "thinking" from analyzing 100,000 chess moves per second to 2.5 million. As a result of this increased speed, human chess grand masters, whose thinking focuses on using clever heuristics, no longer have a clear advantage over a computer's "thinking" ability (Boyce, 2002).

Besides being used to solve chess problems, heuristics are often used in daily life to make decisions or draw conclusions (Bailenson et al., 2000). A commonly used heuristic is called the availability heuristic.

The *availability heuristic* says that we rely on information that is more prominent or easily recalled and overlook other information that is available but less prominent or notable.

For example, the murder rate in the United States actually decreased in the late 1990s. However, during this time, network coverage of homicides increased 473%, which made news of murders more available and, according to the availability heuristic, led people to conclude that murder rates had become epidemic (Comarow, 2001).

Using the availability heuristic to make a decision means taking a mental shortcut. Although heuristics allow us to make quick decisions, they may result in bad decisions, since we make them using shortcuts, which limits the amount of information we use (F. Bower, 1997).

Artificial Intelligence

It took 50 years of effort before scientists learned how to program a computer that could beat Kasparov at chess. One goal of computer science is to develop ***artificial intelligence,*** which means programming machines (computers and robots) to imitate human thinking and problem-solving abilities.

For example, scientists recently developed a "thinking" program modeled on how the brain thinks (neural network). Scientists programmed a computer with this "thinking" program and the basic rules of checkers. In no time, the computer taught itself to play checkers at the expert level (Fogel, 2000). Can you imagine a computer teaching itself to play expert checkers? This represents a major breakthrough in artificial intelligence—teaching machines to think like humans.

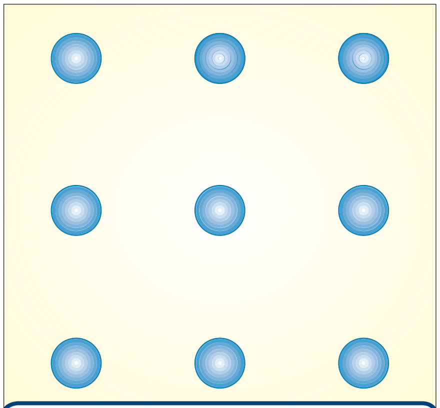
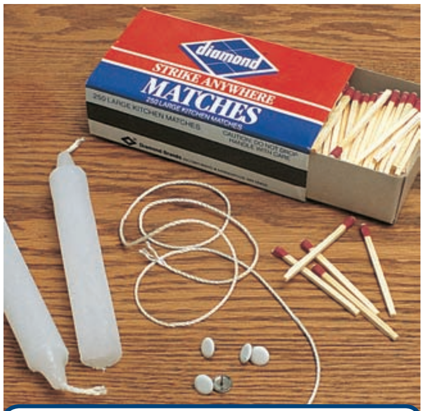
Three Strategies for Solving Problems

What if you get stuck?

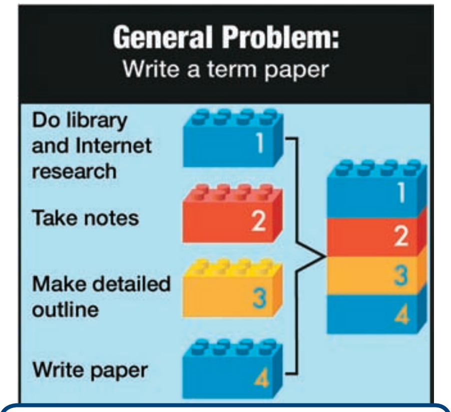
Most of us have had the experience of getting stuck while trying to solve a problem and wondering what to do next. By studying people who are good at problem solving, such as chess players, engineers, and computer programmers, psychologists have identified a number of useful strategies for solving problems. We'll discuss three problem-solving strategies—changing a mental set, using analogies, and forming subgoals. (Solutions to the first two problems appear on page 317.)



It takes new thinking to connect all dots with 4 straight lines without lifting pencil.



How would you mount a candle on the wall using what you see here?



The best strategy for writing a term paper is to break the task into subgoals.

Changing One's Mental Set

Problem. Connect all nine dots shown above by drawing four straight lines without lifting your pencil from the paper or retracing any lines. If, like most people, you have difficulty solving this problem, it may be because of functional fixedness.

Functional fixedness **refers to a mental set that is characterized by the inability to see an object as having a function different from its usual one.**

For instance, you probably have a mental set that a straight line must begin and end on a dot. To solve the nine-dot problem, you need to break out of functional fixedness, which involves thinking of a line as continuing past a dot (T. C. Kershaw & Ohlsson, 2004).

The nine-dot puzzle is a good example of the kind of problem that is often solved in a sudden flash, known as insight, which we discussed earlier (p. 226).

Insight **is the sudden grasp of a solution after many incorrect attempts.**

You can increase your chances of solving a problem by insight if you consider the problem from many different viewpoints and unusual angles and if you decrease your anxiety and concern, which will in turn help you to overcome functional fixedness.

Using Analogies

Problem. Imagine that you have a box of matches, two candles, a piece of string, and several tacks, as shown in the photo above. How would you mount a candle on the wall so that it could be used as a light?

You may solve the candle problem in a flash of insight. However, most of us have to develop a strategy to solve the problem, and a good strategy may involve using an analogy.

An ***analogy*** **is a strategy for finding a similarity between the new situation and an old, familiar situation.**

If you adopt an analogy to solve the candle problem, here's how your thinking might proceed: "I'm familiar with using a shelf to hold a candle on the wall. Which of the objects—candle, string, or box—could serve as a shelf? If I remove the matches, I can tack the box to the wall."

As you gain more experience and knowledge, you become better at using analogies to solve problems. This is one reason that businesses prefer employees with experience: These employees are more likely to use analogies to solve problems.

What about the problem every student must face—writing a paper?

Forming Subgoals

Problem. Suppose your assignment is to write a term paper titled "Creativity and Madness." A useful strategy for writing this paper is to divide the assignment or general problem into a number of subgoals.

Using ***subgoals*** **is a strategy that involves breaking down the overall problem into separate parts that, when completed in order, will result in a solution.**

As shown in the figure above, the first subgoal is doing research and finding a number of articles on creativity and madness. The second subgoal is reading the articles and taking notes. The third subgoal is making a detailed outline of the whole paper. A fourth subgoal is using your outline to write the paper. The strategy of working on and completing each specific subgoal makes the overall project more manageable and reduces unproductive worrying and complaining that can interfere with starting and completing your paper.

The strategy of setting specific goals to solve a problem has some advantages: Goals direct and focus attention, help get you energized and motivated, and increase persistence and lessen procrastination (E. A. Locke & Latham, 2002).

Another problem-solving strategy is to use creative thinking, our next topic.

C. Thinking Creatively

Shawn Carter is a very creative person as Jay-Z the rapper.

Shawn Carter is a very creative person in his Rocawear business.

At the beginning of this module, we told you about Shawn Carter, better known as Jay-Z. Carter grew up living in the dangerous projects, dropped out of high school, and began dealing drugs at a young age. Despite overwhelming odds, Carter succeeded in making ten hit albums, which together have sold nearly 40 million copies. For his creative musical talent, he has received seven Grammy Awards, two MTV Music Awards, an American Music Award, a Billboard Music Award, and countless other honors. Carter is so creative and talented that he completed *The Blueprint,* a critically acclaimed album, in only two days! His creativity has helped him succeed outside of the music business as well. Perhaps most notably, Carter's creativity is evident in his urban clothing brand Rocawear, which has become a multimillion-dollar business due to his creativity in marketing and product development (Ali, 2006; DeCurtis, 2009).

This intriguing story of Shawn Carter (Jay-Z) raises four interesting questions about creativity: How is creativity defined? Is IQ related to creativity? How do creative people think and behave? Is creativity related to psychological problems? Although there are more than 60 definitions of creativity, we'll begin with the one most commonly used (Boden, 1994).

How Is Creativity Defined?

The definition of creative thinking is somewhat different from the definition of a creative individual.

Creative thinking is a combination of flexibility in thinking and reorganization of understanding to produce innovative ideas and new or novel solutions (R. J. Sternberg, 2001).

A ***creative individual*** is someone who regularly solves problems, fashions products, or defines new questions that make an impact on his or her society (H. Gardner, 1993, 2006a).

People can show evidence of creative thinking in many different ways. For example, recognized creative individuals include Albert Einstein, who formulated the theory of relativity; Michelangelo, who painted the Sistine Chapel; Sigmund Freud, who developed psychoanalysis; Dr. Seuss, who wrote rhyming books for children (and adults); the Rolling Stones, a well-known, 40-year-old rock-and-roll band; Ray Kroc, who founded McDonald's worldwide hamburger chain; and Shawn Carter (Jay-Z), who is a rapper.

Because there are so many different examples (and kinds) of creativity, psychologists have used three different approaches to measure creativity: the psychometric, case study, and cognitive approaches (R. J. Sternberg & O'Hara, 2000).

Psychometric Approach

This approach, which uses objective problem-solving tasks to measure creativity, focuses on the distinction between two kinds of thinking—convergent and divergent (Guilford, 1967; Runco, 2004).

Convergent thinking means beginning with a problem and coming up with a single correct solution.

Examples of convergent thinking include answering multiple-choice questions and solving math problems. The opposite of convergent thinking is divergent thinking.

Divergent thinking means beginning with a problem and coming up with many different solutions.

For example, the two problem-solving tasks on page 309 (nine-dot and candle-match puzzles) are used to assess divergent thinking, which is a popular psychometric measure for creativity (Amabile, 1985; Camp, 1994).

Tests of divergent thinking have good reliability, which means that people achieve the same scores across time (Domino, 1994). However, tests of divergent thinking have low validity, which means that creative persons, such as Shawn Carter, may not necessarily score high on psychometric tests of creativity (H. Gardner, 1993).

Case Study Approach

Because the psychometric approach is limited to using objective tests, it provides little insight into creative minds. In comparison, the case study approach analyzes creative persons in great depth and thus provides insight into their development, personality, motivation, and problems.

For example, Howard Gardner (1993) used the case study approach to analyze seven creative people, including Sigmund Freud. Gardner found that creative people are creative in certain areas but poor in others: Freud was very creative in linguistic and personal areas but very poor in spatial and musical areas. Although case studies provide rich insight into creative minds, their findings may be difficult to generalize: Freud's kind of creativity may or may not apply to Shawn Carter's remarkable achievements (Freyd, 1994).

Cognitive Approach

Although case studies provide detailed portraits of creative people, the findings are very personal or subjective and not easily applied to others. In comparison, the cognitive approach tries to build a bridge between the objective measures of the psychometric approach and the subjective descriptions provided by case studies. The cognitive approach, which is also the newest, identifies and measures cognitive mechanisms that are used during creative thinking (Freyd, 1994).

For example, many individuals have reported that one cognitive mechanism vital to creative thinking is the use of mental imagery, which involves thinking in images, without words or mathematical symbols (Finke, 1993). Thus, the cognitive approach involves analyzing the workings of mental imagery and its relationship to creative thinking.

Now, let's see what these three approaches say about creativity.

Is IQ Related to Creativity?

In some cases, such as Michelangelo, Sigmund Freud, and Albert Einstein, creativity seems to be linked to genius. However, creativity is not the same as intelligence, as best illustrated by savants.

Savants **are about 10% of autistic individuals who show some incredible memory, music, or drawing talent.**

Stephen Wiltshire (right photo) is a savant who is world famous for his architectural illustrations and incredible memory. Stephen earned the nickname "human camera" because of his extraordinary ability to look at a landscape for only minutes and then draw it from memory with exceptional detail (Sacks, 2008; Treffert, 2006).

Stephen Wiltshire, "the human camera," paints an aerial view of downtown Madrid after briefly seeing it by helicopter.

Despite their creativity, many savants score below 70 on IQ tests (average score is 100). Savants lack verbal intelligence but excel in visual intelligence, and their right hemispheres are more active than their left during creative activities (Treffert & Wallace, 2002).

Instead of linking creativity to genius, some psychologists believe creativity involves relatively ordinary cognitive processes that result in extraordinary products (Weisberg, 1993). These creative products include inventions (Post-its, genetic crops), new drugs (Viagra), and computer software (video games). When the IQs of creative individuals are closely examined and compared to others, we find that people who are recognized as creative tend to have above-average IQ scores, but those with the highest IQs are not necessarily the most creative (R. J. Sternberg & O'Hara, 2000).

How Do Creative People Think and Behave?

Researchers have studied creative individuals to identify what is unusual about their work habits and psychological traits (Helson, 1996; Simonton, 2000). Here are some of their findings.

Focus. Creative people tend to be superior in one particular area, such as dance, music, art, science, or writing, rather than many areas. For example, Einstein (drawing at right) was superior in the logical-spatial area—the theory of relativity ($E = mc^2$)—but poor in the personal area—developing close relationships.

Creative people can consider problems from different viewpoints and are driven by strong internal goals.

Cognition. Creative individuals have the ability to change mental directions, consider problems from many angles, and make use of mental images. They are also interested in solving unusual problems.

Personality. On the positive side, creative people tend to be independent, self-confident, unconventional, risk-taking, hardworking, and obsessively committed to their work. On the negative side, they tend to have large egos that make them insensitive to the needs of others. They may pursue their goals at the expense of others, and they may be so absorbed in their work that they exclude others.

Motivation. They are driven by internal values or personal goals; this is called intrinsic motivation. They are less concerned about external rewards such as money or recognition, which is called extrinsic motivation. They are motivated by the challenge of solving problems; their reward is the satisfaction of accomplishment. On average, creative people work on a project for about ten years before reaching their creative peaks.

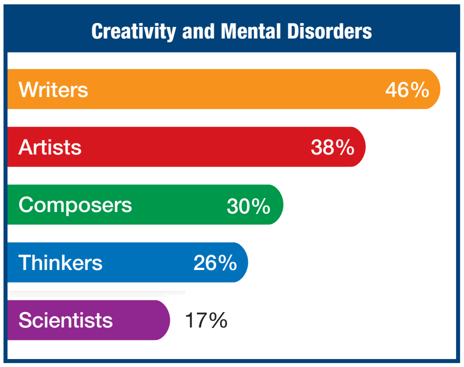
One question often asked about creative people is whether their creative fires are fueled by psychological or mental problems.

Is Creativity Related to Mental Disorders?

There are numerous historical reports of a link between creativity and madness or insanity, more correctly called mental disorders. For example, Mark Twain (Samuel Clemens), Tennessee Williams, Ernest Hemingway, Cole Porter, and Edgar Allan Poe were all reported to suffer from either depression or manic-depression (swings between euphoria and depression) (Jamison, 1995).

A more formal study of 291 creative writers, artists, composers, thinkers, and scientists indicated that 17–46% suffered from mental disorders, especially mood disorders. As the graph on the right shows, writers had the highest percentage of mental disorders, especially alcoholism and depression (R. Post, 1994).

Given the above results, researchers asked: Does the mood disorder contribute to creativity?



One study found that parents with manic-depression (dramatic mood swings), as well as their children, obtained higher scores on tests of creativity than did normal parents and children (Simeonova et al., 2005). This and other research suggest that severe mood change could contribute to creativity by sharpening thoughts and broadening the person's emotional, intellectual, and perceptual views of the world (Jamison, 1995). There are of course many creative individuals (writers) who have achieved creative breakthroughs without having severe emotional problems (J. C. Kaufman & Baer, 2002).

Next, we turn to an important component of creative activities, the development of language.

Photo Credit: © Victor Lerena/epa/Corbis

D. Language: Basic Rules

How many languages are there?

Our ability to use language is one of the most remarkable features of our species (A. R. McIntosh & Lobaugh, 2003). As of this writing, people are believed to speak about 6,900 different languages, and although undiscovered languages continue to be found, it is estimated that by the next century nearly half of the languages will be extinct (Erard, 2009; Garber, 2007; R. G. Gordon, 2005).

Language **is a special form of communication that involves learning complex rules to make and combine symbols (words or gestures) into an endless number of meaningful sentences.**

The reason language is such a successful form of communication arises from two amazingly simple principles—words and grammar.

A *word* is an arbitrary pairing between a sound or symbol and a meaning.

For example, the word *parrot* does not look like, sound like, or fly like a parrot, but it refers to a bird we call a parrot because all of us memorized this pairing as children.

Why is this called a parrot?

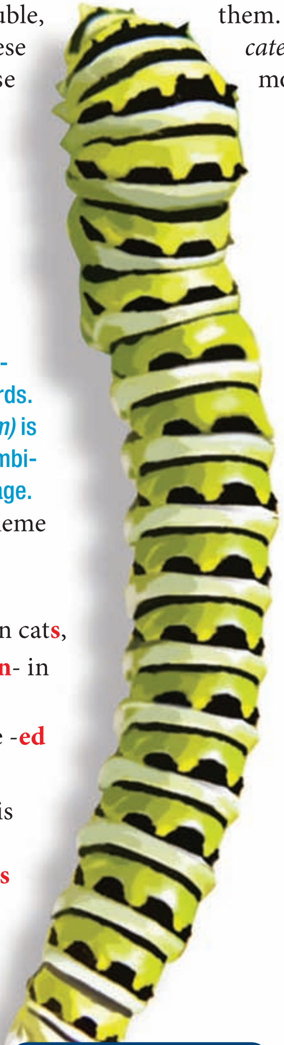
Young adults are estimated to have about 60,000 such pairings or words in their mental dictionaries (Pinker, 1995). However, these 60,000 symbols or words are rather useless unless the users follow similar rules of grammar.

Grammar **refers to a set of rules for combining words into phrases and sentences to express an infinite number of thoughts that can be understood by others.**

For instance, our mental rules of grammar immediately tell us that the headline "Parrot Bites Man's Nose" means something very different from "Man Bites Parrot's Nose." It may seem surprising, but speakers of all 6,900 languages learned the same four rules.

Four Rules of Language

As children, each of us learned, without much trouble, the four rules of language. Now, as adults, we use these rules without being aware of how or when we use them. To illustrate the four rules of language, we'll use the word *caterpillar.* As a child, you may have watched its strange crawling motion, or perhaps you were even brave enough to pick one up.



Learning and using the word *caterpillar* involve four basic rules.

1 The first language rule governs phonology.

Phonology ***(FOE-nawl-uh-gee)*** **specifies how we make the meaningful sounds that are used by a particular language.**

Any English word can be broken down into phonemes.

Phonemes ***(FOE-neems)*** **are the basic sounds of consonants and vowels.**

For example, the various sounds of ***c*** and ***p*** represent different phonemes, which are some of the sounds in the word *caterpillar.* At about 6 months old, babies begin to babble and make basic sounds, or phonemes. We combine phonemes to form words by learning the second rule.

2 The second language rule governs morphology.

Morphology ***(mor-FAWL-uh-gee)*** **is the system that we use to group phonemes into meaningful combinations of sounds and words.**

A *morpheme* ***(MOR-feem)*** **is the smallest meaningful combination of sounds in a language.**

For example, a morpheme may be

a word, such as **cat**,

a letter, such as the **s** in cat**s**,

a prefix, such as the **un**- in **un**breakable,

or a suffix, such as the -**ed** in walk**ed**.

The word **caterpillar** is actually one morpheme, and the word **caterpillars** is two (**caterpillar**-**s**). After we learn to combine morphemes to form words, we learn to combine words into meaningful sentences by using the third rule.

3 The third language rule governs syntax, or grammar.

Syntax, **or *grammar,* is a set of rules that specifies how we combine words to form meaningful phrases and sentences.**

For example, why doesn't the following sentence make sense?

Caterpillars green long and are.

You instantly realize that this sentence is nonsensical or ungrammatical because it doesn't follow the English grammar rules regarding where we place verbs and conjunctions. If you apply the rules of English grammar, you would rearrange the combination of words to read: "Caterpillars are long and green." Although you may not be able to list all the rules of grammar, you automatically follow them when you speak. One way you know whether the word *bear* is a noun or a verb is by using the fourth rule.

4 The fourth language rule governs semantics.

Semantics ***(si-MAN-ticks)*** **specifies the meanings of words or phrases when they appear in various sentences or contexts.**

For instance, as you read "Did Pat pat a caterpillar's back?" how do you know what the word **pat** means, since it appears twice in succession. From your knowledge of semantics, you know that the first **Pat** is a noun and the name of a person, while the second **pat** is a verb, which signals some action.

Somehow you knew that the same word, **pat**, had very different meanings depending on the context. How you know what words mean in different contexts is a very intriguing question.

F. Biological Factors

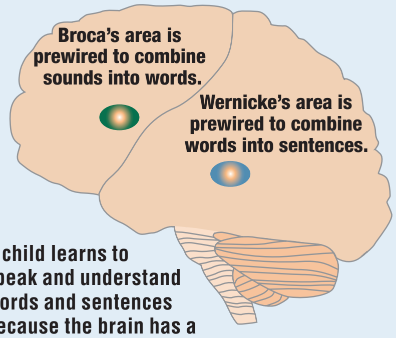
Understanding Language

One of the great mysteries of using and understanding language can be demonstrated by the following two simple but very different sentences:

You picked up a caterpillar.

A caterpillar was picked up by you.

Despite a different word order, you know that these two sentences mean exactly the same thing. How you know that these different sentences mean exactly the same thing was explained by linguist Noam Chomsky (1957). We'll discuss two of Chomsky's revolutionary principles—mental grammar and innate brain program—that allow us to use and understand spoken language with relative ease (McGilvray, 2004).



Broca's area is prewired to combine sounds into words.
Wernicke's area is prewired to combine words into sentences.

A child learns to speak and understand words and sentences because the brain has a built-in, or innate, language program.

Mental grammar. Almost every sentence we speak or understand is formed from a brand-new combination of words. Chomsky pointed out that the brain does not have the capacity to contain a list of all the sentences we will ever use. Instead, Chomsky argued that the brain contains a program or ***mental grammar*** that allows us to combine nouns, verbs, and objects in an endless variety of meaningful sentences. Chomsky's principle of mental grammar answers the question of how we can so easily create so many different sentences. The second question that Chomsky answered was: How do we acquire this mental grammar?

Innate brain program. How is it possible that 4-year-old children, with no formal schooling, can speak and understand an endless variety of sentences? For example, the average 4-year-old child can already determine that the sentence "The caterpillar crept slowly across the leaf" is correct but that the sentence "The crept leaf caterpillar slowly the across" is meaningless. Chomsky's answer is that young children can learn these complex and difficult rules of grammar because our brains come with a built-in, or ***innate, program*** that makes learning the rules of grammar relatively easy (p. 229). The brain's innate program for learning rules of grammar explains how children learn most of the complex rules by age 4 or 5 and how children who are exposed to two languages from birth learn the two distinct vocabularies and grammar rules as quickly as their monolingual peers learn the rules of one language (Kovács & Mehler, 2009). However, it is the interaction between the development of the brain's innate program and a child's range of environmental experiences that results in learning the complicated rules of grammar (Schlaggar et al., 2002).

But how does an innate grammar program, which could be used by any child in any culture, specify the rules for forming and understanding an endless number of meaningful sentences? Chomsky's answer is perhaps his cleverest contribution.

Different Structure, Same Meaning

One of the most difficult questions that Chomsky had to answer was how an idea can be expressed in several different ways, with different grammatical structures, yet mean the same thing.

He answered this question by making a distinction between two different structures of a sentence: surface structure and deep structure.

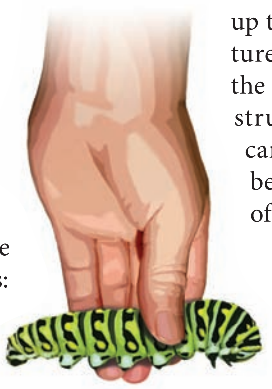
Surface structure refers to the actual wording of a sentence, as it is spoken.

Deep structure refers to an underlying meaning that is not spoken but is present in the mind of the listener.

We can illustrate the difference between surface and deep structures with our same two sentences:

You picked up a caterpillar.

A caterpillar was picked up by you.



You know that the sentence "You picked up a caterpillar" means the same as "A caterpillar was picked up by you" because you recognize that both have the same deep structure.

Notice that these two sentences have different ***surface structures,*** which means they are worded differently. However, according to Chomsky, you are able to look underneath the different surface structures of the two sentences and recognize that they have the same ***deep structure,*** which is why you know they have the same meaning.

Chomsky argues that we learn to shift back and forth between surface and deep structure by applying transformational rules.

Transformational rules are procedures by which we convert our ideas from surface structures into deep structures and from deep structures back into surface ones.

For example, when you hear the two sentences about picking up the caterpillar, you transform the words into their deep structure, which you store in memory. Later, when someone asks what the person did, you use transformational rules to convert the deep structure in your memory back into a surface structure, which can be expressed in differently worded sentences. The distinction between surface and deep structures is part of Chomsky's theory of language.

Chomsky's theory of language says that all languages share a common universal grammar and that children inherit a mental program to learn this universal grammar.

Chomsky's theory, which is widely accepted today, was considered a major breakthrough in explaining how we acquire and understand language (M. C. Baker, 2002). However, one criticism of Chomsky's theory is that he downplays the importance of different environmental opportunities for hearing and practicing sounds, which have been shown to interact with and influence language development (Schlaggar et al., 2002).

Chomsky's idea of an innate mental grammar would predict that children around the world should go through the same stages of language development. Can this be true for all 6,900 languages?

E. Acquiring Language

PowerStudy 4.5™

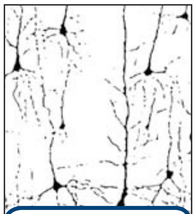
Module 3
B. Neurons: Structure & Function

What do children's brains do?

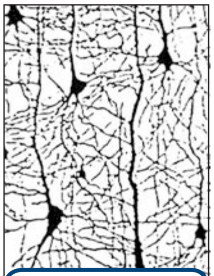
If Chomsky is correct that all children inherit the same innate program for learning grammar, then we would expect children from around the world to go through similar stages in developing language and acquiring the rules for using language. And in fact, all children, no matter the culture or the language, do go through the same stages (Pinker, 1994).

Language stages **refer to all infants going through four different periods or stages—babbling, single words, two-word combinations, and sentences. All children go through these four stages in the same order, and in each stage, children show new and more complex language skills.**

The occurrence of each of the four stages is associated with further development of the brain. At birth, an infant's brain has almost all of its neurons but they have not yet made all their connections (adult brains can grow some new neurons—p. 49). For example, a 6-month-old infant's brain (left figure) has few neural interconnections, which are associated with performing relatively simple behaviors, such as babbling. In comparison, a 24-month-old infant's brain (right figure) has hundreds of neural interconnections, which are associated with more complex behaviors, such as using two-word combinations (Ropper & Samuels, 2009).



6-month-old brain has few connections.



24-month-old brain has more connections.

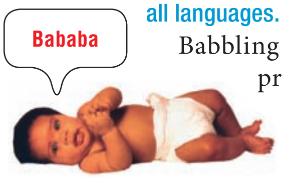
Here are the four stages that each of us went through in learning to speak and understand the language of our parents or caregivers.

Four Stages in Acquiring Language

1 Babbling

One of the key features in human development is that infants begin to make sounds long before they can say real words. Infants repeat the same sounds over and over, and these sounds are commonly called babbling.

Babbling, **which begins at about 6 months, is the first stage in acquiring language. Babbling refers to making one-syllable sounds, such as "dee-dee-dee" or "ba-ba-ba," which are most common across all languages.**



A 6-month-old brain has limited capacity for language.

Babbling is an example of an innate "sound" program in the brain that is involved in making and processing sounds that will eventually be used to form words. Researchers have discovered that by 6 months of age, infants have already learned to discriminate between sounds, such as *ba* from *pa,* and to distinguish sounds in their native language from those used in a foreign language (F. Bower, 2000). These findings indicate that, at an early age, infants have already become accustomed to making and hearing sounds that make up their native languages. At about 9 months, babbling sounds begin to resemble more the vowels and consonants that children will actually use in speaking their native languages.

In children who can hear, babbling is oral. In deaf children who have been exposed only to the sign language of their deaf parents, babbling is manual and not oral. That is, these babies babble by repeating the same hand sign over and over (J. L. Locke, 2006). This means that the brain has an innate program for acquiring language, whether spoken or sign language.

Through endless babbling, infants learn to control their vocal apparatus so that they can make, change, and repeat sounds and imitate the sounds of their parents or caregivers (Hoff, 2009). After babbling, infants begin to say their first words.

2 Single Word

Shortly before 1 year of age, an infant usually performs a behavior that every parent has been eagerly waiting for: to hear the child's first word. At about 1 year of age, infants begin not only to understand words but also to say single words.

Single words **mark the second stage in acquiring language, which occurs at about 1 year of age. Infants say single words that usually refer to what they can see, hear, or feel.**

An infant's ability to form sounds into words begins at about 8 months and results from an interaction between the brain's innate language program and the infant's experience with hearing sounds (Jusczyk & Hohne, 1997). About half the infant's single words refer to objects (juice, cookie, doll, dada), and the other half refer to actions, routines, or motions (up, eat, hot, more) (Pinker, 1994). The infant's single words, such as "Milk" or "Go," often stand for longer thoughts such as "I want milk" or "I want to go out."

A 1-year-old brain has more connections and more capacity for language.

As the infant learns to say words, parents usually respond by speaking in a specific way called parentese (motherese).

Parentese (motherese) **is a way of speaking to young children in which the adult speaks in a slower and higher than normal voice, emphasizes and stretches out each word, uses very simple sentences, and repeats words and phrases.**

Researchers conclude that parentese has at least three functions: attract and hold an infant's attention, aid comprehension, and facilitate language development (Leitzell, 2007). Also, parentese has important cross-cultural benefits. For example, researchers found that the Shuar people from South America, who don't understand or speak English, are able to understand the basic meanings of parentese among English-speaking parents in North America (Bryant & Barrett, 2007). Thus, parentese can convey meaning between people who don't speak the same language.

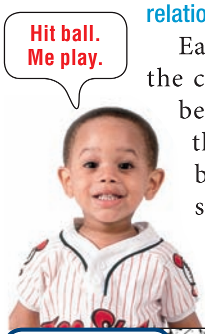
Next, the young child begins to combine words.

Photo Credits: top, From Conel, J. L. 1939, 1941, 1959, *The Postnatal Development of the Human Cerebral Cortex*, 6 Volumes, Cambridge: Harvard; left, © Romilly Lockyer; right, © Royalty-Free/Masterfile

3 Two-Word Combinations

Starting around age 2, children begin using single words that they have learned to form two-word combinations.

Two-word combinations, which represent the third stage in acquiring language, occur at about 2 years of age. Two-word combinations are strings of two words that express various actions ("Me play," "See boy") or relationships ("Hit ball," "Milk gone").



Hit ball.
Me play.

Each of the two words provides a hint about what the child is saying. In addition, the relationship between the two words gives hints about what the child is communicating. For example, "See boy" tells us to look at a specific object; "Daddy shirt" tells us that something belongs to Daddy. The child's new ability to communicate by combining two words and changing their order marks the beginning of learning the rules of grammar. From about 2 years of age through adolescence, a child learns an average of a new word every 2 hours (Pinker, 1994).

A 2-year-old brain has many connections and more capacity for language.

A child's language development is partly dependent on how responsive the parent or caretaker is. A responsive parent shows more contact, awareness, and warmth during the child's verbal interactions. For example, infants whose mothers were more responsive to their speech at 13 months had more advanced language abilities, including larger vocabularies at 21 months, compared to children of less responsive mothers (Tamis-LeMonda et al., 2001).

By the age of 2, a child may have a vocabulary of more than 50 words, many of which will be used in two-word combinations. Although children usually go through a stage of forming single words and then two-word combinations, there is no three-word stage. Instead, at a certain point the child will begin to form sentences, which gradually increase in length through the fourth year.

4 Sentences

Children make a rather large language leap when they progress from relatively simple two-word combinations to using longer and more complex sentences.

Sentences, which represent the fourth stage of acquiring language, occur at about 4 years of age. Sentences range from three to eight words in length and indicate a growing knowledge of the rules of grammar.

However, a child's first sentences differ from adult sentences in that the child may omit the "small words" and speak in a pattern that is called telegraphic speech.

Telegraphic speech is a distinctive pattern of speaking in which the child omits articles *(the),* prepositions *(in, out),* and parts of verbs.

For example, an adult may say, "I'm going to the store." A 3- to 4-year-old child may use telegraphic speech (omit article) and say, "I go to store." However, by the time children are 4 or 5 years old, the structure of their sentences improves and indicates that they have learned the basic rules of grammar.

Basic rules of grammar are the rules for combining nouns, verbs, adjectives, and other parts of speech to form meaningful sentences.

However, as children learn the rules of grammar, they often make errors of overgeneralization.

Overgeneralization means applying a grammatical rule to cases where it should not be used.

For example, after a child learns the rule of forming the past tense of many verbs by adding a ***d*** sound to the end, he or she may overgeneralize this rule and add a ***d*** to the past tense of irregular verbs (and say, for instance, "I goed to store"). By the time children enter school, they usually have a good grasp of the general rules of their language.

I goed to store.
I want blue toy.

A 4- to 5-year-old brain has significantly more connections so that a child can learn the basic rules of complex grammar.

Going through the Stages

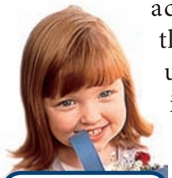
How fast does a child go through the stages?

Parents or caregivers sometimes worry about whether their child is late in developing language. In the real world, normal children pass through the four stages of language at a pace that can vary by a year or more. However, as Chomsky's theory predicts and research has shown, all normal children pass through the four stages, even though some of the stages may begin later or last for shorter or longer periods of time (Pinker, 1994).

1. Babbling

2. Single word

3. Two words



4. Sentences

As children proceed through the stages, there is a continuous interaction between environmental stimuli and brain development. For example, researchers used brain scans to identify maximum neural activity in 3-month-old infants who were listening to recordings of human speech. The infants showed increased neural activity in brain areas that were similar to those used by adults in speaking and understanding language (Dehaene-Lambertz et al., 2002). This study shows how environmental stimulation—hearing language sounds—activated the "language areas" of infants' brains long before infants actually begin speaking. This study is a good example of how the brain and environment interact in the development of spoken language and points out the importance of caregivers regularly talking to (verbally stimulating) their infants.

Next, we'll discuss a number of innate (genetic) and environmental interactions that are important in the development of language.

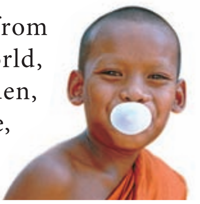
E. Acquiring Language

PowerStudy 4.5™

Module 4
D. Control Centers:
Four Lobes

How does a child learn a particular language?

It is quite amazing how children from different countries around the world, such as Bali, China, Nigeria, Sweden, Japan, United States, Mexico, France, Spain, Russia, and Thailand (right photo), can acquire the sounds, words, and rules of their particular native language. Each child learns his or her own native language because of an interaction between innate (genetic) and environmental (learning) factors.



How did he learn to speak Thai?

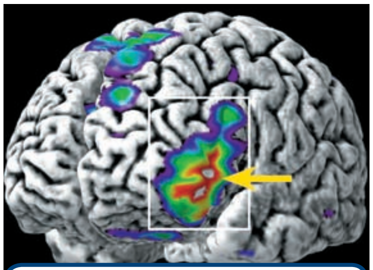
What Are Innate Factors?

All children go through the same four language stages because of innate language factors (Albert et al., 2000).

Innate language factors are genetically programmed physiological and neurological features that facilitate our making speech sounds and acquiring language skills.

We'll examine three innate language features that work together so that we can learn to speak and use language.

Innate physiological features. We have a specially adapted vocal apparatus (larynx and pharynx) that allows us to make sounds and form words. In comparison, the structures of gorillas' and chimpanzees' vocal apparatus prevent them from making the wide variety of sounds necessary to form words (Lessmoellmann, 2006; Pinker, 1994). Without specialized vocal apparatus, humans would be limited to making "animal" sounds.



The brain is genetically programmed to speak and understand.

Innate neurological features. When people speak or use sign language, certain brain areas are activated. The PET scan above shows a side view of the brain: red and yellow indicate the most neural activity (Petitto, 1997). These findings indicate that the left hemisphere of the brain is prewired to acquire and use language, whether spoken or signed. In Module 4, we explained how damage to these same language areas (Broca's and Wernicke's areas) disrupts the use and understanding of language (p. 78). Although your brain is prewired for language, there is a best, or critical, time for learning a language.

Innate developmental factors. Researchers have discovered there is a critical period when acquiring language is the easiest (Shafer & Garrido-Nag, 2007).

The ***critical language period*** is the time from infancy to adolescence when language is easiest to learn. Language is usually more difficult to learn anytime after adolescence.

For example, immigrant children do very well learning English as a second language, while immigrant adults, who are past the critical period, have more difficulty and do less well (Jackendoff, 1994). The critical period for learning language also explains why learning your native language was easy as a child but, as an adult, learning a foreign language is many times more difficult.

Innate biological factors provide the programming so a child can acquire any one of 6,900 languages. Which particular language the child learns depends on his or her environment (parents).

What Are Environmental Factors?

How each child learns a particular language depends on social interactions, one of the environmental factors.

Environmental language factors refer to interactions children have with parents, peers, teachers, and others who provide feedback that rewards and encourages language development, as well as provides opportunities for children to observe, imitate, and practice language skills.

What would happen if a child was deprived of almost all social interactions from ages 1 to 13? Such was the case with Genie, whose mentally disturbed father strapped her to a potty chair in a back room, punished her for making any sounds, and forbade the mother or brother to talk to her. When discovered at age 13 by a social worker, Genie could not speak a single word (Curtiss, 1977). Genie's case illustrates that even though children are prewired by heredity to speak a language, they need certain environmental stimuli, such as listening, speaking, and interacting with others, in order to learn to speak and use language. Genie's case also illustrates the importance of social cognitive learning.

Parentese provides needed stimulation and feedback.

Social cognitive learning refers to the acquisition of language skills through social interactions, which give children a chance to observe, imitate, and practice the sounds, words, and sentences they hear from their parents or caregivers.

For example, within eight months of training, Genie had acquired a vocabulary of about 200 words. However, Genie's long period of social deprivation left its mark, and even after years of continued social interactions, her language ability did not develop much beyond that of a 2- or 3-year-old child (J. C. Harris, 1995).

Children who have the biggest vocabularies and perform best on language tests are those whose parents are the most talkative during the child's first two years (Hart & Risley, 1996). Because watching TV drastically reduces conversations between parents and child, researchers warn parents to limit their child's TV viewing (Christakis et al., 2009). Other researchers encourage parents to use gestures, such as pointing, because children who gesture more at a younger age later score higher on language tests (Rowe & Goldin-Meadow, 2009). These studies suggest environmental and innate factors interact with and influence a child's ability to acquire language.

When children master language, they have a powerful tool for thinking, as we'll discuss after the Concept Review.

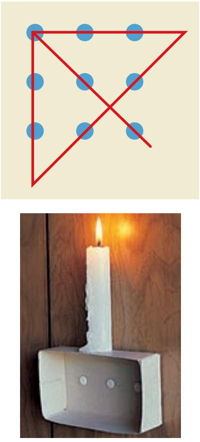
Concept Review

dog (dog, dag) *n.; pl.* **dogs, dog.**
1. any of a large and varied group of domesticated animals *(Canis familiaris)* that have four legs, a tail, two ears, prominent nose, a hairy coat, and a bark.

1. If you form a concept of an object, event, or characteristic by making a list of the properties that define it, you are forming a concept according to the ________________ model.

2. If you form a concept by putting together the average characteristics of an object and then seeing whether a new object matches your average object, you are forming a concept according to (a) ________________ theory. If you develop an idea of a dog of average age, height, weight, and color, you have formed a (b) ________________ of a dog.



Answers to problems on page 309

3. If you search for some rule, plan, or strategy that results in your reaching a certain goal that is currently out of reach, you are engaging in an activity called (a) ________________. During this activity, you go through three states: contemplating the unsolved problem, which is the (b) ________________ state; trying out various operations, rules, or strategies to solve the problem, which is the (c) ________________ state; and reaching the solution, which is the (d) ________________ state.

4. Some problems can be solved by following certain rules. If you correctly follow rules that lead to a certain solution, you are using (a) ________________. If you follow rules that reduce the number of operations or allow you to take shortcuts in solving problems, you are using (b) ________________.

5. When you use a combination of flexibility in thinking and reorganization of understanding to produce innovative ideas and solutions, you are engaging in (a) ________________. If you begin with a problem and come up with many different solutions, you are using (b) ________________ thinking, which is one definition of creative thinking. The opposite of this type of thinking is beginning with a problem and coming up with the one correct solution; this is called (c) ________________ thinking.

6. A system of symbols that we use in thinking, solving problems, and communicating with others is called (a) ________________. There are four rules for learning and using language. How we make the meaningful sounds used by a particular language is covered by the rules of (b) ________________. Any English word can be broken down into basic sounds of consonants and vowels, which are called (c) ________________. How we group phonemes into meaningful combinations of sounds and words is covered by the rules of (d) ________________. The smallest meaningful combination of sounds in a language is called a (e) ________________. How we combine words to form meaningful phrases and sentences is specified by the rules of (f) ________________. How we know the meanings of words in various contexts is covered by the rules of (g) ________________.

7. Chomsky explained that a sentence can be stated in different ways and yet have the same meaning. The actual wording of a sentence is called its (a) ________________ structure. The underlying meaning of the sentence that is not spoken but is present in the mind of the listener is called the (b) ________________ structure. To convert our ideas from surface structures into deep structures and from deep structures back into surface ones, we use (c) ________________ rules.

8. In acquiring language, all children go through the same four stages but at different rates. Beginning at about the age of 6 months, a baby begins making one-syllable sounds, such as "bababa," which is called (a) ________________. By about 1 year of age, a child forms (b) ________________ words, which usually refer to what the child can see, hear, or feel. At about 2 years of age, a child makes (c) ________________, which are strings of two words that express various actions ("Me play") or relationships ("Hit ball," "Milk gone"). At about 4 years of age, a child begins forming sentences, which range from three to eight words in length and indicate a growing knowledge of the rules of (d) ________________.

9. One reason all children acquire a language in the same order is that there are genetically programmed physiological and neurological features in the brain and vocal apparatus. These are known as (a) ________________ factors. Social interactions between the child and others, which offer opportunities for observation, imitation, and practice, are called (b) ________________ factors.

Answers: *1. exemplar; 2. (a) prototype, (b) prototype; 3. (a) problem solving, (b) initial, (c) operations, (d) goal; 4. (a) algorithms, (b) heuristics; 5. (a) creative thinking, (b) divergent, (c) convergent; 6. (a) language, (b) phonology, (c) phonemes, (d) morphology, (e) morpheme, (f) syntax or grammar, (g) semantics; 7. (a) surface, (b) deep, (c) transformational; 8. (a) babbling, (b) single, (c) two-word combinations, (d) grammar or syntax; 9. (a) innate, (b) environmental*

F. Decisions, Thought & Language

Decisions

How do we make decisions?

We make many decisions each day. Some decisions have very important consequences in our lives, such as choosing a college, career, or spouse. Other decisions have much less importance, such as choosing a flavor of ice cream, the color of a shirt, or a movie to watch. We would like to believe that we make decisions, especially important ones, based on thoughtful reasoning. But how do we actually make decisions?

Should I have surgery?

Emotions influence treatment decisions.

Imagine that you are in the hospital and a doctor tells you about your treatment options. One of the treatments involves surgery, and you must decide whether you want to undergo surgery. Would your decision be influenced differently if a doctor tells you that the survival rate of surgery is 80% *or* that there is a 20% chance of dying from surgery? Even though both statements express the same risk, the 80% chance of survival sounds more appealing than the 20% chance of dying. Thinking about the success of surgery is comforting, but thinking about the failure of surgery makes us uncomfortable (De Martino, 2006a).

Research does show that we often base our decisions on emotion rather than intellect (Koenigs et al., 2007; Lehrer, 2009). As we discuss next, research on gambling shows what happens in our brains as we make decisions.

Gambling Decisions

Benedetto De Martino (2006b) and his team of researchers (2006) at the University College of London took brain scans of men and women while they were being asked to make a decision about whether or not to gamble. At the start of the study each subject was given about $100. They were then told they could either ***"keep"*** 40% of their money or ***"lose"*** 60% of their money if they did not gamble. When subjects were told they could ***"keep"*** 40% of their money if they chose to not gamble, subjects gambled only 43% of the time. When told they could ***"lose"*** 60% of their money if they did not gamble, subjects gambled 62% of the time. Even when the chances of winning and losing were identical, the wording of the instructions made a difference in the subjects' decisions.

Gambling decisions are ruled by emotions, not rational thinking.

The results of brain scans showed that the part of the brain responsible for strong negative emotions (amygdala) was very active while subjects were making their decisions, regardless of the choice they made. Researchers concluded that emotions had a strong influence on how subjects made gambling decisions. Further support for the significant role of emotions in decision making comes from research studies showing that people who lack emotions due to brain trauma or injury often have serious difficulties making even simple decisions (A. Damasio, 2006).

Emotions have the power to rule our choices about gambling as well as many other choices we make in life, including how we make political decisions.

Political Decisions

In 2008, John McCain (Republican) and Barack Obama (Democrat) (see right photos) were competing against each other in the U.S. presidential election. How did you decide which candidate to vote for? Were you able to base your vote on only an objective evaluation of their political positions, or were you perhaps influenced by your feelings about having the first African American man be president of the United States?

During presidential elections, people make difficult decisions about which candidate to vote for, and although people may try to make their decisions objectively, research shows our political decisions are significantly influenced by our emotions. For instance, during the 2004 presidential election, a group of "strong" Republicans and a group of "strong" Democrats were asked to evaluate statements made by George W. Bush (Republican) and John Kerry (Democrat) in which both candidates contradicted themselves. Results showed subjects were not critical of their own candidate, but Republicans were as critical of Kerry as Democrats were of Bush. Brain scans showed that during the task, the part of the brain where reasoning takes place was inactive and subjects made completely biased conclusions by ignoring information that could not be disputed. The most active part of subjects' brains during the task was where emotions are processed (Westen, 2006a, 2006b).

Which guided your decision to choose between John McCain (left) and Barack Obama (right) for president—objective thinking or biased emotions?

We've known emotions can bias our decisions, and now researchers report our personalities also bias our political decisions by influencing how we perceive and think about the world and what is good or bad about it (Mayer, 2008).

Because words are so much a part of our reasoning process, we need to know how much words can influence or bias our thinking.

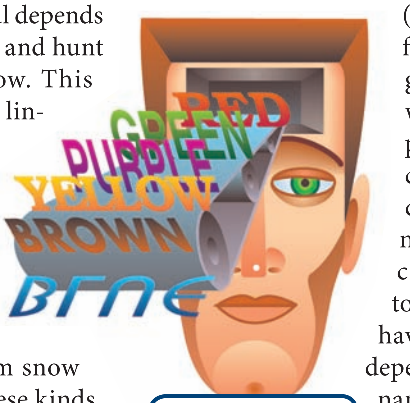
Words and Thoughts

Does language influence thinking?

Almost everyone has heard it said that the Inuit (Eskimos) have dozens of words for snow because their survival depends on knowing how to travel and hunt in different kinds of snow. This particular observation was first made by amateur linguist Benjamin Whorf (1956), who noticed that languages differed in their vocabularies depending on how much emphasis they gave to different objects and events in their environment. For example, Whorf reasoned that because the Inuit (Eskimos) have many names for snow, they must be able to perceive many more kinds of snow than Americans, for whom snow conditions are less important. On the basis of these kinds of observations, Whorf formulated the theory of linguistic relativity.



The ***theory of linguistic relativity*** states that the differences among languages result in similar differences in how people think of and perceive the world.

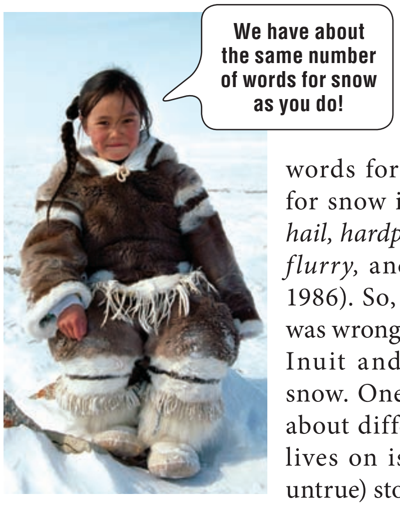
Linguistic relativity theory says differences among languages lead to differences in thinking.

For example, according to the theory of linguistic relativity, people whose language divides colors into only two categories (dark or black and bright or white) should perceive fewer colors. In comparison, people whose language divides colors into eleven categories (black, white, red, yellow, green, blue, brown, purple, pink, orange, gray) should perceive many more colors in their environment. However, researchers discovered that although languages differ in their number of color categories, all languages divide colors into the same basic categories. According to Whorf's theory of linguistic relativity, we would have expected people to perceive colors differently, depending on whether their culture has two or eleven names, but this is not what researchers found (Davies & Corbett, 1997). Thus, people in different cultures seem to perceive colors in similar ways even if they do not have names for different colors (Pinker, 1994).

Now, let's examine Whorf's famous claim that Inuit have more words for snow than do Americans.

Inuit Versus American Words for Snow

In his original article, Whorf (1940) estimated that Inuit (Eskimos) have about seven words for snow: *falling snow, snow on the ground, snow packed hard like ice, slushy snow, drifting snow, snow drift,* and *wind-driven flying snow,* while most Americans use a single word, *snow.* Whorf reasoned that the Inuit's larger vocabulary of snow-related words should make them think and perceive snow very differently than most Americans. Since Whorf's time, the number of snow words attributed to Inuit has ranged from two dozen to about 400 (Pullum, 1991).



We have about the same number of words for snow as you do!

Another linguist did a closer examination and found that Inuit and Americans both have about eight words for snow (English words for snow include *blizzard, sleet, hail, hardpack, powder, avalanche, flurry,* and *dusting*) (L. Martin, 1986). So, as it turns out, Whorf was wrong about how many words Inuit and Americans have for snow. One reason Whorf's story about differences in snow words lives on is that it's a great (but untrue) story (Pullum, 1991).

Although Whorf's story about snow words was untrue, the basic question still remains: Do differences in language mean that people think and perceive the world in different ways? One way to answer this question is to examine how individuals who are bilingual—that is, fluent in two languages—think about and perceive their world.

Thinking in Two Languages

Suppose your native language is Chinese but you are also fluent in English. You are asked to read descriptions of two different people in either Chinese or English and then to write impressions of these individuals. You read a Chinese and an English description of a type of person easily labeled in Chinese—*shi gu,* a person with strong family ties and much worldly experience—but not easily labeled in English. You read an English and a Chinese description of a type of person easily labeled in English—an *artistic* character, a person with artistic abilities who is very temperamental—but not easily labeled in Chinese. Researchers found that when subjects were reading and thinking in Chinese, they formed a clearer impression of the *shi gu* person; when reading and thinking in English, they formed a clearer impression of the artistic character (C. Hoffman et al., 1986). This is one of the few studies that supports the linguistic relativity theory and the idea that language influences thinking (Hardin & Banaji, 1993).

My native language is Chinese, but I also speak English, so which do I think in?

Recent research shows not only that language may influence thinking, but also that it can lead to changes in our personalities. One study including 225 Spanish/English bilingual subjects examined personality characteristics as subjects answered questions in each language. Researchers found that when using English, the bilingual subjects were noticeably more extraverted, agreeable, and conscientious than when speaking in Spanish (Ramirez-Esparza et al., 2006).

We know that words are important tools for thinking, so what happens to an individual's thinking if he or she has great difficulty recognizing printed words? Our next topic is dyslexia.

G. Research Focus: Dyslexia

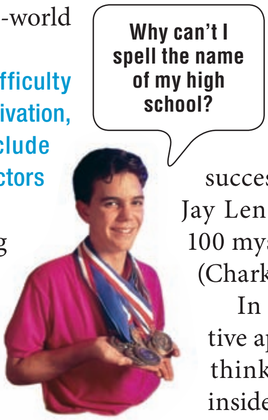
What Kind of Problem Is Dyslexia?

Was that word "bark" or "dark"?

This Research Focus deals with a real-world problem called dyslexia.

Dyslexia **refers to an unexpected difficulty learning to read despite intelligence, motivation, and education. Causes of dyslexia include genetic factors (defects in neural circuitry) and environmental factors (disadvantaged schooling) (S. E. Shaywitz et al., 2003).**

An example of a dyslexic is 16-year-old Steve Goldberg (right photo), who is motivated and intelligent and has won numerous medals for science projects. However, he cannot read or spell the name of his high school, read phone numbers, or tell the difference between the words *dark* and *bark*. Dyslexia, which affects boys and girls equally, accounts for 80% of students identified as having learning disabilities.



Why can't I spell the name of my high school?

Although people with dyslexia struggle with a wide range of reading difficulties, many have normal or above-average IQ scores and some have very successful and creative careers: Tom Cruise, movie actor; Jay Leno, TV talk-show host; Agatha Christie, author of 100 mystery books; and Walt Disney, creator of animations (Charkalis, 2005).

In studying dyslexia, researchers combined the cognitive approach—what happens when we read (not what you think)—with the physiological approach—what happens inside the brain.

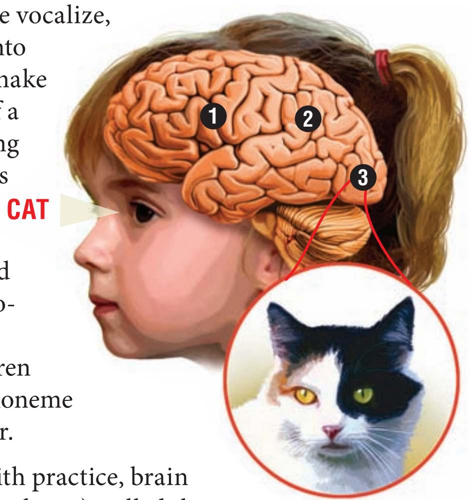
What's Involved in Reading?

Earlier, we explained that children usually have no difficulty learning to speak because their brains come with innate or prewired areas for speaking (p. 316). Learning to read is entirely different from learning to speak because our brains have no innate areas dedicated specifically to reading. Instead, we must spend many years practicing how to read by learning to use three different brain areas that were originally designed to do something else. That's why reading is so difficult to learn (Eden, 2003).

Reading: 3 steps. Learning to read involves using 3 brain areas, each with a different function (Gorman, 2003; S. E. Shaywitz et al., 2003).

1 Phoneme (sound) producer. The first step in reading is to vocalize the word, either silently or out loud. Vocalizing involves changing the letters of each word into their basic sounds, called phonemes. For example, reading the word CAT involves vocalizing or changing the letters C-A-T into the sounds KUH-A-TUH. The phoneme producer is located in brain area #1 (left inferior frontal gyrus) (figure below).

2 Word analyzer. After we vocalize, or change a word's letters into sounds, the next step is to make a more complete analysis of a written word, such as pulling the word apart into syllables and linking syllables to their appropriate sounds. The word analyzer is located in brain area #2 (left parieto-temporal area). When first learning how to read, children rely heavily on using the phoneme producer and word analyzer.



3 Automatic detector. With practice, brain area #3 (left occipito-temporal area), called the automatic detector, becomes more active. The automatic detector takes on a bigger role by developing a permanent file of words so the reader can recognize words on sight, which makes reading a quick, automatic, and effortless process. Normally, these three processes work together almost simultaneously, like members of a team.

Why Can't Dyslexics Read?

One problem dyslexics have is that their phoneme producer is faulty so they cannot easily or quickly distinguish between phonemes (*ba, pa, la*), and this results in problems distinguishing between like-sounding words (*bark, park, lark*), which makes reading difficult (Tallal, 1995). Another problem is that dyslexics have defective neural wiring between the phoneme producer (#1) and the word analyzer (#2) and automatic detector (#3). As a result, they cannot easily or quickly recognize words or their meanings, which makes reading a slow and difficult process (Gorman, 2003; S. E. Shaywitz et al., 2003).

Can Training Help?

Because dyslexic children have deficits in the phoneme analyzer, researchers developed computer games to increase phoneme or sound processing, which is the first step in learning to read. After the dyslexic children played computer reading games, brain scans showed that they actually had increased neural activity in brain area #1, phoneme producer, and brain area #2, word analyzer. They also developed better reading skills, listening comprehension, and word recognition (Gaab, 2008; Temple et al., 2003).

Parents are advised to encourage their dyslexic children to play rhyming games and have their children read aloud while gently correcting their mistakes. Rhyming and reading activities help dyslexic children develop correct associations between sounds and words (Gorman, 2003). According to Dr. Sally Shaywitz (2003), the most successful programs to help dyslexic children use the same core elements: practice with distinguishing between phonemes (computer games), building vocabularies, and increasing comprehension.

Reading problems should be identified early, ideally between the ages of 5 and 7, when brain circuitry and reading skills are being developed and can be most easily influenced (R. Lyon, 1999). Recent research identified two genes that contribute to dyslexia, which means that genetic testing for susceptibility to dyslexia may be possible in the near future (Gruen, 2005).

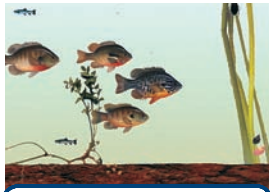
H. Cultural Diversity: Influences on Thinking

Differences in Thinking

How does culture influence thinking?

If you spend most of your time in one culture, you probably don't realize how much your culture influences your thinking (Hong et al., 2000). For example, look at the underwater scene at the right and then look away and describe what you saw.

Differences. When American students looked at this underwater scene and then thought about what they saw, they usually began by describing the biggest, brightest, or most outstanding feature—in this case, focusing on the fish and what they were doing (swimming to the right). In contrast, Japanese students usually began by describing the background and saying the bottom was rocky (Had you noticed?) and the water was green (Had you noticed?). They usually discussed how the fish interact with the background, such as the fish were swimming toward the seaweed. On average, Japanese subjects made 70% more statements about how the background looked than Americans and 100% more statements about the way the objects (fish) interact with the background.



American students' descriptions of this drawing differed from Japanese students'.

Based on these kinds of findings, researchers concluded that Americans usually analyze each object separately, which is called analytical thinking, such as seeing a forest and focusing on the biggest or strangest trees. In comparison, Asian people (Japanese, Chinese, and Koreans) think more about the relationship between objects and backgrounds, which is called holistic thinking, such as seeing a forest and thinking about how the many different trees make up a beautiful forest (Norenzayan & Nisbett, 2000). Researchers suggest that differences in thinking between Americans and Asians—analytical versus holistic—come from differences in social and religious practices and languages (Nisbett, 2000; Nisbett & Miyamoto, 2005).

Male–Female Differences

Do men and women think differently?

Just as culture influences how we think, so do gender differences. Research shows that men and women think and use language differently (Tannen, 1990, 1994).

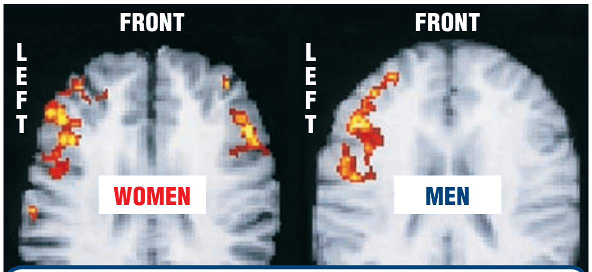
Men and Women Use Language Differently

- Men more frequently use language to express ideas and solve problems. Women more frequently use language to share concerns, daily experiences, and ordinary thoughts.
- Men use language to maintain their independence and position in their group. Women use language to create connections and develop feelings of intimacy.
- Men prefer to attack problems, while women prefer to listen or give support.

Tannen concluded that neither the female nor the male use of language, which strongly reflects how they think, is necessarily better; the two styles are just different.

Brains Process Words Differently

Not only do men and women use language differently, but their brains may process language differently. Researchers used fMRI brain scans (p. 70) to identify which brain areas were most active during language tasks. The left fMRI scan shows that, in women, activity during certain word-processing tasks occurred almost equally in the right and left hemispheres (red and yellow areas indicate maximum activity). In contrast, the right fMRI scan shows that, in men, activity during the same word-processing tasks occurred in only the left hemisphere (B. A. Shaywitz et al., 1995). Other research did not find the same hemisphere differences between men and women, but found they both use different parts of the left hemisphere when processing language (Sommer et al., 2004). Differences in brain functioning between men and women do not indicate that one brain is better than another, only that they function differently (D. Halpern, 2003).

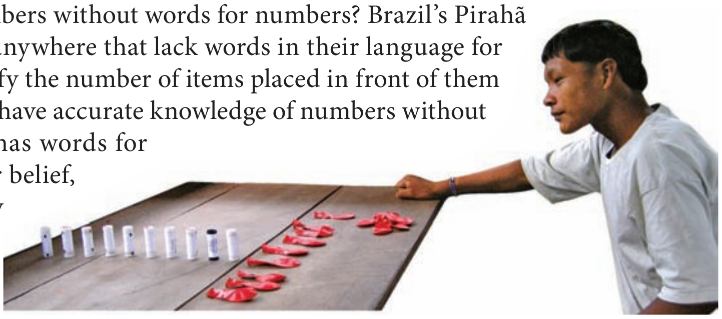


fMRI scans showed women use right and left hemispheres to process language; men use only left.

Difference in Language, Similarity in Thought

Count without words for numbers?

Is it possible to understand the concept of numbers without words for numbers? Brazil's Pirahã people (right photo) are the first group found anywhere that lack words in their language for specific numbers. Yet, Pirahã people can identify the number of items placed in front of them by selecting a matching number of items. They have accurate knowledge of numbers without words for specific numbers. Their language has words for only relative amounts, such as "some" and "more." Contrary to prior belief, counting may not be needed when it comes to thinking about quantity (B. Bower, 2008b; M. C. Frank et al., 2008).



Next, we'll discuss the interesting question of whether animals have language and if my (R. P.) dog really understands what I say.

I. Application: Do Animals Have Language?

Criteria for Language

What does my dog understand?

Like most pet owners, I (R.P.) talk to my dog and he usually behaves as if he understands what I say. For example, my dog Bear (photo below) behaves as if he understands "get your toy," "go for walk," "time to eat," and "watch television." The obvious question is: Has Bear learned a language? The answer to this question hinges on the difference between communication and language. Like many animals, Bear has the ability to communicate.

Communication is the ability to use sounds, smells, or gestures to exchange information.

But language is much more than just communication.

Language is a special form of communication in which an individual learns complex rules for using words or gestures to generate and understand an endless number of meaningful sentences.

Dogs communicate but don't have a language.

Although Bear can communicate—that is, understand my commands and act accordingly—he, like most animals, shows no evidence of meeting the four criteria for having real language.

1 Language, which is a special form of communication, involves ***learning a set of abstract symbols*** (whether words for spoken language or hand signs for sign language).

2 Language involves ***using abstract symbols*** (words or signs) to express thoughts or indicate objects and events that may or may not be present.

3 Language involves ***learning complex rules of grammar*** for forming words into meaningful phrases and sentences.

4 Language involves using the rules of grammar to ***generate an endless number of meaningful sentences.***

Because some animals, such as dolphins and pygmy chimps, show an amazing ability to communicate, researchers are debating whether animals can satisfy all four criteria for language (Begley, 1998a; Savage-Rumbaugh & Lewin, 1994). We'll examine how close several animals come to satisfying the four criteria.

Dolphins

Do dolphins use language?

Dolphins are considered very intelligent, not only because of their ability to learn but also because in proportion to the size of their bodies, dolphins' brains are the largest of nonhuman mammals (smaller than human brains but larger than brains of great apes) (Tyack, 2000). Because dolphins have relatively large brains, researchers are interested in how well they communicate.

In the wild, dolphins use two kinds of sounds for communication: clicks, which they use to probe the sea and "see" their environment, and whistles, which they use in dolphin-to-dolphin communication, probably to express emotional states and identify the animal to the group (L. Herman, 1999).

In testing the ability of dolphins to communicate, psychologist Louis Herman (1999) has been training dolphins to respond to hand signals or whistles. He has taught two dolphins to respond to approximately 50 such signals (see right photos for an example).

Herman found that dolphins can understand a variety of hand signals and perform behaviors in sequence. For example, the hand signal combination "basket, right, Frisbee, fetch" means "Go to the Frisbee on the right and take it to the basket."

More recently, Herman combined "words" by using gestures or whistles in basic "sentences," such as "ball fetch surface hoop." The two dolphins responded correctly to both familiar and novel "sentences" about 85% of the time. Herman concluded that the ability of these two dolphins to pass tests of language comprehension (understanding "sentences"), which indicates an understanding of grammar or syntax, means that dolphins have a relatively sophisticated ability to use language (L. Herman, 1999).

Other evidence for dolphins having impressive communication abilities comes from watching a pair of dolphins carry out a complex sequence of movements in synchrony (referred to as "tandem" movements). Herman described these movements by saying that dolphins "may swim in a circle, leap out of water in a spinning motion, and spit water out of their mouths together" (L. Herman, 2006, p. 150). Researchers have yet to determine how dolphins actually communicate information to each other, such as what movements they will make.

Hand signals in top photo tell dolphin to "jump over person," which it does in bottom photo.

Despite Herman's impressive findings, some scientists remain skeptical. For example, David Kastak, a researcher of animal cognition, said, "What dolphins do may turn out to be a lot more complex than what we thought originally, but do they have what we would call language? No. They are not animals using nouns and verbs" (Mastro, 1999, p. E4).

Although dolphins understand a variety of signals, perform behaviors in sequence, form concepts, and even understand "sentences," they show little evidence of using abstract symbols and applying rules of grammar to generate meaningful sentences to communicate information to other dolphins. It is these criteria that distinguish the ability to use language from the ability to communicate with signs, sounds, or gestures.

Next, let's turn to the apes, which in terms of evolution are the animals closest to humans.

Gorilla and Chimpanzee

What does a gorilla know?

Gorillas and chimpanzees have relatively large and well-developed brains. A gorilla's brain weighs about 500 grams, a chimpanzee's about 400 grams, and a human's about 1,350 grams. However, because gorillas and chimpanzees lack the vocal apparatus necessary for making speech sounds, researchers have taught them other forms of language, such as American Sign Language (P. E. Ross, 1991).

Shown on the right is researcher Francine Patterson using sign language to communicate with Koko the gorilla, who has a vocabulary of about 1,000 signs (Boysen, 2009). Similarly, Beatrice and Allen Gardner (1975) taught sign language to a chimpanzee named Washoe, who learned about 250 signs and passed her language skills on to her son (*Time,* 2007b). The finding that gorillas and chimps can learn sign language raised the question of whether they use language in the same way as humans.

Francine Patterson taught Koko the gorilla a vocabulary of about 1,000 hand signs.

Psychologist Herbert Terrace (1981) analyzed videotapes of chimps using sign language with their trainers. He was particularly interested in the videotapes of a chimp named Nim, who learned more than 125 signs, such as "give orange me." After observing over 20,000 of Nim's signs on videotape, Terrace concluded Nim was using signs more as tools to obtain things than as abstract symbols or words and that Nim never learned to form combinations of more than a few words. Perhaps the most devastating criticism was Nim had primarily learned to imitate or respond to cues from human teachers rather than learning and using rules of grammar to initiate or produce new sentences.

As a result of criticisms by Terrace and others, research monies to study language in animals mostly disappeared in the 1980s (Savage-Rumbaugh & Lewin, 1994). However, in the late 1980s, new findings on bonobos again raised the question of language in animals.

Bonobo Chimp: Star Pupil

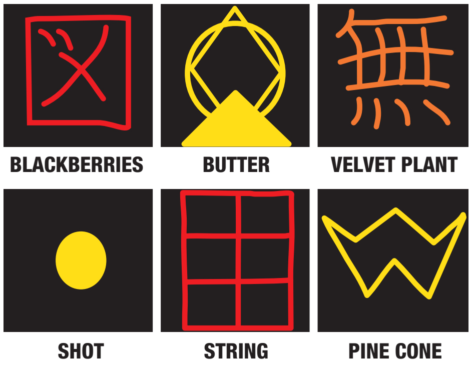
Is this the first real sign of language?

The best evidence for language in animals comes from the work of psychologist Sue Savage-Rumbaugh. She reported that Kanzi, a bonobo (commonly called a pygmy chimp), has remarkable language skills that surpass previous accomplishments of common chimps (Savage-Rumbaugh & Lewin, 1994; Shanker et al., 1999).

Instead of using sign language, Kanzi "speaks" by touching one of 256 symbols on a board (top right photo), each of which stands for a word (Boysen, 2009). For example, Kanzi (bottom right photo) might signal "Want a drink" by touching the symbol for "drink" or signal "Want to play" by touching in sequence two symbols for "hiding" and "play biting."

By the time Kanzi was 6 years old, he had a vocabulary of 90 symbols; at age 12, he knew about 190 symbols but used about 128 regularly. Even more surprising, Kanzi understands about 200 spoken English words, something that common chimps have failed to master.

Perhaps Kanzi's greatest accomplishment is his knowledge of word order. Psychologists tested the ability of Kanzi to respond to 600 spoken English commands that he had not previously encountered, such as "Put the melon in the potty." Savage-Rumbaugh suggests that 17-year-old Kanzi has an ability to use abstract symbols (keyboard) and a kind of primitive grammar (word order) for combining symbols that equals the language ability of a 2-year-old child (Savage-Rumbaugh, 1998). Although chimps can learn more than 400 symbols and even string several symbols together, their language ability is nowhere near that of a high-school student, who has a vocabulary of 60,000 words and can string these words together into an endless number of meaningful sentences, often about abstract concepts (love, patriotism, courage, honor) (M. Hauser, 2003).



Examples of symbols and their meanings

Kanzi has an amazing ability to use and respond to either symbols or English words.

Why did humans develop a complex language while chimps did not? Researchers now believe the development of human language was triggered by a major genetic change (R. Klein, 2002). This conclusion is based on a new finding: the discovery of the first human gene (FOXP2) involved specifically in language. Individuals without this "language" gene are normal in other ways but not in communication; they have specific difficulties pronouncing words and speaking grammatically (Vargha-Khadem et al., 2005). Although ancient humans shared this gene with other animals, researchers discovered there was an important change in this gene's structure when humans and chimps parted evolutionary company (Krause et al., 2007).

Some researchers point to a change in the structure of this "language" gene (FOXP2) as the reason that early humans were able to gradually develop their primitive sounds and clicks into the complex, fluent language that we speak today (Paabo, 2003).

Summary Test

A. Forming Concepts

1. There are two theories of how you have formed your concept of a dog and how you form concepts generally. If you form a concept of an object, event, or characteristic by making a list of the properties that define it, you are using the (a) ______________ model. If you form a concept by constructing an idea of the ideal object and then seeing whether a new object matches that idea, you are using (b) ______________ theory.

2. A concept is a way to group objects, events, or characteristics on the basis of some common property they all share. Concepts perform two important functions: They allow us to (a) ______________ objects, and thus better organize and store information in memory, and to identify things without (b) ______________.

B. Solving Problems

3. The process of searching for some rule, plan, or strategy that results in reaching a certain goal that is currently out of reach is called (a) ______________. We usually go through three states in solving problems: (b) ______________, ______________, and ______________.

4. We win at games by following rules. If we correctly follow a set of rules that lead to a solution, these rules are called (a) ______________. As you gain experience with solving problems, you may use rules of thumb that reduce the number of operations or allow you to take shortcuts in solving problems; these shortcuts are called (b) ______________. In making everyday decisions, you rely on information that is more prominent or easily recalled and overlook other information that is available but less prominent or notable; this is an example of using the (c) ______________ heuristic.

5. By studying how people eventually solve problems, psychologists have discovered a number of useful strategies, including changing our (a) ______________. This often involves breaking out of a pattern called (b) ______________, in which we cannot see an object as having a function different from its usual one.

6. The sudden grasp of a solution after many incorrect attempts is called (a) ______________. Another kind of thinking that is useful in solving problems is to find (b) ______________, which are similarities between new situations and familiar situations. Still another useful strategy for solving problems is to break the problem down into a number of (c) ______________, which, when completed in order, will result in a solution.

C. Thinking Creatively

7. A combination of flexibility in thinking and reorganization of understanding to produce innovative ideas and solutions is referred to as (a) ______________. Psychologists distinguish between two different kinds of thinking. If you begin with a problem and come up with the one correct solution, it is called (b) ______________. If you begin with a problem and come up with many different solutions, it is called (c) ______________, which is another definition of creative thinking.

D. Language: Basic Rules

8. Our most impressive skill is thought to be a special form of communication in which an individual learns complex rules to manipulate symbols (words or gestures) and so generates an endless number of meaningful sentences; this form of communication is called ______________.

9. All of the 6,900 known languages share four basic language rules, which are normally learned during childhood. The first language rule governs (a) ______________, which specifies how we make meaningful sounds that are used by a particular language. The second language rule governs (b) ______________, which specifies how we group phonemes into meaningful combinations of sounds and words. The third language rule governs (c) ______________, which specifies how we combine words to form meaningful phrases and sentences. The fourth language rule governs (d) ______________, which specifies the meanings of words in various contexts.

10. The linguist Noam Chomsky distinguished between how a sentence is worded, which he called the (a) ______________ structure, and the meaning of the sentence, which he called the (b) ______________ structure. Procedures for converting our ideas from surface structures into deep structures and from deep structures back into surface ones are called (c) ______________.

E. Acquiring Language

11. Children around the world acquire language in the same four stages that are associated with growth and development of the (a) ______________. In the first stage, generally at about the age of 6 months, the infant makes one-syllable sounds; this is called (b) ______________. By about 1 year of age, a child forms (c) ______________, which usually refer to what the child can see, hear, or feel. At about 2 years of age, a child makes (d) ______________ to express various actions or relationships.

Photo Credits: (#1) © Haig Kouyoumdjian; (#3) © Craig McClain; (#7) © Victor Lerena/epa/Corbis

At about 4 years of age, a child is forming sentences, which range from three to eight words in length and indicate a growing knowledge of the (e) ______________.

12. A child's beginning sentences differ from adult sentences. A child's speech is called (a) ______________ because it omits articles, prepositions, and parts of verbs. In learning the rules for combining nouns, verbs, and adjectives into meaningful sentences, children often apply a grammatical rule to cases where it should not be used. This type of error is called (b) ______________. Although all children pass through these stages in the same order, they may go through them at different ages and speeds.

13. Children are able to acquire a language with so little formal training because of genetically programmed physiological and neurological features in the brain and vocal apparatus; these features are called (a) ______________ factors. One innate factor is the period of time from infancy to adolescence when language is easier to learn, called the (b) ______________. Children acquire the sounds and rules of a particular language because of their interactions with their surroundings; these interactions are called (c)______________ factors. The approach that emphasizes observation, exploration, and imitation in language acquisition is (d) ______________.

F. Decisions, Thought & Language

14. A study on gambling found that even when people knew that their chances of winning and losing were identical, the wording of what they were told made a difference in their (a) ______________. Another study on how the brain responds when people are making political decisions found that the part of the brain where (b) ______________ takes place is inactive and the most active part of the brain is where (c) ______________ are processed.

15. Whorf has suggested that language determines or influences the way people think and that people with different languages think and perceive their world differently. This is called the theory of ______________. There is only weak support for Whorf's theory.

G. Research Focus: Dyslexia

16. About 80% of learning disabilities are accounted for by (a) ______________, which is an unexpected difficulty in reading despite intelligence, motivation, and education. The three steps in reading involve three different brain areas, each with a different function: Brain area #1 is called the (b) ______________, brain area #2 is called the (c) ______________, and brain area #3 is called the (d) ______________. Individuals with dyslexia have a problem with changing letters into sounds or (e) ______________ and have faulty (f) ______________ connections between brain area #1 and brain areas #2 and #3.

H. Cultural Diversity: Influences on Thinking

17. Men tend to use language to express ideas, maintain their position in the group, and solve (a) ______________, while women use language more to share concerns and daily experiences and develop feelings of (b) ______________.

Image not available due to copyright restrictions

18. fMRI scans of the brain have shown that women process some words equally in both (a) ______________, while men process words only in the (b) ______________ hemisphere.

I. Application: Do Animals Have Language?

19. Many animals have the ability to use sounds, smells, or gestures to exchange information; this is the ability to (a) ______________. Another question is whether animals can communicate with abstract symbols; this is called (b) ______________. To decide that an animal truly uses language, researchers must show that the animal has learned complex rules of (c) ______________ to manipulate symbols (words or gestures) and so generate an endless number of meaningful sentences. The best evidence for language in animals is the (d) ______________, who has matched the language ability of a 2-year-old child.

Answers: *1. (a) exemplar, (b) prototype; 2. (a) categorize, (b) relearning; 3. (a) problem solving, (b) initial state, operations state, goal state; 4. (a) algorithms, (b) heuristics, (c) availability; 5. (a) mental set, (b) functional fixedness; 6. (a) insight, (b) analogies, (c) subgoals; 7. (a) creative thinking, (b) convergent thinking, (c) divergent thinking; 8. language; 9. (a) phonology, (b) morphology, (c) syntax or grammar, (d) semantics; 10. (a) surface, (b) deep, (c) transformational rules; 11. (a) brain, (b) babbling, (c) single words, (d) two-word combinations, (e) rules of grammar; 12. (a) telegraphic, (b) overgeneralization; 13. (a) innate, (b) critical language period, (c) environmental, (d) social cognitive learning; 14. (a) decisions, (b) reasoning, (c) emotions; 15. linguistic relativity; 16. (a) dyslexia, (b) phoneme producer, (c) word analyzer, (d) automatic detector, (e) phonemes, (f) neural or brain; 17. (a) problems, (b) intimacy; 18. (a) hemispheres, (b) left; 19. (a) communicate, (b) language, (c) grammar, (d) bonobo (pygmy chimp)*

Critical Thinking

Music Improves Language Skills in Kids

"Can you tell me how to get, how to get to Sesame Street?" *Sesame Street* has been using music to teach children language for over 40 years. We know children enjoy music. Infants attentively listen to their parents singing to them. Children often sing loudly to themselves and with their peers at school. They seem to be naturally wired for music. Many educators, parents, and television show creators have assumed singing helps children learn language faster. But the real question is whether music simply makes learning more accessible and entertaining for children, or if it actually advances the learning of language.

A recent research study examined the relationship between musical training and language skills, and its results are really interesting. In this study, adults wore electrodes on their scalp to measure brain wave activity while watching and listening to a cellist perform and a person speak. The adults in the study consisted of musicians (with varying years of experience) and nonmusicians. Researchers originally expected the musicians to have an advantage (greater brain activity) only when it came to responding to the cellist and not to speech. However, results showed that musicians had greater responses in their brains to both music and speech than nonmusicians. Specifically, there was a positive correlation between years of musical training and activity in brain areas responsible for speech and communication.

These research findings indicate that musical training improves the same processing skills in the brain and nervous system needed for speaking and reading. If you consider the skills involved in learning music, this finding makes perfect sense. Music training requires the use of many senses, such as watching other musicians, reading lips, touching, and hearing the music. Singing, for example, is a phenomenal example of multisensory learning. When children sing, they use their ears to listen to the sounds and voices around them, their eyes to watch the movement of others, and their entire bodies to develop rhythm and coordination. One beneficial outcome of this multisensory process is that it really facilitates learning. Generally, the more senses involved, the more learning takes place.

Over years of research it has become clear that musical training exercises the very same brain areas necessary for language skills. Teaching letters and words to children through songs is a very effective learning strategy and it helps make learning much more fun! Research clearly supports the work *Sesame Street* has being doing for decades, teaching children language through song and music. It turns out *Sesame Street* and other similar children's television programs have been teaching language skills the right way all along. (Adapted from Gadzikowski, 2007; Musacchia et al., 2007; Schon et al., 2008; Swaminathan, 2007; Tremmel, 2007; Warner, 2007)

QUESTIONS

1 What type of learning takes place as children listen to their parents sing?

2 Specifically, what is used to measure brain wave activity?

3 Does this correlation mean a person with 20 years of musical training will have greater brain activity than a person with 5 years of musical training? Why or why not?

4 How many senses do we have? What are they? Which senses are used when playing music?

5 According to Gardner's multiple-intelligence theory, which three types of intelligence are exhibited when children sing?

6 Which type of aphasia would singing benefit most by helping people speak more fluently?

Visit this book's companion website for more resources to help you study, including learning objectives, additional quizzes, flash cards, updated links to useful websites, and a pronunciation glossary.

Study Guide and WebTutor

Work through the corresponding module in your Study Guide for tips on how to study effectively and for help learning the material covered in the book. WebTutor (an online Study Tool accessed through your eResources account) provides an interactive version of the Study Guide.

Suggested Answers to Critical Thinking

1. Social cognitive learning emphasizes the acquisition of language through social interactions, such as listening to parents sing, which give children the opportunity to observe, imitate, and practice the words and sentences they hear (p. 316).
2. Brain wave activity is measured and recorded by a complex machine called an EEG, or electroencephalogram (p. 152).
3. No. Correlations only describe a relationship between two or more events, which in this example are years of musical training and amount of brain activity. Correlations do not demonstrate cause and effect between variables (pp. 32–33). It is possible for an individual with 5 years of musical training (or even no musical training) to exhibit greater brain activity when listening to music than an individual with 20 years of musical training.
4. We have five senses, which are vision, audition, taste, smell, and touch (Module 5). Playing music uses three of these senses: vision, audition, and touch.
5. The three types of intelligence exhibited during singing are verbal intelligence (using language), musical intelligence (singing), and body movement intelligence (moving bodies to develop rhythm and coordination) (p. 283).
6. Broca's aphasia is when a person cannot speak fluent sentences but can understand written and spoken words (p. 78). Singing helps people speak more fluently and, as such, can be of benefit to people with Broca's aphasia.

Motivation

Why would a blind person climb the world's highest mountains?

Once a middle-school teacher and wrestling coach, Erik Weihenmayer has become one of the most respected and well known athletes in the world. In 2001, Erik climbed to the top of Mount Everest, the world's highest peak. In 2002, he stood on top of Mount Kosciuszko, completing his seven-year journey to climb the Seven Summits, the highest mountain on each of the seven continents. During these adventures, he endured severe winds, −70°F weather, and countless life-threatening situations.

Erik Weihenmayer, a blind man, climbed the Seven Summits, the tallest peak on every continent.

Erik's quests were far from over. In 2003, he joined some of the world's best athletes to compete in the Primal Quest, the toughest multisport adventure race in the world, taking place over ten days across 457 miles of high elevation in the Sierra Nevadas. It involves intense kayaking, mountain biking, caving, whitewater rafting, and trekking. Averaging only 2 hours of sleep a night, Erik and his team became one of only about half of the teams to cross the finish line.

Erik accomplished these amazing feats while facing another major challenge: blindness. He is the only blind person in history to reach the summit of the world's highest peak, Mount Everest, and one of the youngest to climb the Seven Summits. Erik never allows his blindness to interfere with his pursuit of adventure and life fulfillment. For instance, his blindness is accompanied by increased eye pressure, which is exacerbated in high elevations. Erik described this pressure when he reached 19,000 feet during one of his climbs by saying, "It felt like someone stabbed me in the eye with a fork" (Weihenmayer, 1999). Yet, he continued to the top of the peak (adapted from Everest News, 1999; Touchthetop, 2009).

Reporters who question Erik about why he risks his life to climb and pursue dangerous adventures are really asking about his motivation.

Motivation **refers to the various physiological and psychological factors that cause us to act in a specific way at a particular time.**

When you are motivated, you usually show three characteristics:

1. You are ***energized*** to do or engage in some activity.
2. You ***direct*** your energies toward reaching a specific goal.
3. You have differing ***intensities*** of feelings about reaching that goal.

We can observe these three characteristics in Erik's behavior:

1. He was energized to engage in intense sport activities for ten days with little sleep or rest.
2. He directed his energy toward climbing peaks few people had ever conquered—in some cases making him the only blind person to do so.
3. He felt so intensely about reaching his goal that even when exhausted and feeling stabbing pain in his eye, he persisted in reaching the summit.

We'll discuss various motivating forces, including those involved in eating and drinking, sexual behavior, achievement, and, of course, climbing mountains.

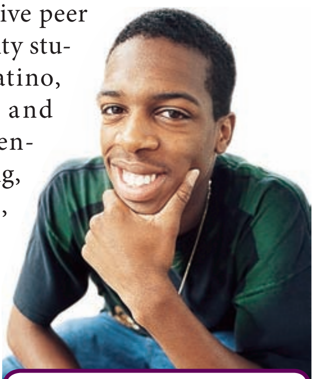
Achievement

Why did friends call him a "White boy"?

Victor remembers being in the seventh grade when some of his Black buddies called him a "White boy" because they thought he was studying too hard. "You can't be cool if you're smart," says Victor, who was Mission Bay High's student body president, had a 3.7 (A–) grade point average, and planned to attend the University of Southern California in the fall (adapted from the *San Diego Union-Tribune,* June 17, 1994).

Victor (photo below) grew up with an obstacle that goes largely unnoticed and is rarely discussed in public: pressure from students in the same racial or ethnic group not to succeed in the classroom. Faced with this negative peer pressure, some minority students (principally Latino, African American, and Native American teenage boys) stop studying, don't do homework, avoid answering questions in class, join gangs, and even drop out of school.



Victor was proud of his A– average, but some of his peers believed that being smart wasn't cool.

Similar to Victor's own experience, students who are doing well in school are often accused of "acting White" by peers in their same racial or ethnic group. Educators believe that such a cultural bias against appearing too smart prevents students from achieving their full potential (R. Fryer, 2005, 2006). How Victor overcame this negative peer pressure and did succeed will be discussed later in this module.

What's Coming

We'll look at four general theories that psychologists use to explain motivation, discuss the differences between social and biological needs, and then focus on specific examples, such as hunger, sexual behavior, and achievement. We'll examine why some people are achievers and others are underachievers. We'll discuss why people become overweight and why dieting is so difficult. We'll look at two serious eating disorders that result more from psychological than from biological factors.

We'll begin with four general theories that psychologists use to explain motivation.

A. Theories of Motivation

PowerStudy 4.5™

Module 10
F. Biological Factors

Why does Erik climb?

Many people who watch or hear about Erik engaging in his many dangerous climbs or other adventures ask, Why is he doing that? The same can be asked of you: Why are you willing to work hard for four to six years to get a college degree? These are questions about motivation. We'll discuss four general theories of motivation—the instinct, incentive, and cognitive theories, and the newest, the brain's reward/pleasure center theory.

Instinct

Is he driven by instincts?

In the early 1900s, William McDougall (1908) claimed that humans were motivated by a variety of instincts.

Instincts are innate tendencies or biological forces that determine behavior.

McDougall listed about half a dozen instincts, such as combat, curiosity, sympathy, and self-assertion. He might have explained Erik's motivation to climb as arising from instincts involving curiosity and self-assertion. But attributing mountain climbing to an instinct is more like labeling than explaining the underlying motivation. At one point, psychologists had proposed over 6,000 instincts to explain every kind of human motivation. Although instincts proved useless in explaining human motivation, they proved useful in explaining animal behaviors because animal researchers redefined instincts as fixed action patterns (FitzGerald, 1993).

A ***fixed action pattern*** is an innate biological force that predisposes an organism to behave in a fixed way in the presence of a specific environmental condition.

Animals have innate biological tendencies called instincts.

For example, the above photo shows how a baboon is innately predisposed to behave in a fixed aggressive pattern—opens mouth, stares, rises on hind feet—in the face of a specific stimulus, a threatening cheetah. Ethologists, researchers who study animal behaviors, reported that fixed action patterns help animals adapt to their natural environments. For example, in Module 10 (p. 228) we explained how birds that can walk immediately after birth become attached to, or imprinted on, the first moving object (animal, human, or basketball) that the baby bird encounters. Once imprinted, the baby bird continues to interact with that bird or object as if it were its parent. Imprinting is an example of a fixed action pattern that is extremely useful in helping young animals survive (Lorenz, 1952).

Instincts represented an early but failed attempt to explain human motivation. We'll jump from the early 1900s to the early 2000s and examine current research that sheds a new light on human motivation.

Brain: Reward/Pleasure Center

What's his reward for climbing?

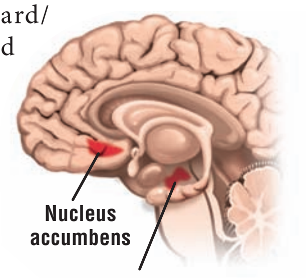
During his climbs up to each of the Seven Summits, Erik was motivated to satisfy various biological needs, such as eating and drinking. The human body is set up genetically to send biological signals to the brain, which is genetically wired to interpret the body's biological signals and thus motivate the person to eat or drink by causing feelings of hunger or thirst (Kalat, 2009). Later we'll describe the body's biological signals and how the brain interprets these signals to produce feelings of hunger or fullness.

One reason you are motivated to eat is that chewing on a favorite food can be so pleasurable. Only recently have researchers discovered that this "eating" pleasure comes from the brain's reward/pleasure center (Dackis & O'Brien, 2001; Dallman et al., 2005).

Food triggers reward center.

The ***reward/pleasure center*** includes several areas of the brain, such as the nucleus accumbens and the ventral tegmental area, and involves several neurotransmitters, especially dopamine. These components make up a neural circuitry that produces rewarding and pleasurable feelings.

Researchers discovered the brain's reward/pleasure center (figure below) by using newly developed brain scans (fMRI—p. 70) that can identify neural activity in the living brain. For example, researchers found that cocaine produced its pleasurable feelings by activating two brain areas, nucleus accumbens and ventral tegmental area, that are involved in the brain's reward/pleasure center (Dackis & O'Brien, 2001). Using this same technique, researchers found that a number of other activities also triggered the brain's reward/pleasure center. Thus, animals are motivated to continually press a lever to obtain brain stimulation, and people are motivated to eat, engage in sex, gamble, use recreational drugs, and listen to "spine-chilling" music because, as brain scans (fMRIs) have shown, all these behaviors activate the brain's reward/pleasure center (Aharon et al., 2001; Bartels, 2002; Begley, 2001; Blood & Zatorre, 2001; Breiter et al., 2001; de Araujo et al., 2008; Grimm, 2007; Shizgal & Arvanitogiannis, 2003). Recently, genes have been linked to several behaviors that trigger the brain's reward/pleasure center, including obesity, risk taking (gambling), smoking, and sexual activity (Harmon, 2006). This means having specific variations of genes makes people more likely to engage in these pleasurable activities.



Reward/pleasure center

Why does Erik climb? Erik may climb because this behavior activates the brain's reward/pleasure center. He may also be motivated to climb by a variety of psychological factors, such as gaining various incentives or fulfilling his expectations, which we'll examine next.

Incentives

Why do you study?

The issue of motivation becomes very personal when we ask you to explain why you sacrificed so much and worked so hard to get into college. Now that you're in college, what is motivating you to study for all those exams and write all those papers? One answer is that you are motivated to get a college degree because it is a very big incentive (Fiske, 2008; Petri & Govern, 2004).

The degree was worth the hard work!

Incentives **are goals that can be either objects or thoughts that we learn to value and that we are motivated to obtain.**

Incentives have two common features. First, they can be either thoughts ("I want to get a degree") or objects (money, clothes) that we LEARN to value. For example, when you were 5 years old, you had not yet learned the value of a good education. Second, the value of incentives can change over time. A pizza is not an incentive at 7 A.M., but it may be an important incentive at 7 P.M. Many of our behaviors are motivated by a variety of incentives, including grades, praise, money, clothes, or academic degrees. You can think of incentives as *pulling* us or motivating us to obtain them.

Would you like a dessert? Incentives explain why there's always room for dessert when we say we are full or why we continue to buy more clothes even when our closets are full. Even though our immediate needs seem to be met ("I'm full" or "I have enough clothes"), highly valued incentives, such as desired foods or great clothes, have the power to motivate or pull us toward obtaining them. Incentives also explain why people often buy things on impulse.

Why does Erik climb? Another reason Erik is motivated to climb probably involves obtaining incentives, such as recognition by national media, speaking invitations, and money from corporate sponsors and sales of his books. However, other equally powerful reasons for Erik's climbing probably involve cognitive factors (Eccles, 2005).

Cognitive Factors

Why do people run marathons?

Thousands of people train for months to run grueling 26-mile-long marathons, in which only the top two or three receive any prize money and the rest receive only T-shirts. What motivates people to endure such agony? The answer can be traced to the early 1960s, when psychologists began applying cognitive concepts to explain human motivation (Bandura, 1986; Deci & Ryan, 1985; Fiske, 2008; B. Weiner, 1991). These cognitive researchers said that one reason people run marathons, usually for no reward other than a T-shirt, has to do with the difference between extrinsic and intrinsic motivation.

Extrinsic motivation **involves engaging in certain activities or behaviors that either reduce biological needs or help us obtain incentives or external rewards.**

Intrinsic motivation **involves engaging in certain activities or behaviors because the behaviors themselves are personally rewarding or because engaging in these activities fulfills our beliefs or expectations.**

Intrinsic motivation explains that people volunteer their services, spend hours on hobbies, run marathons, or work on personal projects because these activities are personally rewarding, fulfilling, or challenging. Intrinsic motivation emphasizes that we are motivated to engage in many behaviors because of our own personal beliefs, expectations, or goals, rather than external incentives (Linnenbrink-Garcia & Fredricks, 2008; Ryan & Deci, 2000).

Why does Erik climb? According to cognitive theory's concept of intrinsic motivation, another reason Erik is motivated to engage in dangerous and almost impossible climbs is that climbing itself is very rewarding to Erik. Erik began climbing to help him meet his own personal goals and expectations, which are powerful motivators. "Often," Erik said, "we are forced to throw out the expectations of others and rise to the level of our own internal potential" (Weihenmayer, 2009).

I need to prove to myself that I can do it!

Explaining Human Motivation

Why did they do that?

Why did you pay $65 for a concert ticket? Why did you run a marathon? Why did you study so much for that test? How could you eat a whole pizza? Why did you drink so much last night? The answers to these questions about human behaviors involve three different factors. You may be motivated because certain behaviors trigger the brain's reward/pleasure center. You may be motivated to obtain incentives, which you have learned to value. You may be motivated by cognitive or intrinsic factors, such as wanting to satisfy your personal beliefs, reach certain goals, or fulfill your expectations. Human motivation is so difficult to explain because it may involve all three of these factors. In addition, you can be motivated by emotional factors (anger, fear, happiness) or personality factors (outgoing, shy, uninhibited), which we'll discuss in Modules 16, 19, and 20.

One of the main functions of emotions is to satisfy a number of biological and social needs, which we'll examine next.

B. Biological & Social Needs

How many needs do you have?

The most popular daytime television programs are the soap operas, which dramatize a whole range of human needs—the good, the bad, the ugly, and the dumb. As the soap opera characters try to satisfy their needs, they get into endless difficulties. We'll discuss some of the more common biological and social needs.

Biological Needs

What are they doing?

It's pretty obvious that the man and his pet pig are about to satisfy their hunger, a basic biological need.

***Biological needs* are physiological requirements that are critical to our survival and physical well-being.**

Satisfying biological needs

Researchers have identified about a dozen biological needs, such as the needs for food, water, sex, oxygen, sleep, and pain avoidance, all of which help to keep our bodies functioning at their best and thus help us survive (Petri & Govern, 2004).

When genes are defective. Perhaps because biological drives are critical for survival, their automatic regulation is built into a newborn's brain. In rare cases, individuals are born with defective genes that cause biological needs to run amok. For example, some children are born with defective "eating" genes that result in never feeling full but being constantly hungry and obsessed with food and eating (Webb et al., 2006). Children with this genetic problem (the Prader-Willi syndrome affects the hypothalamus) can never be left alone with food because they will eat everything in sight.

Another kind of rare genetic problem affecting only 40 families worldwide destroys the ability to sleep. As individuals with this genetic defect (fatal familial insomnia) reach their fifties, they find that one day they cannot sleep through the night and from then on they never sleep again. Over a period of several months, these individuals lose the ability to walk, speak, and think. Finally, within 15 months, their sleepless body shuts down its functions, resulting in coma and death (Grimes, 2006; Max, 2006). These two examples show that the proper regulation of biological needs is critical for healthy physiological functioning and survival.

When psychological factors interfere. Besides genetic defects, psychological factors can interfere with the regulation of biological needs. For example, some individuals develop the rare eating disorder anorexia nervosa, which involves self-starvation. Without professional help, these individuals may starve themselves to death. Eating disorders show how psychological factors can override basic biological needs. We'll discuss eating disorders in the Application section.

Although there are a relatively limited number of biological needs, there are many more social needs.

Social Needs

Why did they get married?

One reason that about 90% of adults in the United States get married is that being married satisfies a number of social needs.

***Social needs* are needs that are acquired through learning and experience.**

Depending on your learning and experiences, you may acquire dozens of social needs, such as the needs for achievement, affiliation (forming social bonds), fun (play), relaxation, helpfulness, independence, and nurturance (Petri & Govern, 2004).

Getting married satisfies social needs.

One reason marriage is so popular is that it satisfies a number of social needs, including affiliation, nurturance, and achievement. The need for affiliation, or forming lasting, positive attachments, is one of our stronger social needs and is important to maintaining physical health and psychological well-being (Simpson & Tran, 2006).

In some cases, the distinction between biological and social needs is blurred. For example, we may eat or drink not only to satisfy biological needs but also to make social contact or deal with stress. Similarly, we may engage in sex for reproduction, which is a biological need, or to express love and affection, which is a social need. Because we have only so much time and energy to satisfy a relatively large number of biological and social needs, how do we decide which needs to satisfy first? The answer may be found in Maslow's hierarchy.

Satisfying Needs

Which need gets satisfied?

You may remember from Module 1 that one of the founders of the humanistic approach in psychology was Abraham Maslow. Maslow was particularly interested in human motivation, especially in how we choose which biological or social need to satisfy. For example, should you study late for an exam and satisfy your social need to achieve, or go to bed at your regular time and satisfy your biological need for sleep? Maslow (1970) proposed that we satisfy our needs in a certain order or according to a set hierarchy (figure on opposite page).

***Maslow's hierarchy of needs* is an ascending order, or hierarchy, in which biological needs are placed at the bottom and social needs at the top. According to Maslow's hierarchy, we satisfy our biological needs (bottom of hierarchy) before we satisfy our social needs (top of hierarchy).**

Do you satisfy biological needs first?

Maslow hypothesized that, after we satisfy needs at the bottom level of the hierarchy, we advance up the hierarchy to satisfy the needs at the next level. However, if we are at a higher level and our basic needs are not satisfied, we may come back down the hierarchy.

We'll examine Maslow's hierarchy of needs in more detail.

Photo Credits: left, © Time & Life Pictures/Getty Images; center and right, © PhotoDisc, Inc.

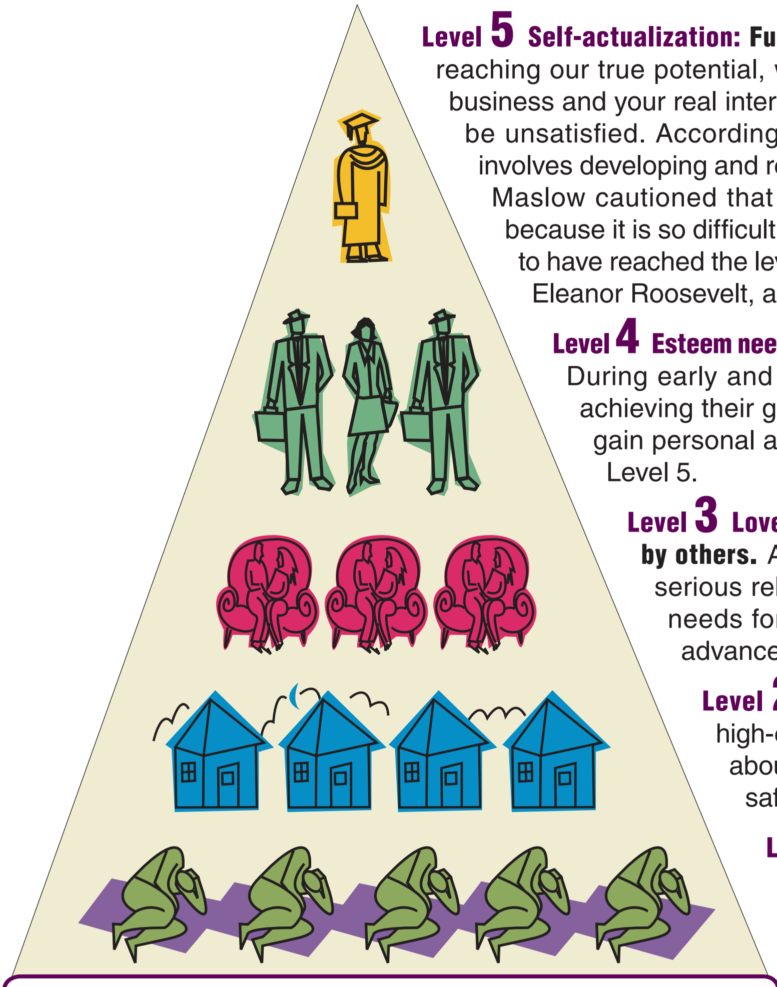
Maslow's Hierarchy of Needs

Which needs do you satisfy first?

If you were very hungry and very lonely at the same time, which need would you satisfy first, your biological need (hunger) or your social need (affiliation)? One answer to this question can be found in Maslow's hierarchy of needs, which says that you satisfy your biological needs before you can turn your attention and energy to fulfilling your personal and social needs. According to Maslow, when it comes to satisfying your needs, you begin at the bottom of the needs hierarchy, with physiological needs, and then work your way toward the top.

After you meet the needs at one level, you advance to the next level. For example, if your physiological needs at Level 1 are satisfied, you advance to Level 2 and work on satisfying your safety needs. Once your safety needs are satisfied, you advance to Level 3, and so forth, up the needs hierarchy.

Maslow's hierarchy of needs is represented by a pyramid and shows the order in which you satisfy your biological and social needs. The first needs you satisfy are physiological or biological ones, so please go to the bottom of the pyramid and begin reading Level 1. Then continue reading Levels 2, 3, 4, and 5, which takes you up the pyramid.



Level 5 Self-actualization: Fulfillment of one's unique potential. If we face roadblocks in reaching our true potential, we will feel frustrated. For example, if you are majoring in business and your real interest and talent is music, your need for self-actualization may be unsatisfied. According to Maslow, the highest need is self-actualization, which involves developing and reaching our full potential as unique human beings. However, Maslow cautioned that very few individuals reach the level of self-actualization because it is so difficult and challenging. Examples of individuals who might be said to have reached the level of self-actualization are Abraham Lincoln, Albert Einstein, Eleanor Roosevelt, and Martin Luther King, Jr.

Level 4 Esteem needs: Achievement, competency, gaining approval and recognition. During early and middle adulthood, people are especially concerned with achieving their goals and establishing their careers. As we develop skills to gain personal achievement and social recognition, we turn our energies to Level 5.

Level 3 Love and belonging needs: Affiliation with others and acceptance by others. Adolescents and young adults, who are beginning to form serious relationships, would be especially interested in fulfilling their needs for love and belonging. After we find love and affection, we advance to Level 4.

Level 2 Safety needs: Protection from harm. People who live in high-crime or dangerous areas of the city would be very concerned about satisfying their safety needs. After we find a way to live in a safe and secure environment, we advance to Level 3.

Level 1 Physiological needs: Food, water, sex, and sleep. People who are homeless or jobless would be especially concerned with satisfying their physiological needs above all other needs. We must satisfy these basic needs before we advance to Level 2.

Maslow's hierarchy of needs suggests the order in which we satisfy our needs.

Conclusion. One advantage of Maslow's hierarchy is that it integrates biological and social needs into a single framework and proposes a list of priorities for the order in which we satisfy various biological and social needs (Fiske, 2008; Frick, 2000).

One problem with Maslow's hierarchy is that researchers have found it difficult to verify whether his particular order of needs is accurate or to know how to assess some of his needs, especially self-actualization, which very few individuals are able to reach (Geller, 1982). Another problem is that people give different priorities to needs: Some may value love over self-esteem, or vice versa (Neher, 1991). We'll discuss Maslow's hierarchy of needs later on when we explain humanistic theories of personality (see p. 443). Despite criticisms of Maslow's hierarchy, it remains a useful reminder of the number and complexity of human needs.

To give you a sample of how psychologists study human motivation, we have selected two biological needs—food and sex—from Maslow's Level 1 and one social need—achievement—from Maslow's Level 4. We consider these needs in the following sections.

C. Hunger

Optimal Weight

Why don't you see fat wolves?

The reason you never see fat wolves is that they, like all animals, have an inherited biological system that carefully regulates their eating so that they maintain their optimal, or ideal, weights (Kolata, 2000b).

Optimal **or** ***ideal weight*** **results from an almost perfect balance between how much food an organism eats and how much it needs to meet its body's energy needs.**

In the wild, animals usually eat only to replace fuel used by their bodies, and thus they rarely get fat. In addition, most wild animals use up a tremendous amount of energy in finding food.

Animals rely on a biological system to regulate weight.

In comparison, home pets may become fat because their owners, having the best of intentions, give the pets too much food or food so tasty that their pets eat too much. And unlike wild animals, home-bound pets may have few opportunities to run around and burn off the extra food or surplus calories.

A *calorie* is simply a measure of how much energy food contains. For example, foods high in fats (pizza, cheeseburgers, french fries, donuts) usually have several times more calories than foods high in protein (fish, chicken, eggs) or high in carbohydrates (vegetables, fruits, grains). The same factors that make pets overweight also make humans overweight.

Overweight

Why the huge increase?

Like animals, we humans have an inherited biological system that regulates hunger to keep us at our ideal weights. However, there is currently a worldwide problem of overweight and obesity.

Overweight **means that a person is 20% over the ideal body weight.**

Obesity **means that a person is 30% or more above the ideal body weight.**

1976	26%
2000	55%
2007	67%

Percentage of adult Americans who are overweight or obese

The numbers on the right show that, over the years, the percentage of adult Americans who are overweight or obese has increased dramatically (J. O. Hill et al., 2003; Kluger, 2007a). Also, the percentage of American youths who are overweight (34%) or obese (20%) has increased at an alarming rate. Research shows that 50–80% of these youths will battle weight problems through adulthood (CDC, 2006a; Kotz, 2007a).

Overweight and obesity are primarily caused by two factors: eating more than is required to fuel the body's energy needs and not getting enough exercise to burn off surplus calories (CDC, 2006c). For example, some college freshmen gain 6 to 9 pounds, primarily because of all-you-can-eat dining halls and late-night junk food (Hellmich, 2008; Levitsky, 2003). Also, probably because marriage is associated with eating more and being less active, married people gain an average of 6 to 9 pounds more than their single peers (Gordon-Larsen, 2007).

From an evolutionary perspective, consuming nutritionally dense food became necessary to provide energy needed for the demanding lifestyle of hunting and gathering. However, over time, our lifestyles have become increasingly sedentary, creating energy imbalances that explain our rising obesity rates (Leonard, 2009).

Being overweight or obese significantly shortens people's life span and increases their risk for heart disease, stroke, high blood pressure, clogged arteries, and adult-onset diabetes (B. Healy, 2006; Hsu, 2006; Whitlock et al., 2009). In the United States, annual medical spending on overweight and obese patients is $92.6 billion (Finkelstein et al., 2003).

However, solving the problem of being overweight or obese is complicated because eating is influenced by three hunger factors.

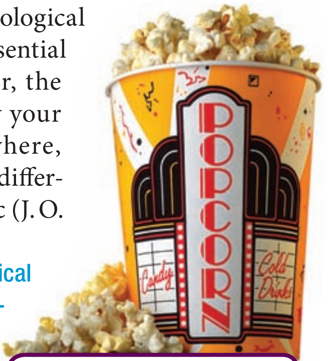
Three Hunger Factors

What controls your eating?

Hunger is considered a biological drive because eating is essential to our survival. However, the way in which you satisfy your hunger drive—when, where, and how much you eat—is influenced by three different factors: biological, psychosocial, and genetic (J. O. Hill et al., 2003).

Biological hunger factors **come from physiological changes in blood chemistry and signals from digestive organs that provide feedback to the brain, which, in turn, triggers us to eat or stop eating.**

If your eating was regulated primarily by biological factors, as in most animals, you would keep your weight at optimal levels. The facts that 67% of adults are overweight or obese and that some individuals suffer from serious eating problems indicate the influence of both psychosocial and genetic factors.



Psychosocial hunger factors can override other factors.

Psychosocial hunger factors **come from learned associations between food and other stimuli, such as snacking while watching television; sociocultural influences, such as pressures to be thin; and various personality problems, such as depression, dislike of body image, or low self-esteem.**

Genetic hunger factors **come from inherited instructions found in our genes. These instructions determine the number of fat cells or metabolic rates of burning off the body's fuel, which push us toward being normal, overweight, or underweight.**

These three hunger factors interact to influence your weight. For example, because of psychosocial factors, some of us eat when we should not, such as during stress. Because of biological factors, some of us may respond too much or too little to feedback from our digestive organs. Because of genetic factors, some of us can eat more calories and still maintain optimal weight.

We'll discuss these three hunger factors, beginning with biological factors.

Biological Hunger Factors

Why do you start eating?

The Japanese sumo wrestler on the right is Konishiki, nicknamed Meat Bomb (now retired). He is 6 feet 1 inch tall and weighs 580 pounds, which is considered normal by sumo standards but obese by Western medical charts. He maintains his huge body by consuming about 10,000 calories daily, which is 3–5 times the amount required by an average-sized man. Konishiki's eating is partly regulated by biological hunger factors, which come from peripheral and central cues (Woods et al., 2000).

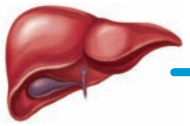
Peripheral cues come from changes in blood chemistry or signals from digestive organs, which secrete various hormones. ***Central cues*** result from activity in different brain areas, which in turn results in increasing or decreasing appetite.

Peripheral and central cues make up a complex biological system that evolved over millions of years to help humans and animals maintain their best weights for survival.

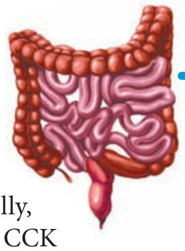
Peripheral Cues

Signals for feeling hungry or full come from a number of body organs that are involved in digestion and regulation of blood sugar (glucose) levels, which is the primary source of fuel for the body and brain.

1 When empty, the ***stomach*** secretes a hormone, ghrelin, which carries "hunger signals" to the brain's hypothalamus, the master control for hunger regulation (Raloff, 2005). When the stomach is full, stretch receptors in its walls send "full signals" to the brain's hypothalamus, which decreases appetite (Chaudri et al., 2006; Kluger, 2007).



2 The ***liver*** monitors the level of glucose (sugar) in the blood. When the level of glucose (blood sugar) falls, the liver sends "hunger signals" to the brain's hypothalamus; when the level of glucose rises, the liver sends "full signals" to the hypothalamus (Woods et al., 2000).

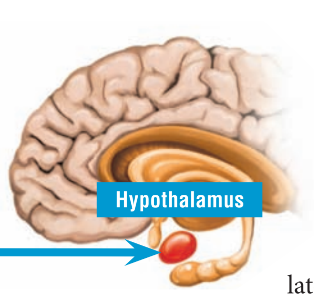


3 The ***intestines*** also secrete ghrelin, which carries "hunger signals" to the hypothalamus, increasing appetite. The intestines also secrete another hormone called PYY, which carries "full signals" to the hypothalamus, decreasing appetite (Raloff, 2005). Finally, the intestines secrete a hormone called CCK (cholecystokinin), which signals the hypothalamus to inhibit eating (Kluger, 2007).

4 ***Fat cells*** secrete a hormone, called leptin, which acts on the brain's hypothalamus. If levels of leptin are falling, the hypothalamus increases appetite; if levels are rising, the hypothalamus decreases appetite. The secretion of leptin helps maintain a constant level of body fat and defend against starving the body to death (Rui, 2005).

Summary. The stomach and intestines secrete a number of "hunger" or "full" hormone signals that act on the hypothalamus, which is the master control for regulating eating and produces central cues for increasing or decreasing appetite.

Central Cues



1 The brain has an area with different groups of cells that are collectively called the ***hypothalamus.*** Each group of cells is involved in a different kind of motivation, including regulation of thirst, sexual behavior, sleep, intensity of emotional reactions, and hunger. We'll focus on two groups of cells, the lateral and ventromedial hypothalamus, that affect hunger in opposite ways, either increasing or decreasing appetite.

2 The ***lateral hypothalamus*** refers to a group of brain cells that receives "hunger signals" from digestive organs—increase in ghrelin, fall in level of blood glucose, and fall in levels of leptin. The lateral hypothalamus interprets these "hunger signals" and increases your appetite (Kluger, 2007; Woods et al., 2000).

For example, electrical stimulation of the lateral hypothalamus causes rats to start eating, while destruction of the lateral hypothalamus causes rats to stop eating and even starve without special feeding.

3 The ***ventromedial hypothalamus*** refers to a group of brain cells that receives "full signals" from digestive organs—a full stomach activates stretch receptors, rise in level of blood glucose, rise in levels of leptin, and increase in the hormones PYY and CCK. The ventromedial hypothalamus interprets these "full signals" and decreases appetite.

For example, stimulation of the ventromedial hypothalamus causes rats to stop eating, while destruction of the ventromedial hypothalamus causes rats to overeat. Research with rats genetically prone to obesity shows that certain brain cells in their hypothalamus don't grow much and are less sensitive to leptin, compared with other rats (Bouret et al., 2008). In addition, various chemicals affect other cells of the hypothalamus and regulate our appetites for specific foods (Kluger, 2007).

Summary. The hypothalamus is involved in regulating different kinds of motivated behaviors; in this case, we focused on hunger. The hypothalamus has one group of cells, called the lateral hypothalamus, that responds to "hunger signals" by increasing your appetite so you start eating. The hypothalamus has another group of cells, called the ventromedial hypothalamus, that responds to "full signals" by decreasing your appetite so you stop eating. This wonderfully complex biological system for regulating hunger is hard-wired and present in a newborn's brain. Although this system is designed to keep us at our ideal weights, we'll discuss genetic and psychological factors that can interfere with this system and cause overeating and even starvation.

C. Hunger

Genetic Hunger Factors

Are identical twins always the same weight?

Researchers generally find that identical twins (photo on right), even when separated soon after birth and reared in adopted families, are much more alike in weight than fraternal twins reared apart (T. J. Bouchard et al., 1990). This similarity in weight is due to genetic hunger factors.

Identical twins share the same genes and thus are similar in weight.

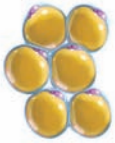
Genetic hunger factors **come from inherited instructions found in our genes. These instructions determine the number of fat cells or metabolic rates of burning off the body's fuel, which push us toward being normal, overweight, or underweight.**

On the basis of twin studies, researchers concluded that inherited factors contribute 70–80% to the maintenance of a particular body size and weight, while environmental factors contribute the other 20–30% (Bulik et al., 2003). The finding that genetic hunger factors contribute 70–80% to having a certain body size and weight explains why identical twins have similar body types. The finding that environmental factors contribute 20–30% to body size explains why one twin may weigh a little more or less than the other.

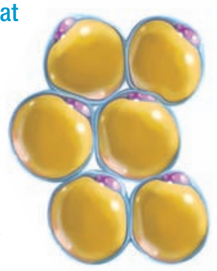
Research shows that people who have a commonly found variation of a gene are at an increased risk of becoming obese. Scientists now believe there may be as many as 100 different fat genes and are working to identify them (C. Bouchard, 2009; Christman, 2006).

So far, psychologists have identified four genetic hunger factors.

1 We inherit different numbers of fat cells.



Fat cells, **whose number is primarily determined by heredity, do not normally multiply except when people become obese. Fat cells shrink if we are giving up fat and losing weight (left) and greatly enlarge if we are storing fat and gaining weight (right) (Fried, 2008; Spalding et al., 2008).**

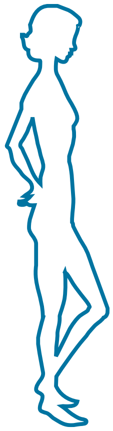


People who inherit a larger number of fat cells have the ability to store more fat and are more likely to be fatter than average.

2 We inherit different rates of metabolism.

Metabolic rate **refers to how efficiently our bodies break food down into energy and how quickly our bodies burn off that fuel.**

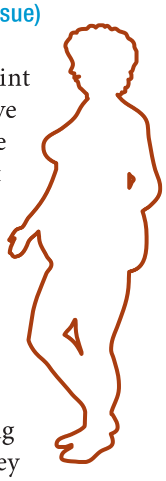
For example, if you had a low metabolic rate, you would burn less fuel, be more likely to store excess fuel as fat, and thus may have a fatter body. In comparison, if you had a high metabolic rate, you would burn off more fuel, be less likely to store fat, and thus may have a thinner body (left figure). This means that people can consume the same number of calories but, because of different metabolic rates, may maintain, lose, or gain weight. There are only two known activities that can raise metabolic rate: exercise and smoking cigarettes. Research shows that exercise raises metabolic rate 20–30% and nicotine raises it 4–10%. That's the reason exercise helps dieters lose weight and smokers generally gain weight when they stop smoking (Aamodt & Wang, 2008; Audrain et al., 1995).



3 We inherit a set point to maintain a certain amount of body fat.

The *set point* refers to a certain level of body fat (adipose tissue) that our bodies strive to maintain constant throughout our lives.

For example, a person whose body has a higher set point will try to maintain a higher level of fat stores and thus have a fatter body (right figure). In comparison, a person whose body has a lower set point will maintain a lower level of fat stores and thus have a thinner body (Woods et al., 2000). If a person diets to reduce the level of fat stores, the body compensates to maintain and build back fat stores by automatically lowering the metabolic rate and thus consuming less fuel. That's the reason dieters may lose weight for the first two or three weeks and then stop losing; the body has lowered its metabolic rate. Researchers concluded that because the body protects its fat stores, long-term dieting will be unsuccessful in treating overweight people unless they also exercise (Leibel et al., 1995).



4 We also inherit weight-regulating genes.

Weight-regulating genes **play a role in influencing appetite, body metabolism, and secretion of hormones (leptin) that regulate fat stores.**

For example, the mouse on the left has a gene that increases a brain chemical (neuropeptide Y) that increased eating, so it weighs three times as much as the normal-weight mouse on the right (Gura, 1997). Researchers also found a gene that can jack up metabolism so that calories are burned off as heat rather than stored as fat (Warden, 1997). In total, researchers have found 11 genetic mutations than can disrupt appetite regulation, leading someone to continue to eat without feeling full (Kluger, 2007).

You have seen how genetic hunger factors are involved in the regulation of body fat and weight. But genes alone cannot explain our obesity epidemic (Gillman, 2007).

Next, we'll explore several psychological factors involved in the regulation of eating and weight.

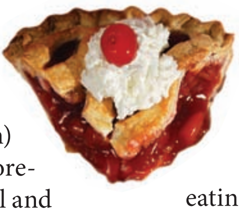
Psychosocial Hunger Factors

Always room for dessert?

Many of us have a weakness for certain foods, and mine (R. P.) is for desserts. Even though my biological and genetic hunger factors may tell me (my brain) when to start and stop eating, I can use my large forebrain to override my innately programmed biological and genetic factors. My forebrain allows me to rationalize that one dessert can do no harm. This kind of rationalizing comes under the heading of psychosocial hunger factors.



Psychosocial hunger factors come from learned associations between food and other stimuli, such as snacking while watching television; sociocultural influences, such as pressures to be thin; and various personality traits, such as depression, dislike of body image, or low self-esteem.

Psychosocial hunger factors can have an enormous effect on our eating habits and weight and contribute to many problems associated with eating, such as becoming overweight, eating when stressed or depressed, and bingeing (A. Ward et al., 2000). We'll discuss three psychosocial hunger factors—learned associations, social-cultural influences, and personality traits.

Learned Associations

The best examples of how *learned associations* influence eating are when we eat not because we're hungry but because it's "lunchtime," because foods smell good, because our friends are eating, or because we can't resist large portions (Hellmich, 2005).

It's tough to pass on supersizing, even though we don't need it all.

Americans often rely on external cues to stop eating, such as the end of a TV program or getting to the bottom of a soda, which, combined with a preference for large portions and tasty junk foods high in calories, has led to a rising rate of overweight and obesity in both children and adults (Hellmich, 2005; Rozin et al., 2003; Wansink et al., 2007).

Another learned association that influences eating is that we eat more when we experience stress (Macht, 2007). For instance, 76% of female and 33% of male college students report eating more when they feel stress, and unfortunately for them, college usually involves plenty of stress (Hellmich, 2008)!

Health professionals advise us to unlearn many of our learned food associations. We should eat only when hungry and eat smaller portions and healthier foods (Pi-Sunyer, 2003; Story et al., 2008).

Social-Cultural Influences

Obesity rates vary across the globe: Japan, 4%; Italy, 10%; France, 11%; Germany, 14%, United Kingdom, 24%, and United States, 34% (OECD, 2009). Here are examples of how *social-cultural influences* affect body weight.

Czech Republic. In the 1970s, the Czech Republic government subsidized cheap fatty sausage and dairy products. The result was that 45% of Czech women and a smaller percentage of men are obese. Also, the Czech Republic has the world's highest death rates from heart disease. The government instituted programs to encourage healthier eating habits, which were effective until fast-food restaurants opened all over the country (Elliott, 1995; Jarrett, 2006).

In Chinese, "xiao pangzi" means "little fatties."

China. In parts of China, fatty fast foods have become very popular along with a more sedentary lifestyle. This has resulted in an increase in obesity rates over the last 15 years: from 12.8% in 1991 to 29% in 2006 (CDC, 2008e). In addition, there has been an alarming increase in obesity among children, who are pampered by a culture that prizes well-nourished children as indicating affluence and well-being (Mydans, 2003).

United States. In the United States, there are many cultural pressures on females, in particular, to be thin. For example, the mass media advertise that the ideal female is one with a slender body (think size 0 models). As a result, many American females report being dissatisfied with their weight and see themselves as overweight even when they are not. Some also develop an eating disorder as a result (Mayo Clinic, 2006a). Currently, there are some media efforts to counter traditional beauty stereotypes and promote the acceptance of a wider definition of beauty (Dove, 2009).

Personality & Mood Factors

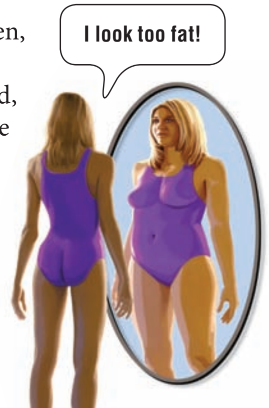
If a person has certain *personality traits,* he or she may be at greater risk for overeating as well as developing serious eating disorders, such as overeating when stressed or depressed, going on food binges (bulimia nervosa), or starving oneself (anorexia nervosa).

The particular personality traits that have been associated with eating problems include heightened sensitivity to rejection, excessive concern with approval from others, high personal standards for achievement, a history of physical or sexual abuse, and the need to have control (over oneself or one's body) (Polivy & Herman, 2002). Someone with these kinds of personality traits, which are often accompanied by stress, anxiety, and emotional upset, may find it very difficult and sometimes almost impossible to control his or her eating (J. E. Brody, 2003).

Mood factors, such as stress, anxiety, and depression, can lead to bursts of overeating or indulgence in sweet and unhealthy foods. Overeating when under emotional strain is called "emotional eating" and occurs in otherwise healthy people (Macht, 2007).

Although hunger is considered a biological need, you have seen how psychosocial hunger factors can influence where, when, and how the hunger drive is satisfied. And, as we'll discuss in the Application section, there are extreme cases in which psychosocial factors can override the hunger drive.

Next, we'll discuss another very important biological need, sexual behavior.



I look too fat!

Personality traits influence eating habits.

D. Sexual Behavior

PowerStudy 4.5™
Module 4
A. Genes & Evolution

Why do lions know how to do it?

Although we don't look, sound, or behave the same as lions do, we share similar biological and genetic factors that regulate sexual behavior. The sexual behavior of lions and most animals is controlled chiefly by genetic and biological factors, which means that most animals engage in sex primarily for reproduction.

In most animals, sexual behavior is regulated by genetic and biological factors.

Genetic sex factors include inherited instructions for the development of sexual organs, the secretion of sex hormones, and the wiring of the neural circuits that control sexual reflexes.

Biological sex factors include the action of sex hormones, which are involved in secondary sexual characteristics (facial hair, breasts), sexual motivation (more so in animals than in humans), and the development of ova and sperm.

Lions, like most animals, generally avoid sexual interactions unless the female is in heat, which means she is ovulating and can be impregnated. In comparison, humans engage in sexual behavior for many reasons, which points to psychological sex factors.

Psychological sex factors play a role in developing a sexual or gender identity, gender role, and sexual orientation. In addition, psychological factors can result in difficulties in the performance or enjoyment of sexual activities.

For example, otherwise healthy men and women may report difficulties in sexual activities arising from stress, anxiety, or guilt, which can interfere with the functioning of genetic and biological sex factors. One reason psychological factors play such an important role in human sexual behavior is that our large forebrains have the capacity to think, reason, and change our minds and thus increase, interfere with, or completely block sexual motivation, performance, or enjoyment.

As we did for the hunger drive, we'll discuss, in order, the influences of genetic, biological, and psychological factors on sexual behavior.

Genetic Influences on Sexual Behavior

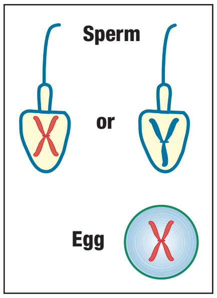
Which sex organ?

How we develop a particular sex organ, male or female, is determined primarily by a genetic program that is contained in a single human cell about the size of a grain of sand (Faller et al., 2004).

Sex Chromosome

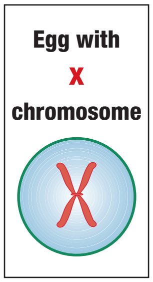
Unlike the other cells of our body, which contain 46 chromosomes (23 pairs), the sperm and egg each contain half that number and are called sex chromosomes (figure below).

The ***sex chromosome,*** which is in the sperm or the egg, contains 23 chromosomes, which in turn have genes that contain instructions for determining the sex of the child.

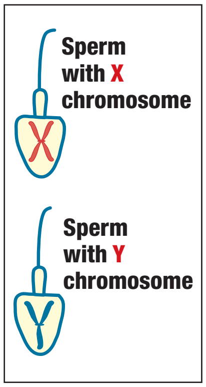


As we discussed earlier (p. 68), each chromosome is made up of a long strand of DNA (deoxyribonucleic acid). On this long strand of DNA are hundreds of genes, which contain the chemically coded instructions for the development and maintenance of our bodies. In the figure above, notice that some sperm have an **X** chromosome and some have a **Y,** which contain different genetic instructions and, as you'll see, result in the development of different sex organs (penis or vagina).

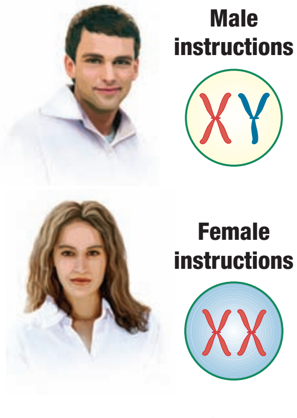
1 The human egg contains one of the sex chromosomes, which is always an **X** chromosome. Thus, each human egg has a single **X** chromosome.



2 A human sperm also contains one of the sex chromosomes. However, the sperm's chromosome can be either an **X** chromosome, which has instructions for development of ***female sex organs*** and body, or a **Y** chromosome, which has instructions for male sex organs and body. Thus, the sperm (**X** or **Y**) determines the sex of the infant.



3 During fertilization, a single sperm penetrates an egg and results in a fertilized egg with 23 pairs of chromosomes. If the last pair has the combination **XY,** it means the egg contains the genetic instructions for developing a male's sex organs (top right figure). If the last pair has the combination **XX,** it means the egg contains the genetic instructions for developing a female's sex organs (bottom right figure).



Following fertilization, the human cell, which is called a ***zygote,*** will divide over and over many thousands of times during the following weeks and months and eventually develop into a female body with female sex organs or a male body with male sex organs.

How an unborn infant actually develops male or female sex organs is an interesting story, especially since everyone begins as a female.

Genetic Influences (continued)

Differentiation

Although it would seem that at fertilization you are destined to be either a male or a female, there is actually no physical difference between a male and a female embryo for the first four weeks of development in the womb. During this time period, the embryos are identical and have the potential to develop into either a male or a female. At about the fifth week, the embryo begins to differentiate into either a male or a female because of the presence or absence of certain sex hormones (Bendsen et al., 2006).

Male Sex Organ and Male Brain

XY = High Testosterone

Presence of **high** testosterone results in a male brain.

In an embryo that began from an **XY** fertilized egg, the **Y** sex chromosome has instructions for the development of male testes. At about the fifth week, the testes begin to grow and produce tiny amounts of male hormones or ***androgens,*** one of which most people know as ***testosterone.***

The presence of high testosterone does two things: It triggers the development of the male sexual organ (penis), and it programs a particular area of the brain, called the hypothalamus, so that at puberty it triggers the pituitary gland to secrete hormones on a continuous basis, which results in the continuous production of sperm.

Female Sex Organs and Female Brain

XX = Low Testosterone

Presence of **low** testosterone results in a female brain.

In an embryo that began from an **XX** fertilized egg, the second **X** sex chromosome contains instructions for the development of ovaries.

The presence of low testosterone in the developing embryo does two things: It leads to the automatic development of female sexual organs (clitoris and vagina), and the hypothalamus, which is normally programmed for female hormonal functions, keeps its female program. Thus, at puberty, this female-programmed hypothalamus triggers the pituitary gland to secrete hormones on a cyclic basis, which results in the menstrual cycle.

Importance of Testosterone

The ***presence*** of testosterone, which is secreted by fetal testes, results in male sexual organs and a male hypothalamus; the ***absence*** of testosterone results in female sexual organs and a female hypothalamus (Kalat, 2009).

When the infant is born, the doctor identifies the infant's sex organs and says those famous words, "It's a boy" or "It's a girl." At that point a hormonal clock begins ticking and its alarm will set off biological factors at puberty.

Biological Influences

PowerStudy 4.5™
Module 4
F. Endocrine System

You have seen how genetic sex factors influence the development of the body's sex organs. The next big event to affect a person's sex organs and sexual motivation occurs at puberty as a result of biological sex factors.

Sex hormones secreted during puberty both directly and indirectly affect our bodies, brains, minds, personalities, self-concepts, and mental health. We'll focus on how sex hormones affect our bodies.

Sex hormones. Before and shortly after birth, sex hormones are released in our bodies.

Sex hormones, which are chemicals secreted by glands, circulate in the bloodstream to influence the brain, body organs, and behaviors. The major male sex hormones secreted by the testes are ***androgens,*** such as testosterone; the major female sex hormones secreted by the ovaries are ***estrogens.***

Testosterone

Sex hormones remain inactive until puberty, when a recently discovered hormone called kisspeptin stimulates the production of androgens and estrogens to prepare the body for reproduction (Roa et al., 2008).

Male hypothalamus triggers release of **testosterone.**

Male–female differences. The presence or absence of testosterone in the womb causes different neural programming so that the male hypothalamus functions differently from the female hypothalamus.

The ***male hypothalamus*** triggers a continuous release of androgens, such as testosterone, from the testes. The increased level of androgens causes the development of male secondary sexual characteristics, such as facial and pubic hair, muscle growth, and lowered voice.

The ***female hypothalamus*** triggers a cyclical release of estrogens from the ovaries. The increased level of estrogens causes the development of female secondary sexual characteristics, such as pubic hair, breast development, and widening of the hips. The cyclical release of hormones (estrogen and progesterone) also regulates the menstrual cycle.

Female hypothalamus triggers release of **estrogen.**

Sexual Motivation

In humans, normal sexual development and motivation depend upon levels of sex hormones being within the normal range. In rare cases, males are born with an extra X chromosome, XXY or Klinefelter's syndrome, which results in undersized testes and penis, decreased secretion of testosterone, infertility, no development of secondary sexual characteristics at puberty, and little or no interest in sexual activity. However, when given testosterone replacement at puberty, males regain sexual interest and drive (Lanfranco et al., 2004). Thus, the absence of sex hormones interferes with normal sexual development and motivation.

Recently, a creative group of researchers studied whether women's ovulatory cycle affects their success as lap dancers in gentlemen's clubs. Results showed that during the time of their cycle when there is an increase in sexual hormones, women earned the most money giving men lap dances (G. Miller et al., 2007). This and other studies find that men are sensitive to women's peaks in sexual hormones, which results in their increased sexual motivation and desire (Gangestad et al., 2002; Haselton & Gangestad, 2006).

As genetic and biological factors guide our bodies toward physical sexual maturity, numerous psychological factors are preparing our minds for psychological sexual maturity. Next, we'll examine these psychological sex factors.

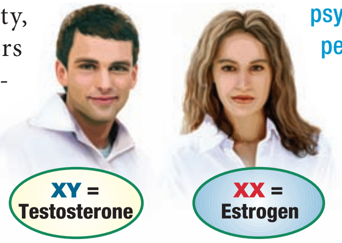
D. Sexual Behavior

Psychological Influences on Sexual Behavior

How do boys and girls become men and women?

As boys and girls go through puberty, various genetic and biological factors prepare their bodies for sexual maturity (Ojeda et al., 2006). At the same time their bodies are developing, boys and girls are observing, imitating, and learning behaviors of their mothers, fathers, older siblings, and other adults in their environments. At this point, psychological sex factors come into play.

Psychological sex factors play a role in developing a sexual or gender identity, gender role, and sexual orientation. In addition, psychological factors can result in difficulties in the performance or enjoyment of sexual activities.



Sex hormones activate many physical and psychological changes.

Genetic, biological, and psychological sex factors combine and interact to result in boys and girls developing into sexually mature men and women.

Three psychological sex factors are especially important—gender identity, gender roles, and sexual orientation. We'll discuss each in turn, beginning with gender identity.

Gender Identity

Between the ages of 2 and 3, a child can correctly answer the question "Are you a boy or a girl?" The correct answer indicates that the child has already acquired the beginnings of a gender identity (Blakemore, 2003).

Gender identity, which was formerly called sexual identity, refers to the individual's subjective experience and feelings of being either a male or a female.

The doctor's words, "It's a girl" or "It's a boy," set in motion the process for acquiring a gender identity. From that point on, parents, siblings, grandparents, and others behave toward male and female infants differently, so that they learn and acquire their proper gender identity (C. L. Martin et al., 2002). For example, the little girl in the right photo is checking out a pretty dress in the mirror, a behavior that she has observed her mother doing and that she is now imitating.

By age 3, children know if they **are** boys or girls.

Gender identity is a psychological sex factor that exerts a powerful influence on future sexual thoughts and behavior, as clearly illustrated in the case of someone with a gender identity disorder, who is commonly referred to as a transsexual.

Gender identity disorder is commonly referred to as transsexualism. A transsexual is a person who has a strong and persistent desire to be the other sex, is uncomfortable about being one's assigned sex, and may wish to live as a member of the other sex (American Psychiatric Association, 2000).

Transsexuals usually have normal genetic and biological (hormonal) factors, but for some reason, they feel and insist that they are trapped in the body of the wrong sex and may adopt the behaviors, dress, and mannerisms of the other sex. There is no clear understanding of why transsexuals reject their biological sex; no physical cause or connection has been identified (McHugh, 2009). Current data indicate the incidence of transsexualism is about the same for males and females (Bartlett et al., 2000). Infrequently, adults with gender identity disorder may seek surgery to change the sex organs they were born with to the other sex. Because transsexuals acquire gender identities that do not match their external sex organs, they experience problems in thinking and acting and may not easily fit into or be accepted by society (Friess, 2009). However, the vast majority of people do acquire gender identities that match their external sex organs.

As you acquire a male or female gender identity, you are also acquiring a matching gender role.

Gender Roles

After the first step in becoming psychologically sexually mature, which is acquiring a male or female gender identity—"I'm a boy" or "I'm a girl"—comes the second step, which is acquiring a gender role.

Gender roles, which were formerly called sex roles, refer to the traditional or stereotypical behaviors, attitudes, and personality traits that society designates as masculine or feminine. Gender roles greatly influence how we think and behave.

Between the ages of 3 and 4, American children learn the stereotypical or traditional expectations regarding the kinds of toys, clothes, and occupations for men and women. By the age of 5, children have acquired many of the complex thoughts, expectations, and behaviors that accompany their particular gender role of male or female (Best & Thomas, 2004).

By age 5, a child knows how a boy or girl **behaves**.

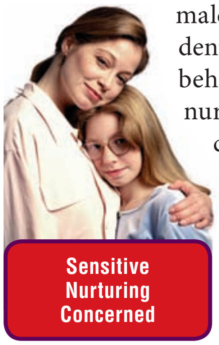
For example, young boys learn stereotypical male behaviors, such as playing sports, competing in games, engaging in rough-and-tumble play, and acquiring status in his group. In comparison, girls learn stereotypical female behaviors, such as providing and seeking emotional support, emphasizing physical appearance and clothes, and learning to cooperate and share personal experiences (Ruble et al., 2006; Rudman & Glick, 2008).

As children, we all learned early on to adopt a male or female gender role, often without being aware of how subtly we were rewarded for imitating and performing appropriate sex-typed behaviors. Learning and adopting a gender role continue through adolescence and into adulthood and result in very different gender roles.

Photo Credits: center, © Fancy Collection/SuperStock; bottom, © George Simian/Corbis

For instance, adult American women tend to show stereotypical gender roles that can be described as socially sensitive, nurturing, and concerned with others' welfare. In comparison, adult American men tend to show gender roles that can be described as dominant, controlling, and independent (Eagly et al., 2004; Rudman & Glick, 2008).

Dominant
Controlling
Independent

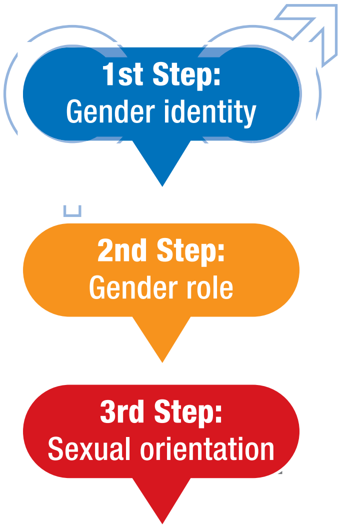


Function. A major function of gender roles is to influence how we think and behave. Notice that male gender roles—dominant, controlling, and independent—can lead to different kinds of sexual thoughts and behaviors than female gender roles—socially sensitive, nurturing, and concerned. Thus, some of the confusion, conflict, and misunderstanding over sexual behavior come from underlying differences in gender roles. A major task a couple will have in establishing a healthy, loving relationship is to work out the many differences in thoughts, beliefs, and expectations that come from combining two different gender roles.

After we acquire a gender role, the next step involves knowing one's sexual orientation.

Sexual Orientation

In answering the question "Do you find males or females sexually arousing?" you are expressing your sexual orientation, which is the third step in reaching psychological sexual maturity.



Sexual orientation, **also called sexual preference, refers to whether a person is sexually aroused primarily by members of his or her own sex, the opposite sex, or both sexes.**

Homosexual orientation **refers to a pattern of sexual arousal by persons of the same sex.**

Heterosexual orientation **refers to a pattern of sexual arousal by persons of the opposite sex.**

Bisexual orientation **refers to a pattern of sexual arousal by persons of both sexes.**

A recent national survey of sexual orientation found that the vast majority (90%) of the American population reported having a heterosexual orientation, 2% a homosexual orientation, 2% a bisexual orientation, and the remaining 6% declined to identify their sexual orientation (Mosher et al., 2005).

Of several models that explain how we develop a particular sexual orientation, the interactive model is perhaps the most popular (Money, 1987; Zucker, 1990).

The *interactive model of sexual orientation* says that genetic and biological factors, such as genetic instructions and prenatal hormones, interact with psychological factors, such as the individual's attitudes, personality traits, and behaviors, to influence the development of sexual orientation.

Genetic and biological factors. There is debate over how much genetic and biological factors influence sexual orientation. Some researchers prefer the term *sexual preference* because it suggests that we have considerable freedom in choosing a sexual orientation and that genetic and biological factors do not play a major role (Baumrind, 1995; Byne, 1997). Other researchers prefer the term *sexual orientation* because they believe genetic and biological factors play a major role (M. Diamond & Sigmundson, 1997). A case that involved changing a person's gender identity intensified this heated debate.

Changing gender identity. In the 1960s, genetic and biological factors were thought to play minor roles in developing gender identity. That's because some babies who were born with inconclusive sex organs (tiny penis, no testicles) were said to be girls and were raised as girls; others were said to be boys and were raised as boys. Later, when these children reached puberty, doctors discovered that some of these "girls" actually had the chromosomes of males and some of the "boys" had the chromosomes of females. However, some of those raised as "girls" decided to remain female and received corrective surgery (a vagina) and hormones (developed breasts). Others raised as "boys" decided to remain male and also received corrective surgery and hormones. In these cases, children chose the gender identity and orientation that matched their upbringing, not their genetic makeup. Based on such cases, researchers believed that gender identity and gender orientation could be changed if, before the age of 2, infants were assigned a gender identity and raised accordingly (Money, 1987). However, another case has questioned this belief.

Tragic case. While doctors were doing a routine medical procedure to repair an 8-month-old male's foreskin, they accidentally destroyed the infant's penis. As a result, doctors advised the parents to raise the boy (John) as a girl (Joan). However, since about the age of 8, Joan had been unhappy being and acting like a female and began to suspect that she was really a boy. By the time Joan was 14, she had received corrective surgery (a vagina) and hormonal treatment to physically look like a girl (developed breasts) but was so unhappy she threatened suicide and told doctors she thought she was a boy. After much discussion, doctors agreed to help Joan change back to John. In his 30s, John got married and reported he never liked being a female and was very happy being a male. Based on Joan-John's experience, researchers believe that individuals are genetically and biologically predisposed for having a male or female gender identity, which is not easily changed by being raised a certain way (boy or girl) (M. Diamond & Sigmundson, 1997). This case suggests that, unlike previously believed, humans may have a genetic predisposition to develop a male or female gender identity and gender orientation.

D. Sexual Behavior

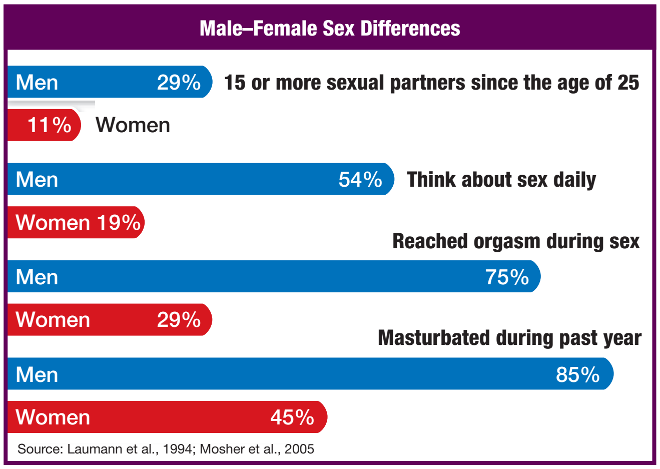
Male–Female Sex Differences

How are men different from women?

After we have acquired a gender identity, gender role, and sexual orientation, there remain the sometimes difficult and complex decisions about when, where, and with whom sexual behavior is appropriate. Virtually every sex survey during the past 30 years reports that men think about sex more, have more sexual partners, reach orgasm more, and masturbate more than women (right graph). Why men consistently report more sexual activity and are allowed more sexual freedom than women has come to be known as the double standard (M. Crawford & Popp, 2003).

The ***double standard for sexual behavior*** refers to a set of beliefs, values, and expectations that subtly encourages sexual activity in men but discourages the same behavior in women.

The existence of a double standard allowing more freedom in sexual behavior for men than for women is well established (Peplau, 2003). How these male–female differences in sexual behavior came about is explained by two different theories—the biosocial theory and the evolutionary theory.



Source: Laumann et al., 1994; Mosher et al., 2005

Because of their importance, we'll discuss how each theory explains the male–female differences in sexual behaviors.

Biosocial Theory

There are two major questions about male–female sexual behavior that need answering. First, why do men consistently report greater interest in sex as shown by increased frequency of sexual activities, a greater number of extramarital affairs, and a desire for more sex partners (about 18 partners) than women (about 4 or 5 partners) (Buss & Schmitt, 1993)? Second, in an international study of 37 cultures, 10,000 individuals were asked to state their top priorities in choosing a mate. Across all cultures and all racial, political, and religious groups, why do men generally value physical attractiveness more than women, while women value the financial resources of prospective mates twice as much as men do (Buss et al., 1990)? One answer to these questions comes from the biosocial theory of sexual differences.

Biosocial theory, which emphasizes social and cultural forces, says that differences in sexual activities and in values for selecting mates developed from traditional cultural divisions of labor: Women were primarily childbearers and homemakers, while men were primarily providers and protectors.

According to the biosocial theory, the double standard arose from men's roles as protectors and providers, which allowed them greater control of and access to women and in turn allowed and encouraged greater sexual freedom. In comparison, women's roles restricted and discouraged sexual activities and protected against potential problems with jealousy, which could disrupt or interfere with being successful childbearers and homemakers (right photo) (W. Wood & Eagly, 2002).

Biosocial theory focuses on the importance of different social and cultural pressures that resulted in men and women developing different social roles, which in turn led to men and women developing differences in sexual behavior, which today we call the double standard.

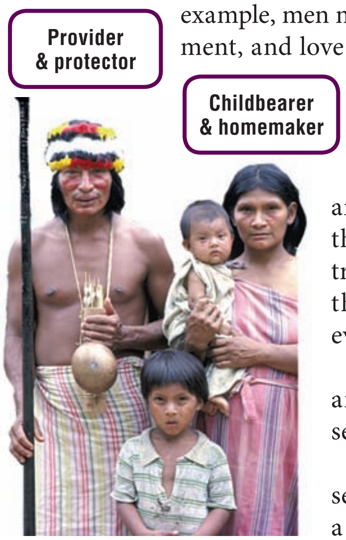


Photo Credit: Royalty-Free

Evolutionary Theory

A different explanation for the differences in sexual behavior between men and women comes from evolutionary theory.

Evolutionary theory, which emphasizes genetic and biological forces, says that our current male–female differences in sexual behavior, which we call the double standard, arise from genetic and biological forces, which in turn grew out of an ancient set of successful mating patterns that helped the species survive.

According to evolutionary theory, men developed a greater interest in sex and desire for many attractive sex partners because it maximized their chances for reproduction. In comparison, women would not benefit from indiscriminate and frequent mating because it would place them at risk for having offspring of low quality and create an unstable environment for raising their children. Instead, women placed a high priority on finding a man who was a good protector and provider, so she and her children would have a better chance for survival (Gangestad & Simpson, 2000).

Evolutionary theory explains many other sexual behaviors. For example, men may deceive women about their feelings, commitment, and love to gain sexual access, and women may deceive men about their chances of gaining sexual access to evoke jealousy in existing mates and increase their perceived mate value (Buss, 2003; Haselton et al., 2005). Even some homosexual behavior among animals can be explained by evolutionary theory. For instance, female couples in the albatross family (large sea birds) may raise more chicks than male–female couples, which suggests an evolutionary advantage (N. Bailey & Zuk, 2009).

Evolutionary theory explains the occurrence and development of male–female differences in sexual behavior (Buss, 2009; de Waal, 2002).

Next, we'll return to a controversial question in sexual behavior: Why does an individual develop a homosexual orientation?

Homosexuality

Were the brothers born gay?

According to national surveys, about 3% of the American male population are homosexual (gay) and about 1.5% of the female population are homosexual (lesbian). The question of whether sexual orientation is determined by choice or biological factors results in varied public opinion. A recent survey found that half of American adults believe sexual orientation is a result of *only* biological factors, one-third believe it is a result of choice *and* biological factors, and a smaller percentage believe it is a result of *only* choice (R. Epstein, 2006).

Both brothers are gay and share similar genetic factors.

The acceptance of homosexuality by Americans has certainly increased in recent years, but it remains a deeply divisive issue. Many people say they would be more accepting of homosexuality if it were shown to be a genetic predisposition, since it would be similar to inheriting other preferences, such as being left-handed (Leland, 1994). We'll discuss recent genetic/biological and psychological factors that bear on the question of whether brothers Rick and Randy (above photo) were genetically predisposed to be gay or chose to be gay.

Genetic/Biological Factors

During the past 20 years, there has been a growing search for genetic and hormonal influences that contribute to the development of homosexuality. Some evidence comes from the study of sexual orientation in twins. For example, studies on identical male and female twins found that, if one male or female twin of an identical pair was gay, about 31–65% of the time so was the second twin; this compared to 8–30% for fraternal twins and 6–11% for adopted brothers or sisters (J. M. Bailey & Zucker, 1995; Kendler et al., 2000b). However, these and other twin studies are criticized because some of the twins were not reared separately, so it is impossible to determine the effects of similar environments on sexual orientation. More recent research provides strong evidence that homosexual orientation has a genetic cause and that no single gene determines sexual orientation, but rather numerous genes are involved (M. Abrams, 2007; Rahman & Wilson, 2008).

Another kind of evidence comes from studies on genetic similarities among brothers. Researchers studied over 900 men who had at least one sibling and examined numerous factors including their sexual orientation, the number of biological and nonbiological siblings they had, and whether or not they lived with their siblings. Results found the only factor that increases the likelihood of a man having a homosexual orientation is having several older biological brothers. While the national rate of men having a homosexual orientation is about 3%, the rate increases to about 5% for men who have several older biological brothers (Bogaert, 2006a, 2006b). These results further support the role of genetic and biological factors, such as prenatal environment, in determining sexual orientation.

To examine biological factors involved in the development of sexual orientation, one study scanned people's brains as they smelled male and female odors associated with sexual attraction. Results showed that in heterosexual men, the hypothalamus (involved in sexual responses—pp. 80, 339) became activated only when smelling the female odor, but in homosexual men, activation occurred only when smelling the male odor. Thus, activation in the part of the brain involved in sexual responses is determined by sexual orientation and not biological sex. However, researchers cannot conclude whether changes in brain activity are the cause or the result of men's sexual orientation (Savic, 2005; Savic et al., 2005). Other brain research found the right hemisphere is slightly larger than the left in both men and women who are attracted to women, whereas, in men and women who are attracted to men, the brains are more symmetrical. Thus, sexual orientation may be reflected in brain structure (Savic & Lindström, 2008).

If there is a genetic/biological predisposition to homosexuality, we might expect a person would become aware of his or her homosexual orientation before learning about or engaging in homosexual behavior and despite pressure from parents, siblings, or peers to develop a heterosexual orientation. Research shows the average age when homosexual males report beginning to have same-sex attraction is 10 and for homosexual females it is 12, which is usually before they know much about or engage in homosexual behavior (Savin-Williams, 2005).

All the above findings suggest that, to a certain extent, Rick and Randy were born with genetic or biological tendencies that played a role in the development of a homosexual orientation. Researchers continue to actively pursue studies on the genetic and biological factors possibly involved in sexual orientation. There are also psychological factors worth considering.

Psychological Factors

In studying psychological factors, researchers observe the behaviors of young children and consistently find that young boys who prefer girl playmates and girls' toys, avoid rough-and-tumble play, and wear girls' clothing have a tendency to develop a homosexual orientation (Dawood et al., 2000). In addition, adult gay men and lesbian women recall engaging in more behaviors of the opposite sex as children than do heterosexual adults (J. M. Bailey & Zucker, 1995). Although these studies are correlational and cannot show cause and effect, they do suggest that certain psychological factors (kinds of play behaviors and preferences) are associated with developing a homosexual orientation (Dawood et al., 2000).

I knew I was gay before I did anything.

One psychological factor that influenced attitudes on homosexuality was that, until the 1970s, virtually all professional health organizations considered homosexuality to be an abnormal condition that often required psychotherapy to change. However, over the past 30 years, countless studies found that homosexuals scored about the same as heterosexuals on a wide variety of mental health tests, meaning that homosexuals are as mentally healthy as heterosexuals (K. P. Rosenberg, 1994). For these reasons, most professional health organizations now consider homosexuality a normal form or expression of sexual behavior and discourage all discriminatory practices toward homosexuals.

Next, we'll discuss several of the more common sexual problems and their treatments.

D. Sexual Behavior

Sexual Response, Problems, and Treatments

What are some of the problems?

Various surveys report that 10–52% of men and 25–63% of women aged 18 to 59, married and unmarried, experience a variety of sexual problems (Heiman, 2002). Some seek help for their problem, while others are ashamed or embarrassed and suffer in silence. There are two categories of sexual problems—paraphilias and sexual dysfunctions.

Paraphilias, commonly called sexual deviations, are characterized by repetitive or preferred sexual fantasies involving nonhuman objects, such as sexual attractions to particular articles of clothing (shoes, underclothes).

Sexual dysfunctions refer to problems of sexual arousal or orgasm that interfere with adequate functioning during sexual behavior.

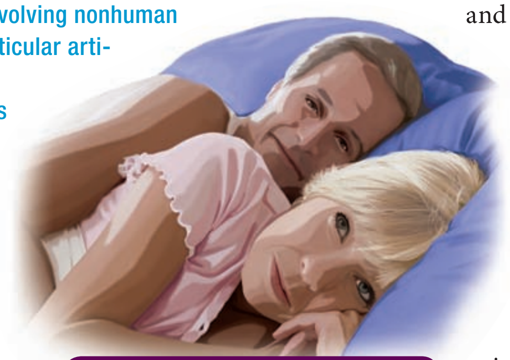
When a person seeks help for a sexual problem, the clinician will check whether the causes are organic or psychological.

Organic factors refer to medical conditions or drug or medication problems that lead to sexual difficulties.

For example, certain medical conditions (such as diabetes mellitus), medications (such as antidepressants), and drugs (such as alcohol abuse) can interfere with sexual functioning.

Psychological factors refer to performance anxiety, sexual trauma, guilt, and failure to communicate, all of which may lead to sexual problems.

Four-stage model. To understand how psychological factors cause sexual problems, it helps to know Masters and Johnson's (1966) four-stage model of the sexual response.



Masters and Johnson proposed four stages of the human sexual response.

1st stage: Excitement. The body becomes physiologically and sexually aroused, resulting in erection in the male and vaginal lubrication in the female.

2nd stage: Plateau. Sexual and physiological arousal continues in males and females.

3rd stage: Orgasm. Men have rhythmic muscle contractions that cause ejaculation of sperm. Women experience similar rhythmic muscle contractions of the pelvic area. During orgasm, women and men report very pleasurable feelings.

4th stage: Resolution. Physiological responses return to normal.

Problems. Sexual problems can occur at different stages. For example, some individuals cannot reach stage 1, excitement, while others can reach stages 1 and 2 but not stage 3, orgasm.

There were few successful treatments for sexual problems until Masters and Johnson (1970) published their treatment program, which has several stages. First, the therapist provides basic information about the sexual response and helps the couple communicate their feelings. Then the therapist gives the couple "homework," which is designed to reduce performance anxiety. Homework involves learning to pleasure one's partner without genital touching or making sexual demands. This nongenital pleasuring is called sensate focus. After using ***sensate focus,*** the couple moves on to genital touching and intercourse. Sex therapists have expanded and modified Masters and Johnson's program and report considerable success with treating many sexual problems.

We'll discuss two common sexual problems and their treatments.

Premature or Rapid Ejaculation

John and Susan had been married for three years and were both 28 years old. When the clinician asked about their problem, Susan said that sex was over in about 30 seconds because that's how long it took for John to have an orgasm. John replied that he had always reached orgasm very quickly and didn't realize it was a problem. Susan said that it was a problem for her (Althof, 1995). John's problem is called premature ejaculation.

Premature or ***rapid ejaculation*** refers to persistent or recurrent absence of voluntary control over ejaculation, in which the male ejaculates with minimal sexual stimulation before, upon, or shortly after penetration and before he wishes to.

Premature or rapid ejaculation is the most common male sexual problem and is reported by 20–40% of adult men (L. Lyon et al., 2008). A common treatment for it is called the squeeze technique. First, the partner stimulates the man's penis to nearly full erection. Then, the partner squeezes the head of the penis, which reduces arousal and erection. This squeeze procedure is repeated until the male develops a sense of control over arousal and ejaculation (Riley & Segraves, 2006; Waldinger, 2008). This procedure has proved successful in treating premature ejaculation.

Inhibited Female Orgasm

Greta and Bill had been married for five years and were in their late twenties. When asked about their problem, Greta said that she didn't think she had ever had an orgasm. She added that she loved Bill very much but that she was becoming less interested in sex (Durand & Barlow, 2006). Greta's problem has a name; it is called inhibited female orgasm.

Inhibited female orgasm refers to a persistent delay or absence of orgasm after becoming aroused and excited.

About 10% of women never reach orgasm, and many others do so only occasionally (L. Lyon et al., 2008). Difficulty in reaching orgasm is one of the most common complaints of women seeking help for sexual problems (Laumann et al., 2005).

Psychological treatment begins with sensate focus, during which the couple learns to pleasure each other and the woman learns to relax and enjoy her body's sensations. The man is told how to help a woman reach orgasm—for example, by using his hand or, in Greta's case, using a vibrator (Durand & Barlow, 2006). This program has proved successful in treating inhibited female orgasm.

Next, we'll discuss a sexual problem that involves a potentially deadly transmitted disease—AIDS.

AIDS: Acquired Immune Deficiency Syndrome

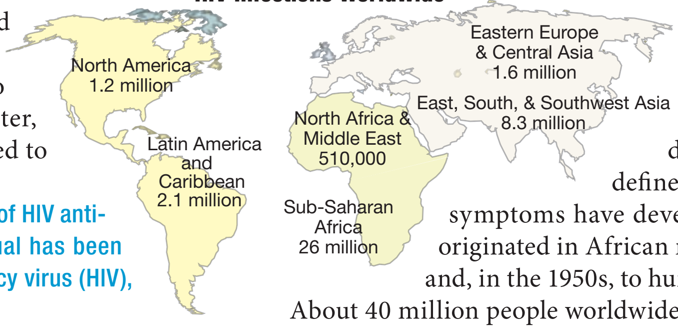
What is AIDS?

On June 5, 1981, the U.S. Centers for Disease Control and Prevention issued a report describing five gay men in Los Angeles who had a rare form of pneumonia. Later, this rare pneumonia was determined to be one symptom of HIV.

HIV positive **refers to the presence of HIV antibodies, which means that the individual has been infected by the human immunodeficiency virus (HIV), which is believed to cause AIDS.**

AIDS (acquired immune deficiency syndrome) **is a life-threatening condition that is present when the individual is HIV positive and has a level of T-cells (CD4 immune cells) no higher than 200 per cubic milliliter of blood or has developed one or more of 26 specified illnesses (for example, pneumonia, skin cancer). It may take years or even decades for HIV to develop into AIDS.**

HIV Infections Worldwide



North America
1.2 million
Latin America and Caribbean
2.1 million
Eastern Europe & Central Asia
1.6 million
North Africa & Middle East
510,000
East, South, & Southwest Asia
8.3 million
Sub-Saharan Africa
26 million

The criterion of T-cell levels below 200 became a part of the definition of AIDS in 1993. T-cells are a critical part of the body's immune system, which fights against toxic agents (viruses and bacteria). Because of this change, some people who were previously defined as being HIV positive are now defined as having AIDS, even if no obvious symptoms have developed. Researchers report that HIV originated in African monkeys, then spread to chimpanzees and, in the 1950s, to humans (Bailes et al., 2003).

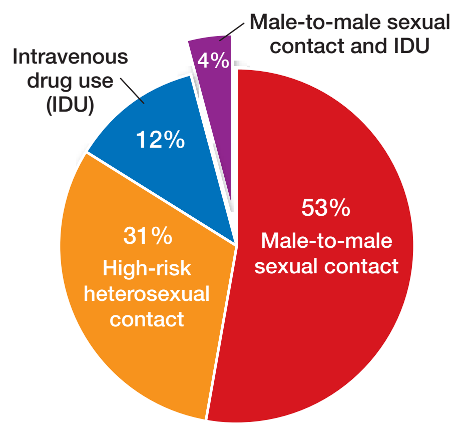
About 40 million people worldwide are infected with HIV and one more person gets infected every 8 seconds, with people aged 13–29 being at highest risk (CDC, 2008d). About 25 million people have died of AIDS since the first case was reported in 1981, making it one of the most deadly diseases in history (Engeler, 2006; Gerlach, 2006). As shown in the map (above), the AIDS virus is widespread and has reached epidemic levels in Sub-Saharan Africa (Gerlach, 2006). Currently, over 1 million people in the United States are living with HIV (CDC, 2009).

Risk for AIDS

HIV cannot survive in air, in water, or on things that people touch. There are no reports of individuals getting AIDS through casual contact, such as through touch. HIV survives best in blood tissues and some bodily fluids, such as semen and vaginal fluids. Thus, people who come in physical contact with blood or bodily fluids (semen or vaginal fluids) from someone who has HIV are at risk for getting AIDS.

The pie chart below shows that in the United States, those people at greatest risk for AIDS are gay men and heterosexual intravenous drug users (high-risk heterosexual contact) (CDC, 2008d). In the rest of the world, about 75% of AIDS cases are spread through heterosexual intercourse (S. Sternberg, 2002).

How People Get AIDS



Progression of Disease

After infection, the AIDS virus replicates rapidly and intensively. As a result, newly infected individuals are 100–1,000 times more infectious than they are throughout the remainder of the disease (Koopman, 1995). In addition, newly infected individuals have no symptoms and the presence of antibodies to HIV cannot be confirmed biochemically for at least 60 days. Thus, the newly infected person is regarded as a walking time bomb.

HIV destroys T-cells (CD4 cells), which are immune cells that fight off toxic agents (viruses and bacteria). It takes an average of 7 years for a person infected with HIV to develop AIDS (T-cell count below 200) and another 2 to 3 years after that to develop diseases that result in death. The reason a person with AIDS is especially susceptible to infections and diseases is that HIV slowly destroys a person's immune system's defenses, which means the body loses its ability to fight off toxic agents (infections or diseases).

Because of yet unknown qualities of their immune systems, about 10% to 17% of HIV-infected individuals will be AIDS-free 20 years after infection. Researchers are studying these AIDS-free individuals to find out how their immune systems can fight off AIDS (Kolata, 2000a).

Treatment

The number of AIDS-related deaths began to decrease in the late 1990s as a result of breakthroughs in drugs. The new drug treatment program has patients taking a drug "cocktail" of many pills daily, which include several new drugs (protease inhibitors and HIV-inhibiting drugs). In many cases, these new drugs reduce HIV to undetectable levels, but the drugs still do not wipe out the virus. Instead, the virus "hides out" in the body and returns if patients stop taking the drugs, which means these drugs must be taken for life. Because the anti-HIV drugs reduce life-threatening symptoms, these drugs have enabled AIDS patients to live longer. The earlier patients begin HIV treatment, the better their chance of survival (S. Sternberg, 2008b).

The dramatic decreases in deaths from AIDS because of the drug cocktails used in the early 1990s have slowed greatly. That's because HIV became resistant to some of the "new" drugs and some patients stopped taking the drugs because there were too many pills to take or because of side effects (nausea, brittle bones) (S. Sternberg, 2008a). In 2006, the first once-a-day pill for HIV treatment was approved so people no longer have to take so many pills (S. Sternberg, 2006). Researchers continue to search for new drugs and vaccines to treat HIV/AIDS (Karlin, 2008; *Science Daily,* 2009a).

Now, we'll discuss a cruel cultural influence on female sexual behavior.

Photo Credit: © S. Wanke/PhotoDisc, Inc.

E. Cultural Diversity: Genital Cutting

Good Tradition or Cruel Mutilation?

What is genital cutting?

Men have a long history of trying to control the sexual motivation of women. In many countries, men want to marry virgins and insist that women remain virgins until marriage, although the men do not hold themselves to the same standards. One extreme example of men controlling the sexual motivation and behavior of women is found in parts of Africa, Indonesia, and the Arabian Peninsula, where young girls undergo genital cutting before they become sexually mature (Corbett, 2008; MacInnis, 2006).

Genital cutting **involves cutting away the female's external genitalia, usually including her clitoris and surrounding skin (labia minora). The remaining edges are sewn together, which leaves only a small opening for urination and menstruation.**

At age 13, Soraya Mire underwent genital cutting.

Soraya Mire (above photo) remembers the day her mother said, "I'm going to buy you some gifts." Soraya, who was 13, obediently got into the car with her mother and driver. They didn't go shopping but stopped at a doctor's house. Once inside, they went into an operating room where a doctor asked Soraya to lie on the operating table. He tied her feet down with a rope so she could not move. Her mother said it was time for Soraya to become a woman and undergo genital cutting.

Like her mother and her mother's mother, Soraya underwent this ancient rite of passage. But unlike them, Soraya broke the silence to fight this cruel mutilation. At age 36, Soraya made a documentary film called *Fire Eyes* to protest the practice of genital cutting (Tawa, 1995).

About 3 million women a year and a total of 140 million women have undergone genital cutting (formerly called female circumcision), mostly in childhood and often without anesthesia or sterile procedures. Genital cutting has taken place for the past 5,000 years and is currently practiced in about 28 African countries by people of all different religious, ethnic, and cultural groups (Associated Press, 2006f; MacInnis, 2006; E. Rosenthal, 2006; WHO, 2008).

What Is Its Purpose?

In many of the poorer societies of Africa and Ethiopia, genital cutting is a common ritual to physically mark young girls and increase their chances for future marriage. Many African nations have placed government bans on genital cutting, but few are enforcing the rules (Corbett, 2008; Ras-Work, 2006).

Girls commonly undergo genital cutting before they reach puberty, usually between the ages of 4 and 10. The primary reason for genital cutting is the men's belief that if women are surgically deprived of receiving sexual pleasure, they will remain clean and virginal until marriage. Men in these societies often refuse to marry a woman who has not undergone genital cutting because they believe that she is unclean and not a virgin (Associated Press, 2006f; A. Walker & Parmar, 1993).

The male equivalent of genital cutting would be amputation of the male's penis.

Are There Complications?

Because of the high social status of Soraya's father, who was a general, her genital cutting was performed by a doctor. However, in the majority of cases, it is done by someone with no medical training who uses a knife, razor, or sharp stone and less than sterile procedures (Associated Press, 2006f).

Young girl is being held while undergoing genital cutting.

Because the genital area has a high concentration of nerves and blood vessels, genital cutting results in severe pain, bleeding, and even hemorrhaging, which can lead to shock and death. Because of poor surgical procedures, girls endure many medical complications, including infections, cysts, and scarring. This procedure also makes menstruation and intercourse painful and childbirth dangerous (Nour, 2000; E. Rosenthal, 2006).

Girls submit to the fear, pain, and trauma of genital cutting for varied and complex reasons. Parents have genital cutting done in the beliefs that it is for the good of their daughters, that their religion requires it, that it will make their daughters marriageable, and that it is necessary to maintain female chastity (Corbett, 2008; Nour, 2000). However, after genital cutting many women suffer anxiety and depression from worry about their disfigured genitals, menstruation difficulties, and fear of infertility (Caldwell et al., 1997).

Is There a Solution?

The United Nations health organizations have endorsed laws against genital cutting, but such laws cannot eliminate this strong sociocultural tradition. As one supporter of genital cutting said, "This procedure helps to keep women's sexual drives at acceptable and reasonable levels" (Daniszewski, 1997). Although Westerners are horrified by this barbaric practice, many African societies consider this practice part of their culture and do it out of love for their daughters (Corbett, 2008). For example, when a newspaper in Ghana, Africa, published articles in favor of banning genital cutting, local women had great success in getting support to keep this ancient practice and reject values from the outside world.

In 2002, the Kenyan president banned genital cutting, but it is still being practiced in some regions. Feminists in Egypt and other African nations who are fighting this cruel tradition have run into considerable resistance from both men and women who approve of it (Lacey, 2002, 2003). Genital cutting is an extreme example of how far human societies (men) will go to control the sexual behavior of women.

We have discussed two biological drives, hunger and sex. After the Concept Review, we'll examine an important social need—achievement.

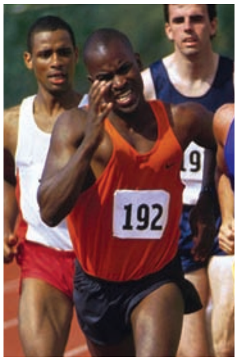
Photo Credits: top, *Los Angeles Times*, photo by Gina Ferazzi; bottom, © Mariella Furrer

Concept Review

1. Physiological or psychological factors that cause us to act in a specific way at a particular time are included in the definition of ________________.

2. Innate biological forces predispose an animal to behave in a particular way in the presence of a specific environmental condition. These ways of behaving are called ________________.

3. There are several areas in the brain, including the nucleus accumbens and ventral tegmental area, that make up a neural circuit called the (a) ________________ center. This center especially uses the neurotransmitter (b) ________________. Many behaviors (eating, engaging in sex, gambling) that activate this center are (c) ________________ with pleasurable feelings.



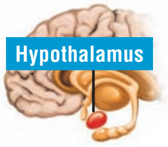
4. External stimuli, reinforcers, goals, or rewards that may be positive or negative and that motivate one's behavior are called ________________.

5. When we perform behaviors to reduce biological needs or obtain various incentives, we are acting under the influence of (a) ________________ motivation. When we perform behaviors because they are personally rewarding or because we are following our personal goals, beliefs, or expectations, we are acting under the influence of (b) ________________ motivation.

6. Needs that are not critical to your survival but that are acquired through learning and socialization, such as the needs for achievement and affiliation, are called (a) ________________ needs. Needs that are critical to your survival and physical well-being, such as food, water, and sex, are called (b) ________________ needs.

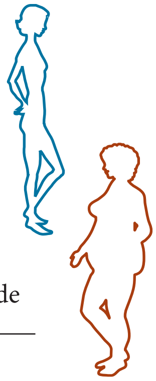
7. The ascending order or hierarchy with biological needs at the bottom and social needs at the top is ________________. This idea assumes that we satisfy our biological needs before we satisfy our social needs.

8. There are three major factors that influence eating. Cues that come from physiological changes are called (a) ________________ factors. Cues that come from inherited instructions are called (b) ________________ factors. Cues that come from learning and personality traits are called (c) ________________ factors.



9. Biological cues for hunger that come from the stomach, liver, intestines, and fat cells are called (a) ________________ cues. Biological cues that come from the brain are called (b) ________________ cues.

10. The part of the hypothalamus that is involved in feelings of being hungry is called the (a) ________________; the part that is involved in feelings of being full is called the (b) ________________.



11. We inherit the following genetic factors involved in weight regulation: a certain number of (a) ________________ cells that store fat; a certain (b) ________________ rate that regulates how fast we burn off fuel; a certain (c) ________________ point that maintains a stable amount of body fat; and weight-regulating (d) ________________ that influence appetite, metabolism, and hormone secretion.

12. Psychological factors that influence eating include (a) ________________ associations, (b) ________________ influences, and (c) ________________ variables.

XY = High Testosterone

13. Genetic sex factors involve the 23rd chromosome, called the (a) ________________, which determines the sex of the child. Biological sex factors include sex hormones, which for the male are called (b) ________________ and for the female are called (c) ________________. Psychological sex factors include the subjective feeling of being male or female, which is called (d) ________________; adopting behaviors and traits that society identifies as male or female, which is called (e) ________________; and being more sexually aroused by members of the same or opposite sex, which is called (f) ________________.

14. Findings from the sexual orientation of identical twins and the shared genetic material from gay brothers are examples of (a) ________________ factors in the development of a homosexual orientation. Young boys who prefer girls' toys and girl playmates and engage in opposite-sex behaviors show a tendency to develop a homosexual orientation, which shows the effects of (b) ________________ factors on sexual orientation.

15. A person who has been infected by the human immunodeficiency virus but has not yet developed any illnesses is said to be (a) ________________. A person whose level of T-cells has dropped to 200 per cubic milliliter of blood but who may or may not have developed an illness is defined as having (b) ________________.

Answers: *1. motivation; 2. fixed action patterns; 3. (a) reward/pleasure, (b) dopamine, (c) rewarded or encouraged; 4. incentives; 5. (a) extrinsic, (b) intrinsic; 6. (a) social, (b) biological; 7. Maslow's hierarchy of needs; 8. (a) biological, (b) genetic, (c) psychosocial; 9. (a) peripheral, (b) central; 10. (a) lateral hypothalamus, (b) ventromedial hypothalamus; 11. (a) fat, (b) metabolic, (c) set, (d) genes; 12. (a) learned, (b) social-cultural, (c) personality; 13. (a) sex chromosome, (b) androgens, (c) estrogens, (d) gender identity, (e) gender role, (f) sexual orientation; 14. (a) genetic, (b) psychological; 15. (a) HIV positive, (b) AIDS*

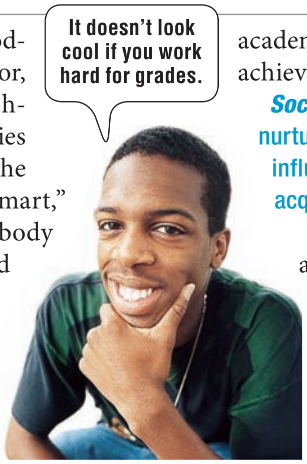
F. Achievement

Need for Achievement

Why did Victor succeed?



It doesn't look cool if you work hard for grades.

At the beginning of the module, we told you about Victor, an African American high-school student whose buddies called him a "White boy" because they thought he was studying too hard. "You can't be cool if you're smart," says Victor, who was Mission Bay High's student body president, had a 3.7 (A–) grade point average, and planned to attend the University of Southern California in the fall (adapted from the *San Diego Union-Tribune,* June 17, 1994).

Victor (right photo) grew up with an obstacle that goes largely unnoticed and is rarely discussed in public: pressure from students in the same racial or ethnic group not to succeed in the classroom (R. Fryer, 2005). Educators believe that the high dropout rates for minorities result, in part, from peer pressure not to succeed in school or show academic achievement (McWhorter, 2000). For Victor, academic achievement was one of his many social needs.

Social needs, such as the desire for affiliation or close social bonds, nurturance or need to help and protect others, dominance or need to influence or control others, and achievement or need to excel, are acquired through learning and experience.

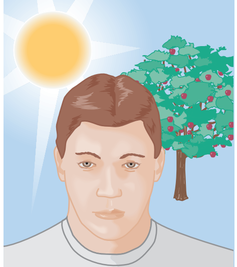
If you are working hard to achieve academic success, you are demonstrating your social need for achievement.

The ***achievement need*** refers to the desire to set challenging goals and to persist in pursuing those goals in the face of obstacles, frustrations, and setbacks.

The achievement need not only is a major concern of college students but also ranks high (Level 4 out of 5) in Maslow's hierarchy of needs. We'll discuss four questions related to the achievement need: How is the need for achievement measured? What is high need for achievement? What is fear of failure? What is underachievement?

How Is the Need for Achievement Measured?

Do you have a strong need to achieve? Researchers David McClelland and John Atkinson tried to answer this question with a test called the Thematic Apperception Test, or TAT.



What do you think is going on in this TAT card?

The ***Thematic Apperception Test,*** commonly called the ***TAT,*** is a personality test in which subjects are asked to look at pictures of people in ambiguous situations and to make up stories about what the characters are thinking and feeling and what the outcome will be.

For example, the sample TAT card on the left shows a young man with a sad expression and a bright sun and fruit tree in the background. If you were taking the TAT, you would be asked to describe what is happening in this card. To measure the level of achievement, your stories would be scored in terms of achievement themes, such as setting goals, competing, or overcoming obstacles (J. W. Atkinson, 1958; D. C. McClelland et al., 1953). The TAT assumes that the strength of your need to achieve will be reflected in the kinds of thoughts and feelings you use to describe the TAT cards. However, TAT stories are difficult to score reliably because there is no objective way to identify which thoughts and feelings indicate level of achievement (Keiser & Prather, 1990). More recently, objective ***paper-and-pencil tests*** have been developed to measure achievement motivation because these tests are easier to administer and score and have somewhat better reliability and validity than the TAT (R. M. Kaplan & Saccuzzo, 2009).

However, measuring the need for achievement has proved difficult because it relates to intrinsic motivational factors that include beliefs and expectations, which have proved difficult to quantify (Petri & Govern, 2004).

What Is High Need for Achievement?

There is perhaps no better example of individuals with high need for achievement than Olympic athletes. One example is Michael Phelps, who has won 16 Olympic medals, including 8 gold medals in 2008 (the individual record for the most gold medals at a single Olympics). Michael's performances have earned him countless other awards, including several World Swimmer of the Year awards. He trains for at least 5 hours a day, 6 days a week, to be the best swimmer he can be. Michael has all the traits of someone with a high need for achievement (J. W. Atkinson & Raynor, 1974; D. C. McClelland, 1985).

Michael Phelps trains 5 hours a day, 6 days a week.

High need for achievement is shown by those who persist longer at tasks; perform better on tasks, activities, or exams; set challenging but realistic goals; compete with others to win; and are attracted to careers that require initiative.

Although the vast majority of us will not make the Olympics, most of us will show varying degrees of the need to achieve by doing our best, striving for social recognition, and working to achieve material rewards (Hareli & Weiner, 2002). This need for achievement will vary based on cultural factors, such as parental influence (Maehr, 2008).

The idea that there is a need for achievement and that it motivates many of our behaviors has generated a great deal of research. However, measuring a person's need for achievement and making predictions about an individual's level of achievement have proved difficult for two reasons: The TAT and paper-and-pencil tests have limited reliability and validity (p. 287), and achievement motivation is difficult to quantify because it involves intrinsic motivation (p. 331), which includes one's personal beliefs and expectations (Petri & Govern, 2004).

If we consider one side of a coin to be a need for achievement, then the other side is fear of failure and making excuses for failing.

Fear of Failure

Why do some fail?

Just as some individuals may be motivated by a need for achievement, others may be motivated by a fear of failure. J. W. Atkinson (1964) believed that, in order to understand why a person succeeds or fails in reaching a goal, we must examine not only a person's need for achievement but also the fear of failure.

Fear of failure **is shown by people who are motivated to avoid failure by choosing easy, nonchallenging tasks where failure is unlikely to occur.**

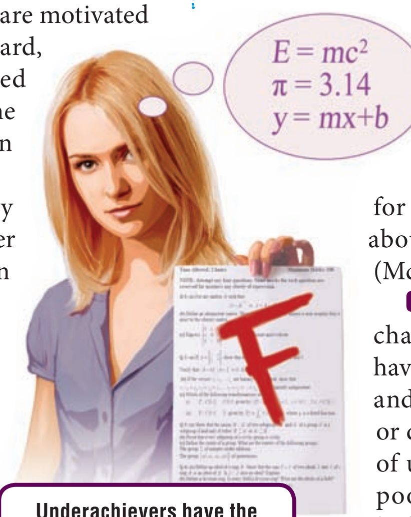
For example, fear of failure may motivate a student to study just enough to avoid failing an exam but not enough to get a good grade or set higher academic goals. In fact, the fear of failure is a good predictor of poor grades: The greater a student's fear of failure, the poorer his or her grades (W. E. Herman, 1990). Atkinson said that individuals who are motivated primarily by a fear of failure will never do as well, work as hard, or set goals as high as those who are motivated by a need for achievement. Also, the greater one's fear of failure, the greater the chances of trying to look good by engaging in self-handicapping (Zeidner & Matthews, 2005).

Self-handicapping. If a person is motivated primarily by the fear of failure, how does this individual explain his or her poor performances yet keep a good self-image? One solution is to use self-handicapping (E. Jones & Berglas, 1978).

Self-handicapping **refers to doing things that contribute to failure and then using these very things, knowingly or unknowingly, as excuses for failing to achieve some goal.**

For example, instead of studying for an exam, a student goes to a movie and then does poorly on the test. He excuses his bad grade by saying he didn't study, which is an example of self-handicapping. Researchers found that individuals with low self-esteem are most likely to engage in self-handicapping because it is one way to look good to their peers and thus protect their already low self-esteem (Elliot & Church, 2003). Self-handicapping excuses may involve health (missed sleep, have a cold), drug use (have a hangover), unrealistically high goals (How could I possibly do that?), or procrastination (I didn't have enough time). In the short term, self-handicapping helps preserve our positive self-image and self-esteem, but in the long term, it interferes with taking personal responsibility to achieve our goals (Rhodewalt & Vohs, 2005).

One example of how fear of failure affects motivation is seen in individuals who are underachievers.



Underachievers have the ability but not the motivation.

Underachievement

Why do some underachieve?

One of our friends described his 14-year-old son, Rich, as having all the brains in the world but doing nothing with them. Although Rich is a computer wizard, he gets terrible grades in school, never does his homework, and doesn't seem to have any ambition. Rich might be called an underachiever.

Underachievers **are individuals who score relatively high on tests of ability or intelligence but perform more poorly than their scores would predict.**

The most common examples of underachievers are students who score relatively high on ability or intelligence tests but perform poorly in school or academic settings (Lupart & Pyryt, 1996). Researchers found that underachievement is not related to socioeconomic class, that there are two or three male underachievers for every female underachiever, and that about 15% of students are underachievers (McCall, 1994).

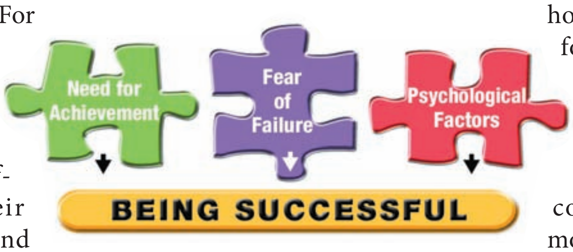
Characteristics. The psychological characteristics of underachievers include having a poor self-concept, low self-esteem, and poor peer relationships and being shy or depressed. The cognitive characteristics of underachievers include fear of failure, poor perceptions of their abilities, and lack of persistence. This means that underachievers are less likely to persist in getting their college degrees, holding on to jobs, or maintaining their marriages (McCall, 1994). Thus, underachievement reduces performance in academic, job, and marital settings, and its effects may last through adulthood.

The paradox of underachievement is that underachievers have the abilities but are not motivated to use them. Clinicians, counselors, and researchers are developing treatment programs to help underachievers change their beliefs and expectations so they will develop the motivation to use their considerable abilities (McCall, 1994).

Three Components of Success

Why is a person successful?

Explaining why some students are more successful than others involves the interaction of three components that we have just discussed: need for achievement, fear of failure, and psychological factors (self-concept, self-esteem, and confidence in one's abilities). For example, researchers wondered why some minority children from low-income homes were successful in school while others were not. Those minority students who succeeded had higher self-esteem, had more confidence in their abilities, and received more support and encouragement from a parent or caregiver (Finn & Rock, 1997). Researchers also found that students who were more successful in school had come from more stimulating home environments (parents spoke more to children, children had more books and watched less television) (Cleveland et al., 2000). Thus, having a stimulating home environment leads to a higher need for achievement, which in turn leads to more success in life. Finally, successful students not only worked harder but also liked what they were doing. This "enjoyment of work" is an important cognitive factor that greatly influences motivation and is our next topic.

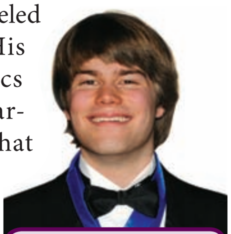


F. Achievement

Cognitive Influences

Do you work for love or money?

Each year, over 1,600 seniors compete in the Intel Science Talent Search to win the most prestigious high-school science award in the United States. One winner was Eric Larson (photo below), a senior from Oregon who has always enjoyed science, especially thinking about questions no one else can answer. Larson's project classified mathematical objects called fusion categories, which no one had labeled before (Bedrosian, 2009; Crepeau, 2009). His work has implications for theoretical physics and computer science (Ehrenberg, 2009). Larson's love of science is a motivating force that comes from various cognitive factors.



INTRINSIC MOTIVATION
Competent
Determined
Personally rewarding
Enjoyable

Cognitive factors in motivation **refer to how people evaluate or perceive a situation and how these evaluations and perceptions influence their willingness to work.**

Eric Larson perceives science projects as interesting and enjoyable and works hard to complete them. He describes science and math as "beautiful" (Larson, 2009). Compared to Larson's love of science, others find science projects hard and boring and take science courses only because they are required. The difference between taking science courses because of a love of science and because of course requirements illustrates the difference between two kinds of motivation—intrinsic motivation and extrinsic motivation (Ryan & Deci, 2000).

Intrinsic motivation **involves engaging in certain activities or behaviors without receiving any external rewards because the behaviors themselves are personally rewarding or because engaging in these activities fulfills our beliefs or expectations.**

Larson's dedication to science is in large part fueled by intrinsic motivation, which is related to feeling competent, curious, and interested, having self-determination, and enjoying the task, whether it's a science project, work you like, a hobby, or volunteer work. In comparison, extrinsic motivation involves different factors.

Extrinsic motivation **involves engaging in certain activities or behaviors that either reduce biological needs or help us obtain incentives and external rewards.**

EXTRINSIC MOTIVATION
Competitive
Get recognition
Obtain incentives
Make money

If you do a job, task, or assigned work because it is required, your motivation is often extrinsic, which may involve being evaluated or competing, or seeking recognition, money, or other incentives, such as acquiring a car or home. Another major difference between intrinsic and extrinsic motivation is that working because of intrinsic motivation (loving what you're doing) makes you feel powerfully motivated. Without intrinsic motivation there would be less donations and fewer people would volunteer their time or donate their blood (Deci et al., 1999).

So, here's an interesting question: What would happen to intrinsic motivation if you got paid for doing something that you love doing?

Intrinsic Motivation

What happens if volunteers get paid?

Would receiving money for volunteering to give blood "turn off" or decrease the intrinsic motivation of donors to the point that they might give less blood or none at all?

Researchers generally believed that if people were given external rewards (money, awards, prizes, or tokens) for doing tasks (donating blood) from intrinsic motivation, their performance of and interest in these tasks would decrease (Deci & Moller, 2005). Because of the widely held belief that external rewards decreased intrinsic motivation, many books advised that rewards should not be used in educational settings, hospitals, or volunteer organizations because such rewards would do more harm than good. Recent reviews of this issue indicate that the effects of external rewards on intrinsic motivation are more complex than originally thought.

Researchers have reached three general conclusions about the influence of external rewards on intrinsic motivation (Deci & Moller, 2005; Eisenberger et al., 1999; Lepper et al., 1999). First, giving unexpected external rewards does not decrease intrinsic motivation, but people may come to expect such rewards. Second, giving positive verbal feedback for doing work that was better than others may actually increase intrinsic motivation. Third, giving external rewards for doing minimal work or completing a specific project may decrease intrinsic motivation.

Recent studies indicate that, unlike previously thought, external rewards that are unexpected or involve positive verbal feedback may increase intrinsic motivation. External rewards that are tied to doing minimal work or completing a specific project may decrease intrinsic motivation. For example, when parents or teachers praise children, the praise is likely to increase intrinsic motivation if the praise is sincere and promotes the child's feelings of being competent and independent. In contrast, insincere praise, praise for very small accomplishments, or praise that is controlling rather than rewarding may decrease intrinsic motivation (Deci & Moller, 2005).

People who donate blood are usually intrinsically motivated.

For a long time it was also thought that external rewards automatically decreased creative work and interest. But researchers have found that the effects of giving children a reward for completing a creative task depend on how children perceive the reward. If they perceive the reward as a treat, it will increase their intrinsic interest, but if they see the reward as external pressure to be creative, it will decrease their intrinsic interest (Eisenberger & Armeli, 1997). All these studies show that external rewards influence cognitive factors, which in turn may increase or decrease intrinsic motivation.

Next, we'll examine how poor and minority students can overcome educational disadvantages.

Photo Credits: top, Courtesy of Intel Corporation; bottom left and right, © PhotoDisc, Inc.

Why Did Poor and Minority Students Do Well?

How should poor and minority students be educated?

There has been a long history of research indicating that poor and minority children do not perform as well as their middle-class and White peers in many schools across the United States. Over many years, it has become increasingly clear that educating poor minority students to the national standards of proficiency is certainly possible, but requires considerable effort.

In order to develop school programs to help poor and minority students overcome their academic disadvantages, education policy makers rely on research findings that identify factors that have an important influence on children's intellectual and academic achievement. For instance, researchers report that parents who are professionals speak more to their children than parents who are on welfare. Also, children of professionals hear many more words of encouragement than welfare children, and welfare children hear many more words of discouragement than children of professionals. The outcome for young children who hear fewer words spoken by their parents and receive a lot of discouragement is lower IQ scores and poorer academic success than for children who hear many words and receive a lot of encouragement (Hart & Risley, 2006).

Other related research reports that children from middle-class families have parents who are more sensitive, more encouraging, and less detached. Researchers conclude that although wealth influences children's IQs and academic success, parenting style matters even more. Thus, the advantages of middle-class children are due primarily to the language their parents use and their parents' child-rearing approach (Brooks-Gunn, 2006).

Procedure and Results

By using research findings about the disadvantages of poor and minority children to develop education programs, many schools have been able to educate these students to meet and rise above national standards of proficiency. The schools that best educate poor and minority children follow three practices. First, the school day is much longer; the first class often begins before 8 A.M., the last class ends after 4 P.M., and summer vacations are limited to one month. Second, there are clearly stated education goals and principals closely monitor whether or not teachers are achieving the goals. Teachers are very committed to these goals, and some go as far as making themselves available in the evenings to help students with their homework. Third, these schools not only are teaching students academics, but also are teaching them character, such as how to sit in class, make appropriate eye contact, and work cooperatively in a team (Tough, 2006).

Respect
Enthusiasm
Achievement
Citizenship
Hard Work

Not only are students taught academics, such as reading and math, but slogans, such as REACH, are used to help them build character.

Some of the best-recognized schools for their success in educating poor and minority students are operated by KIPP (Knowledge Is Power Program). One of the slogans KIPP schools use to teach students proper classroom behavior is SLANT (Sit up, Listen, Ask questions, Nod, and Track the speaker with their eyes). Children in KIPP schools appreciate the valuable lessons they receive about respectful behavior, saying it even helps them to pay better attention to speakers. KIPP schools use other slogans too, such as the one in the above photo and "All of Us Will Learn." Research findings indicate that the "noncognitive" skills these schools are teaching students, such as patience, respect, self-control, and motivation to work hard, have an important role in children's future academic and career success (Tough, 2006).

Many of the KIPP schools have demonstrated their effectiveness by improving students' performances on state exams. For instance, recent state exam scores for middle-school students at one KIPP school in New York were 12% higher than the state average. When compared to scores from other children in their high-poverty neighborhoods, 86% of KIPP eighth-grade students scored at grade level in math, but only 16% of students attending other schools reached math proficiency. This is especially impressive because when students enter KIPP schools, they are usually at least two grade levels behind (Tough, 2006).

Conclusions

Children from low-class families who are behind in school need more than the same education provided to middle-class families. These children have a lot of catching up to do and therefore need a better, more intensive education. Results on the effect these special schools have on students' academic performance suggest that schools should not only focus on academics, but also include personality and behavioral curriculum. Programs like KIPP offer promise in reducing the academic achievement and IQ gap between low-class and minority students and middle-class and White students. Yet, these relatively few programs are only a beginning to a large-scale educational issue that requires substantial public school reform (Tough, 2006).

H. Application: Eating Problems & Treatments

Dieting: Problems, Concerns, and Benefits

Why is dieting so difficult?

Some of us have learned to eat at certain times (learned associations) or eat when stressed (personality variables), or we come from families that encourage eating to show appreciation (cultural influences). Any of these psychosocial factors—learned associations, personality variables, or cultural influences—can override our genetic and biological factors and lead us to become overweight. The percentage of adult Americans who are overweight or obese has increased dramatically, from 26% in 1976 to 67% in 2007 (J. O. Hill et al., 2003; Kluger, 2007). Losing weight is difficult because the body is genetically designed to store extra calories as fat and because our large forebrains are good at rationalizing why we need to eat another piece of pizza and have a late-night snack.

We'll use the dieting experiences of television talk-show host Oprah Winfrey to illustrate the difficulties of dieting and how best to maintain an optimal weight.

Overweight and Dieting

190 pounds

In the 1970s, when Oprah Winfrey was in her twenties, she weighed 140 pounds. By the mid-1980s, Oprah weighed 190 pounds, which is considered overweight for her height and frame. She described getting home from work and being overwhelmed by a compulsion to eat. When her weight reached 211, she decided it was time for a diet program (B. Greene & Winfrey, 1996).

In the 1980s, Oprah went on a diet and lost nearly 70 pounds. She showed off her slim figure on TV and said she was finally cured of overeating. She was wrong.

142 pounds

In the 1990s, Oprah did not make the necessary changes in her lifestyle and she regained all her lost weight and then some, reaching about 237 pounds (*People,* March 14, 2005, p. 148).

237 pounds

In 2005, through devoted dieting and exercise, Oprah got down to a trim and fit 160 pounds. She believed she was finished with her ongoing weight battle. Unfortunately, she was wrong again. Only four years later, she now tops the scale at 200 pounds. She asks herself, "How did I let this happen again?" (Winfrey, 2009).

Like all bodies, Oprah's body has two physiological factors that make it difficult to keep off lost weight.

Physiological factors. One physiological factor is that Oprah's body, which is set up to store a certain amount of fat, automatically adjusts to any decrease in fat stores by lowering its ***rate of metabolism*** (J. M. Friedman, 2003). This results in her body more efficiently burning fuel so she must eat even less or exercise more to avoid regaining lost weight. Another physiological factor is that Oprah's body has a ***genetically fixed set point,*** which maintains her fat stores at a stable level. If the level of fat stores drops below her set point, her body compensates by increasing her appetite so her fat stores will return to their former level (J. M. Friedman, 2003). This means the body fights a reduced food intake with two physiological actions: reducing the rate of metabolism and trying to increase fat stores.

160 pounds

200 pounds

Like most dieters who have regained their lost weight, Oprah admitted, "I didn't do whatever the maintenance program was. I thought I was cured. And that's just not true. You have to find a way to live in the world with food" (*People,* January 14, 1991, p. 84). After dieting, people like Oprah need to develop a ***maintenance program*** to eat less and exercise more.

Psychological factors. Oprah also realized that food had become more than nutrition. "For me, food was comfort, pleasure, love, a friend, everything. Now I consciously work every day at not letting food be a substitute for emotions" (Tresniowski & Bell, 1996, p. 81). Thus, some dieters need a change in lifestyle so that they don't eat when stressed or depressed.

Diet Program/Lifestyle

Oprah's difficulties in controlling her weight confirm the experiences of many dieters who have found it not only difficult to lose weight but even more difficult to keep the weight off. Researchers agree that the best way to keep weight off is by monitoring your weight daily, and when you begin to regain, immediately start eating better and increasing your exercise (Wing, 2005). Researchers found that a program of exercise and diet involves four factors: (1) changing one's attitudes toward food (making it less important); (2) changing one's eating patterns (consuming fewer calories); (3) developing a regular exercise program (a critical part of a weight program); and (4) perhaps the most important, sticking to this weight program over the long term, often for a lifetime (J. E. Brody, 2000b).

Low-fat or low-carbohydrate diet? There has been a big debate over which of these diets is more effective. Dieters report that a low-fat diet works better for some, while a low-carbohydrate diet works better for others. A recent long-term study found that low-carb diets beat low-fat diets in weight loss, but the results from other studies are mixed (Seppa, 2008a; Shai et al., 2008). However, researchers report that whichever diet you choose, the ONLY reason you lose weight is that you're consuming fewer calories (Christensen, 2003). And, don't forget the exercise.

Food addiction. Obesity has been suspected to be a result of an addiction to food. But neurological connections between overeating and drug addiction have only recently been found. For instance, overeaters and drug addicts have deficiencies in dopamine (a chemical that makes us feel good). Also, similar brain activation patterns have been found during food and drug cravings (C. Brownlee, 2005; Grimm, 2007). Thus, obese people may be compulsively driven to eat food just as drug addicts are driven to use drugs.

Next, we'll discuss the causes and treatments of two serious eating disorders.

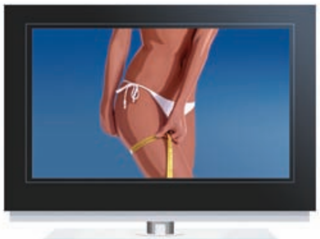
Serious Eating Disorders

Must you be thin?

On the beautiful tropical island of Fiji, a bulky body had always been viewed as a beautiful body and women complimented each other on gaining weight. But then TV arrived in 1995 and began showing programs full of young, slender females and commercials with slim models. After watching these programs, young girls began to develop a different body image—being slim. By 1998, the incidence of an eating disorder (bulimia nervosa) had almost doubled to 29% of young girls. Girls said they wanted to be thin because everyone on TV who has everything is slim (Becker et al., 2002). This is an example of how cultural factors can encourage eating disorders. We'll discuss two serious eating disorders, anorexia nervosa and bulimia nervosa, their causes and treatments.



TV programs change people's body image.

Anorexia Nervosa

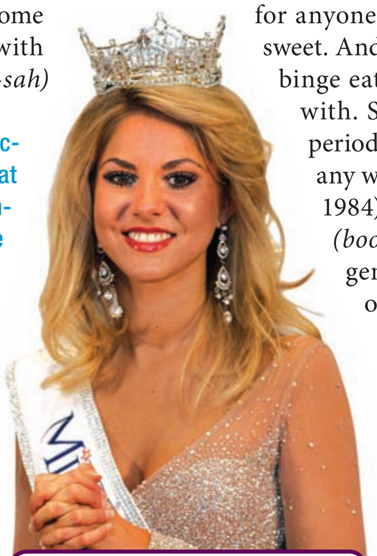
Miss America 2008, Kirsten Haglund (right photo), developed anorexia nervosa at age 15. The lack of nutrition caused her collarbones to stick out, and her energy was so depleted that she felt exhausted after walking up only a few stairs (Haglund, 2008). Kirsten, now 20, has overcome her eating disorder and helps those struggling with anorexia nervosa *(an-uh-REX-see-ah ner-VOH-sah)* (Haglund, 2008; Wilkins, 2009).

Anorexia nervosa is a serious eating disorder characterized by refusing to eat and not maintaining weight at 85% of what is expected, having an intense fear of gaining weight or becoming fat, and missing at least three consecutive menstrual cycles. Anorexics also have a disturbed body image: They see themselves as fat even though they are very thin (American Psychiatric Association, 2000).

Anorexia nervosa, as defined by these symptoms, is a relatively rare disorder that affects about 0.5% to 3.7% of U.S. girls and women and a much lower percentage of boys and men (NIMH, 2008a).

Risk factors. One risk factor for anorexia nervosa is a dysfunctional family. These children have parents who set excessively high standards they cannot possibly achieve (Eggers & Liebers, 2007). Another risk involves personality factors, such as being very anxious, compulsive, rigid, and a perfectionist (Bulik, 2006; Gura, 2008a). Recent brain scan studies show that the parts of the brain that normally respond to the pleasurable, rewarding aspects of eating do not seem to work in people with anorexia (Kaye, 2008). Thus, there may be multiple risk factors for developing anorexia nervosa.

Treatment. Well-established psychological treatments for anorexics have had limited success, and drugs have not been too useful (V. V. W. McIntosh et al., 2005; B. T. Walsh et al., 2006). A relatively new treatment program has reported success using a form of family therapy. Parents are asked to become involved in helping their anorexic daughter to start eating and then gradually letting her control her own eating (Tyre, 2005). Generally, recovery is difficult: About 30% make a full recovery; about 35% regain some weight but maintain a poor body image; about 25% have chronic, recurrent symptoms; and about 5% die from starvation or suicide (Eggers & Liebers, 2007).



Kirsten Haglund had anorexia and never saw herself as skinny.

Bulimia Nervosa

Carol's life seemed perfect when she was growing up, but all the time something was terribly wrong. "It was like I had to live in this fantasy world where everything was sweet and good and I got straight A's," Carol explains. "I started work when I was really young and I would do anything for anyone there and everyone thought I was so nice and so sweet. And I was just dying inside, literally." Carol, who began binge eating at the age of 15, was not overweight to begin with. She would eat a huge amount of food in one brief period and then force herself to vomit as a way of avoiding any weight gain (adapted from the *Daily Aztec*, March 22, 1984). Carol's disorder, which is called bulimia nervosa *(boo-LEE-me-ah ner-VOH-sah),* affects about 2% of the general population and about 8% of people who are overweight or obese (DeAngelis, 2002).

Bulimia nervosa is characterized by a minimum of two binge-eating episodes per week for at least three months; fear of not being able to stop eating; regularly engaging in vomiting, use of laxatives, or rigorous dieting and fasting; and excessive concern about body shape and weight (APA, 2000).

Risk factors. One risk factor involves cultural pressures to develop a slim body, as seen in the increase in bulimia nervosa among Fijian girls. Another risk factor involves personality characteristics, such as being excessively concerned about appearance, being too sensitive, and having low self-esteem and high personal standards for achievement. For some, bouts of depression, anxiety, mood swings, and problems with social relationships may trigger episodes of bulimia nervosa, which may lead to obesity (Stice, 2002).

Treatment. The psychological treatment for bulimia nervosa may involve ways to control weight as well as one of two kinds of psychotherapy: cognitive-behavioral therapy, which focuses on substituting positive thoughts for negative ones, or interpersonal therapy, which focuses on improving a person's social functioning (Z. Cooper & Shafran, 2008; Hilbert et al., 2007; G. T. Wilson et al., 2002). Drug treatment for bulimia nervosa, which involves the use of antidepressants and possible unwanted side effects, was shown to be less effective than psychotherapy (Mitchell et al., 2007). Follow-up studies report that about 50% of bulimics recover fully. The half who do not recover may vomit as a long-term habit or overeat while no longer vomiting (Eggers & Liebers, 2007).

The eating disorders of anorexia and bulimia nervosa clearly illustrate how various personality and psychosocial factors can not only influence but even override the normal functioning of one of our basic biological needs, food.

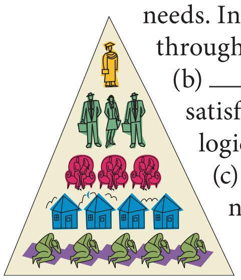
Summary Test

A. Theories of Motivation

1. The combined physiological and psychological factors that cause you to act in specific ways at particular times are referred to as (a) ______________. When motivated, you usually exhibit three characteristics: you are (b) ______________ to do something; you (c) ______________ your energies toward a specific goal; and you have different (d) ______________ of feelings about reaching that goal.

2. There are four general theories that together help explain human motivation. The theory that applies primarily to animal motivation involves innate biological forces that determine behavior. This is called the (a) ______________ theory. The reward/pleasure center theory says there are several areas in the brain, including the (b) ______________ and ______________, that especially use the neurotransmitter (c) ______________. Many behaviors (eating, engaging in sex, gambling) that activate this center are (d) ______________ with pleasurable feelings. The theory that says we are motivated by external rewards is called the (e) ______________ theory. The theory that distinguishes between extrinsic and intrinsic motivations is called the (f) ______________ theory. If we are motivated because we find the activities personally rewarding or because they fulfill our beliefs or expectations, our motivation is said to be due to (g) ______________ motivation.

B. Biological & Social Needs



3. Food, water, and sleep are examples of (a) ______________ needs. In comparison, needs that are acquired through learning and socialization are called (b) ______________ needs. The theory that we satisfy our needs in ascending order, with physiological needs first and social needs later, is called (c) ______________. According to this theory, needs are divided into five levels: biological, safety, love and belongingness, esteem, and self-actualization.

C. Hunger

4. If there is an almost perfect balance between how much food an organism needs to maintain the body's energy needs and how much the organism actually eats, the organism's weight is said to be (a) ______________. Three different factors influence the hunger drive. Factors that come from physiological changes in blood chemistry and signals from digestive organs that provide feedback to the brain, which, in turn, triggers us to eat or stop eating, are called (b) ______________ factors. Factors that come from learned associations between food and other stimuli, sociocultural influences, and various personality problems are called (c) ______________ factors. Factors that come from inherited instructions contained in our genes are called (d) ______________ factors.

5. Biological factors that influence eating come from two different sources. Cues arising from physiological changes in your blood chemistry and signals from your body organs are called (a) ______________; cues from your brain are called (b) ______________.

6. Genetic factors that influence hunger come from four different sources: the number of cells that store fat, which are called (a) ______________; your rate of burning the body's fuel, which is called your (b) ______________; the body's tendency to keep a stable amount of fat deposits, which is called the (c) ______________; and a number of (d) ______________ genes that influence appetite, metabolism, and secretion of hormones regulating fat stores.

D. Sexual Behavior

XY = High Testosterone

7. Human sexual behavior is influenced by three different factors. Inherited instructions for the development of sexual organs, hormonal changes at puberty, and neural circuits that control sexual reflexes are called (a) ______________ factors. The fact that humans engage in sexual behavior for many reasons besides reproduction and the fact that humans experience sexual difficulties that have no physical or medical basis indicate the influence of (b) ______________ factors on sexual behavior. Factors that regulate the secretion of sex hormones, which play a role in the development of secondary sexual characteristics, influence sexual motivation (more so in animals than in humans), regulate the development of ova and sperm, and control the female menstrual cycle, are called (c) ______________ factors.

8. Biological sex factors include the secretion of sex hormones, which is controlled by an area of the brain called the (a) ______________. The major male sex hormones secreted by the testes are called (b) ______________, and the major female sex hormones secreted by the ovaries are (c) ______________. When hormone levels are within the normal range, there is little (d) ______________ between levels of sex hormones and sexual motivation in humans.

9. Three psychological sex factors are the individual's subjective experience and feelings of being a male or a female, which is called (a) ______________; traditional or stereotypical behaviors, attitudes, and personality traits that society designates as masculine or feminine, which are called (b) ______________; and whether a person is sexually aroused primarily by members of his or her own sex, the opposite sex, or both sexes, which is called (c) ______________.

Photo Credits: (#1) © Richard Sjoberg; (#4) Courtesy of Jeffrey M. Friedman, Rockefeller University

10. The findings that identical twins are often alike in their sexual orientation and that homosexual brothers shared similar inherited material indicate the influence of (a) ______________ factors on homosexual orientation. The finding that genetic factors do not necessarily determine sexual orientation indicates the influence of (b) ______________ factors on sexual orientation.

11. There are two kinds of sexual problems. Problems that are characterized by repetitive or preferred sexual fantasies involving nonhuman objects (articles of clothing) are called (a) ______________. Problems of sexual arousal or orgasm that interfere with adequate functioning during sexual behavior are called (b) ______________. When a person seeks help for a sexual problem, the clinician will check whether the causes are (c) ______________ or ______________.

12. If a person has been infected by the human immunodeficiency virus (HIV) but has not yet developed one or more of 26 illnesses, that person is said to be (a) ______________. A person whose level of T-cells (CD4 immune cells) has dropped to below 200 per cubic milliliter of blood (one-fifth the level of a healthy person) and who may or may not have any other symptoms is said to have (b) ______________.

E. Cultural Diversity: Genital Cutting

13. In some cultures the female's external genitalia, usually including her clitoris and surrounding skin (labia minora), are cut away; this practice is called ______________. Girls often submit to the fear, pain, and trauma of this procedure so as to gain social status, please their parents, and comply with peer pressure. A number of feminists in Africa have formed a society to fight the sexual mutilation of females.

F. Achievement

14. High in Maslow's needs hierarchy is a desire to set challenging goals and persist in pursuing those goals in the face of obstacles, frustrations, and setbacks. This social need is called the (a) ______________. Someone who persists longer at tasks, shows better performance on tasks, activities, or exams, sets challenging but realistic goals, competes with others to win, and is attracted to careers that require initiative is said to have a high (b) ______________. Individuals who score relatively high on tests of ability or intelligence but perform more poorly than their scores would predict are called (c) ______________. Individuals who choose either easy, nonchallenging tasks or challenging tasks where failure is probable and expected are said to be motivated by (d) ______________.

15. If you engage in behaviors without receiving any external reward but because the behaviors themselves are personally rewarding, you are said to be (a) ______________ motivated. If you engage in behaviors to reduce biological needs or obtain external rewards, you are said to be (b) ______________ motivated.

G. Research Focus: Overcoming Educational Disadvantages

R E A C H

16. Schools that best educate poor and minority students have (a) ______________ class days, and clearly stated (b) ______________ and teach students not only academics but also (c) ______________. Research findings indicate that the (d) ______________ skills these schools are teaching students, such as patience and respect, have an important effect on children's future academic and career success.

H. Application: Eating Problems & Treatments

17. A healthy weight-maintenance program, which can reduce the risk of serious medical problems of (a) ______________ people, involves changing (b) ______________ toward food, changing (c) ______________ patterns, developing an (d) ______________ program, and sticking to a long-term (e) ______________ program. Two serious eating disorders are a pattern characterized by bingeing, fear of not being able to stop eating, and regularly purging the body, which is called (f) ______________; and another pattern in which a person starves to remain thin, has a fear of being fat, and has a disturbed body image, which is called (g) ______________.

Answers: *1. (a) motivation, (b) energized, (c) direct, (d) intensities; 2. (a) instinct, (b) nucleus accumbens, ventral tegmental area, (c) dopamine, (d) rewarded or encouraged, (e) incentive, (f) cognitive, (g) intrinsic; 3. (a) biological, (b) social, (c) Maslow's hierarchy of needs; 4. (a) ideal or optimal, (b) biological, (c) psychosocial, (d) genetic; 5. (a) peripheral cues, (b) central cues; 6. (a) fat cells, (b) metabolic rate, (c) set point, (d) weight-regulating; 7. (a) genetic, (b) psychological, (c) biological; 8. (a) hypothalamus, (b) androgens, (c) estrogens, (d) correlation or association; 9. (a) gender identity, (b) gender roles, (c) sexual orientation; 10. (a) genetic, (b) psychological; 11. (a) paraphilias, (b) sexual dysfunctions, (c) psychological, physiological; 12. (a) HIV positive, (b) AIDS; 13. genital cutting; 14. (a) achievement motive, (b) need for achievement, (c) underachievers, (d) fear of failure; 15. (a) intrinsically, (b) extrinsically; 16. (a) longer, (b) education goals, (c) character, (d) noncognitive; 17. (a) overweight, (b) attitudes, (c) eating, (d) exercise, (e) maintenance, (f) bulimia nervosa, (g) anorexia nervosa*

Critical Thinking

Viagra for Men *and Women?*

Eric (not his real name), who was 64 and happily married, was diagnosed with prostate cancer. He chose to have his prostate gland removed, knowing there was a 50–50 chance of becoming impotent, which is the inability to have an erection (also called erectile dysfunction). After surgery, Eric did become impotent and developed a terrible fear that his wife would leave him. Eric volunteered for a study on a brand new drug to treat impotence. For Eric, the new drug worked so well that he called it a "wonder drug" because it gave him back a normal married life. This drug later became known as Viagra (sildenafil).

What's unusual about Viagra is that it was discovered by accident. Scientists were looking for drugs to treat heart disease and found that, while one drug didn't work on heart disease, it did cause erections. Scientists changed goals and began testing the particular drug on men who were impotent.

It was not until the early 1980s that scientists figured out the plumbing behind erections. They discovered that when a man feels aroused, his penis releases a gas, nitric oxide, which activates an enzyme (cyclic GMP), which triggers the blood vessels in the penis to relax, which allows blood to rush in and cause stiffness (erection). Scientists found that Viagra worked by keeping the enzyme around longer so that blood vessels stayed relaxed longer, which allowed blood to flow in and cause an erection.

Estimates are that between 10 and 20 million American men suffer some degree of impotence. For many of these men, the idea of having an erection 20 to 40 minutes after taking Viagra is very appealing. Viagra, "the little blue pill," has been available for 10 years, and similar drugs have followed because of the skyrocketing sales. Viagra and similar drugs account for 19 million prescriptions a year, more than $1.5 billion!

Despite its incredible success, Viagra doesn't work for 30–40% of men who have impotence. Some of these men experience unwanted side effects, such as one man who stopped taking Viagra because "your face gets very hot, you feel like your heart is beating faster than it should, there's anxiety" (Leland, 1998, p. 68). Also, although Viagra can cause erections, it may not resolve the underlying sexual difficulties in unhappy relationships. Finally, a few hundred deaths have been associated with Viagra, which resulted in a warning label about not prescribing Viagra for men with certain heart problems. Still, drug manufacturers cannot ignore Viagra's effectiveness on so many men. In fact, they are hoping to find the magic "pink pill" for women.

In past research with women who have decreased sexual desire, Viagra has not proved effective, since the percentage of women (21%) who reported improved sexual functioning with Viagra was about the same as for those who took placebos. However, in recent, more targeted research with women, researchers report that Viagra seems to counteract orgasm problems caused by taking antidepressants (72% reported improvement). This is a significant finding because antidepressants are strongly associated with reducing orgasms in women and are one of the major reasons many women stop taking needed depression medication.

Although Viagra is not a miracle pill for all men and women, for about 70% of men who suffer some degree of impotency, especially after prostate surgery, and about 70% of women who lack the ability to reach orgasm as a result of side effects from antidepressant medication, Viagra appears to be a very good deal. (Adapted from BBC News, 2003; J.S. Cohen, 2001; Horowitz, 1999; Kotz, 2008; Leland, 1998; L. Lyon et al., 2008; Mestel, 1999; Nurnberg et al., 2008; Roan, 1998; N. Seppa, 2008b)

QUESTIONS

1 What are the two different causes of sexual problems (dysfunctions), and which one applies to Eric?

2 Why do you think that Viagra was discovered by accident?

3 How is the transmitter involved in producing an erection (a gas called nitric oxide) different from most other transmitters discussed earlier (p. 54)?

4 Why might men who are not impotent want to try Viagra?

5 What is one reason that Viagra did not work in 30–40% of those who tried it?

6 What is one reason that Viagra did not improve sexual functioning in women?

Suggested Answers to Critical Thinking

1. There are two general causes of sexual dysfunctions. One cause involves organic factors, such as medical problems or problems caused by drugs. The other cause involves psychological factors, such as anxiety, sexual trauma, guilt, or communication difficulties, all of which lead to sexual problems. In Eric's case, the cause was organic, since he had no problems with having an erection until his prostate gland was removed.
2. Although finding a pill to treat impotence was a high priority, scientists did not yet understand how erections occurred and so did not know where to look for a drug to treat impotence. It was by accident that scientists, who were initially studying a drug to treat heart disease, found a drug that produced erections.
3. All the transmitters discovered earlier were chemicals (pp. 54–55). That's why finding that the transmitter involved in erections was a gas (nitric oxide) was completely unexpected.
4. Men with no erectile problems may want to try Viagra because they incorrectly believe that Viagra increases not only erections but also sexual desire and motivation, which it doesn't.
5. The reasons Viagra did not work in 30–40% of men with erectile problems may be serious organic (medical) problems or psychological problems (low sexual motivation, fear or anxiety about performing), which Viagra doesn't necessarily help.
